(Haguenau et al., 1958). The structures (Haguenau and Beard, 1962) consist of densely osmiophilic particles of the size of ribosomes and among them particles (650 A) composed of circular membranes and of a size smaller than the characteristic particles (800 A) usually encountered. An outer ring of ribonucleoprotein granules surrounds these particles (Haguenau and Beard, 1962). These structures appear in clusters in the cytoplasm of tumor cells (Dmochowski et al., 1964) (Figs. 19.28 and 19.28A). These small particles or granules described as virosomes (Heine et al., 1962b) and the circular images or virospheres may represent precursor material for the synthesis of Rous sarcoma virus (Haguenau and Beard, 1962). The virospheres may represent incomplete virus particles formed in an abortive process of synthesis (Beard, 1963). The structures described as viroplasm have been observed, as will be shown later, in myeloblastosis, erythroblastosis, visceral lymphomatosis, and nephroblastoma (Beard, 1963; Dmochowski et al., 1961).

It has recently been shown that Rous sarcoma virus is formed and liberated by budding of the plasma membrane of fibroblasts grown in vitro and infected with Rous virus (Haguenau et al., 1962) and

of the plasma membrane of tumor cells in vivo (Heine et al., 1962b; Dmochowski et al., 1964) (Figs. 19.29 and 19.30). This budding phenomenon has originally been described in erythroblastosis (Benedetti and Bernhard, 1958), in myeloblastosis (Dmochowski, 1961, 1963; Dmochowski et al., 1961), and in nephroblastoma (Dmochowski, 1961, 1963; Dmochowski et al., 1961). Budding of plasma membranes has recently been observed in visceral lymphomatosis (Dmochowski et al., 1961).

The budding of the plasma membrane

FIG. 19.29 — Budding of plasma membrane of a Rous sarcoma cell. ×180,000.
FIG. 19.30 — More advanced stage of budding. Arrows indicate the stalk with which an almost fully formed virus particle is attached to the plasma membrane. ×420,000.

of Rous sarcoma cells has not been noted in all the previous extensive studies (Bernhard et al., 1956; Epstein, 1957; Haguenau et al., 1958, 1960a, b). This may serve as an example of the error of sampling which may occur in electron microscope studies of any type of changes in cells and of the erroneous conclusions which may be based on such sampling. It appears that while the frequency of the changes of various types induced by chicken tumor viruses may vary, these viruses may all have a similar mode and similar sites of development with one or another site occurring more frequently, according to the type of infected cell, without any qualitative differences for any type of the virus strain involved.

Virus particles, similar to those found in vacuoles of the cytoplasm of Rous sarcoma cells and in the intercellular spaces of the Rous tumor are present in high-speed centrifugal pellets from extracts of Rous sarcoma tumors. A correlation could be established between the potency of tumor extracts and the number of virus particles seen in sections of these tumors or in the pellets from cell-free extracts of such tumors (Epstein, 1957, 1958; Haguenau et al., 1958).

No changes of a specific character could be observed in the nucleus or nucleolus of Rous sarcoma cells, except for small dense bodies present in the nuclear sap (Haguenau, 1960).

Studies on the ultrastructure of other chicken tumors such as Murray-Begg endothelioma (Rouiller et al., 1956) and of Fujinami myxosarcoma (Mannweiler and Bernhard, 1958) have led to the discovery of characteristic (800 A) virus particles, similar to those found in Rous sarcoma, but they have failed to demonstrate the changes observed in the studies on Rous sarcoma. These tumors require reinvestigation in the light of recent findings in Rous sarcoma.

MYELOBLASTOSIS (GRANULOBLASTOSIS)

The myeloblastosis strain of chicken leukosis, later described as the BAI strain A, was originally isolated by Hall et al. (1941) from chickens with neurolymphomatosis and later studied extensively by Johnson (1941) and by Beard and his associates (1956, 1963).

In sections of myeloblasts present in the spleen, bone marrow, and the circulating blood of chickens with myeloblastosis induced by BAI strain A myeloblastosis virus only few changes have been reported (Beard, 1963) which could be related to virus infection. These changes consisted of cytoplasmic vacuoles in myeloblasts, with occasional characteristic virus particles (800 A). While most of the virus particles were found outside the cells (Bonar et al., 1959, 1960; Parsons et al., 1959). Otherwise, the myeloblasts have been found similar to those present in normal chicken bone marrow (Beard, 1963). It is as yet unknown to what extent these findings have been associated with the stage of infection or of the progression of neoplasia. In other studies (Dmochowski, 1960 a–c, 1961, 1963; Dmochowski et al., 1958b, 1959a, 1961, 1964), examination of the spleen from chickens in advanced stages of myeloblastosis, particularly of the areas diagnosed histologically as replaced by neoplastic or tumorous cells (myeloblasts), changes have been observed in the myeloblasts or cells of the myeloid series which

could be interpreted as related to virus synthesis and comparable to those seen in myeloblasts grown *in vitro* and obtained from the infected chickens (Beard, 1963). Similar changes have been found in reticular cells and macrophages more frequently than in myeloblasts (Parsons *et al.*, 1959). While this is undoubtedly the case, there appears to be little doubt that in the advanced stages of myeloblastosis, changes in the cells present in the spleen which lead to the enlargement of the cytoplasm of the cells, make the diagnosis of the type of cell involved frequently difficult. However, similar changes have been observed in the reticular cells, macrophages, and myeloblasts in the spleen of chickens with myeloblastosis (Dmochowski *et al.*, 1964).

The changes consist of cytoplasmic inclusions (Dmochowski, 1961) or gray bodies or viroplasts (Beard, 1963) in various stages of formation and vacuolization, fully or partially filled with the characteristic virus particles (800 A). These inclusions, surrounded by a single or a double membrane or apparently without a membrane (Figs. 19.31, 19.32, 19.32A, 19.33, 19.33A, 19.33B), filled with osmiophilic material of varying density, could conceivably be interpreted as related to mitochondria. They frequently

appear to be in various stages of vacuolization and contain virus particles in varying numbers.

Less frequently encountered changes consist of aggregations of dense osmiophilic granules (Figs. 19.34 and 19.34A with apparently empty circular images, similar in many respects to the structures present in the cytoplasm of Rous sarcoma cells and in that of erythroblasts (Beard, 1963; Dmochowski *et al.*, 1964), and in the epithelial cells of nephroblastoma (Dmochowski *et al.*, 1961).

Further changes, observed in myeloblasts in the spleen of chickens with myeloblastosis, also less frequently encountered than the cytoplasmic inclusions or gray bodies or viroplasts, consist of the budding of plasma membrane of myeloblasts which apparently leads to virus particle formation (Dmochowski *et al.*, 1961, 1964; Beard, 1963) (see Fig. 19.35).

Similar changes, but more frequently present, have been observed in myeloblasts grown *in vitro* (Parsons *et al.*, 1958; Bonar *et al.*, 1959, 1960). Cytoplasmic inclusions (gray bodies or viroplasts) of varying number and size, and with virus particles in various stages of formation, have been found to increase in frequency and extent
FIG. 19.31—Appearance of a cell in the spleen of chicken with myeloblastosis with an inclusion containing virus particles present in the cytoplasm. ×28,000.

FIG. 19.32 — Appearance of another cell in the spleen of a chicken with myeloblastosis, showing numerous cytoplasmic inclusions (A) containing virus particles. ×12,000.

with the time of growth of myeloblasts *in vitro* (Bonar et al., 1960). These inclusions change in appearance, alter in density, and undergo vacuolization. These structures appear to be the sites of virus formation (Parsons et al., 1958). No particular localization of these bodies in the cytoplasm could be noted. The presence of virus particles at all stages of the changes in the viroplasts indicates that these structures are involved in virus synthesis (Haguenau and Beard, 1962). It is likely that the substance of cytoplasmic inclusions or viroplasts is used for virus particle formation which then may be transported in the vacuoles to the cell surface (Beard, 1963). These structures appear to be specific loci of virus synthesis as, like the coat of virus particles, they dephosphorylate adenosine triphosphate (Beaudreau et al., 1958). They are similar in size to mitochondria.

There is conflicting evidence available about the origin of these cytoplasmic inclusions or viroplasts. Although no virus particles have been found in unaltered mitochondria (Bonar et al., 1960), an anal-

FIG. 19.32A — Part of the cell in Fig. 19.32, marked A, showing cytoplasmic inclusions with virus particles in different stages of formation. ×60,000.
FIG. 19.33 — Part of the cytoplasm of a macrophage in the spleen of a chicken with myeloblastosis, showing cytoplasmic inclusions, some marked A and B, in different stages of vacuolization, containing virus particles. ×23,000.

ysis of the appearance of the various cytoplasmic inclusions appears to indicate that mitochondria undergo a series of alterations, starting from the loss of internal structure which is being gradually replaced by dense osmiophilic material in which virus particles appear (Dmochowski et al., 1961, 1964). The increase in the number of particles is associated with the disappearance of the osmiophilic material and is followed by progressive vacuolization of the cytoplasmic inclusions. In such inclusions, strands (Bonar et al., 1959, 1960) and membranes (Dmochowski and Grey, 1958; Dmochowski et al., 1958b, 1959a, 1961; Dmochowski, 1960 a–c, 1961) have been observed. These membranes or strands may, but need not necessarily, indicate the origin

FIG. 19.33A — Part of the cell in Fig. 19.33, marked A, at higher magnification. ×64,000.
FIG. 19.33B—Part of the cell in Fig. 19.33, marked B, at higher magnification. ×64,000.

of the cytoplasmic inclusions from altered mitochondria.

There is substantial evidence available that the viroplasts do not develop from mitochondria but from the granules or their precursors which appear in the cells of myeloid series during their normal maturation to the granulocytic series of blood cells (Haddad et al., 1960; Weinstein et al., 1960; Sommer et al., 1962). This evidence is based on cytochemical studies which demonstrated adenosine triphosphatase activity in these granules, in viroplasts or cytoplasmic inclusions, and in the outer coat of virus particles (Beard et al., 1963). These studies have also led to the conclu-

sion that the granules develop from precursor material in the cytoplasm (Beard, 1963) and not, as originally suggested, from mitochondria (Bernhard et al., 1955). Viroplasts as well as the granules of normal myelocytes exhibit strong adenosine triphosphatase activity. There appears to be however a considerable difference between the enzymes per se of the normal granules and those of the viroplasts, as shown by freeze-drying in vacuo and by fixation with formaldehyde (Weinstein et al., 1960). The size and the number of viroplasts increase in cultures containing 5-methyl tryptophan (Weinstein et al., 1960). Myeloblasts taken

FIG. 19.34—Part of the cytoplasm of a cell in the spleen of chicken with myeloblastosis, showing viral matrix or viroplasm, framed and marked with letter A. ×23,000.
FIG. 1934A—Part of Fig. 19.34 at higher magnification. Arrows indicate circular images surrounded by dense osmiophilic granules. X77,000.

directly from the circulating blood of chickens with myeloblastosis only seldom show the presence of viroplasts and little or no evidence of adenosine triphosphatase activity (Haddad *et al.*, 1960). The results of phase contrast microscopy and of staining for adenosine triphosphatase parallel the observations made in the electron microscope (Haddad *et al.*, 1960).

Studies of the bone marrow of normal chickens grown in tissue culture and infected with myeloblastosis virus (Beaudreau *et al.*, 1958; 1960) have demonstrated that after 3 weeks in culture, the infected cells show multiplication of myeloblasts with liberation of myeloblastosis virus in tissue culture fluids. The ultrastructure of these cells is identical with that of myeloblasts obtained from the circulating blood of chickens with myeloblastosis and grown *in vitro*. Myeloblasts from both sources show structures in the cytoplasm, the so-called viroplasts or cytoplasmic inclusions. Both types of cells reproduce myeloblastosis in chickens (Beaudreau *et al.*, 1960).

Thus, tissue culture studies of myeloblasts grown *in vitro* confirmed and extended (Haguenau and Beard, 1962; Beard, 1963) the observations reported on myeloblasts present in the spleen, liver, and bone marrow of chickens with myeloblastosis. However, no structures such as viroplasm or viral matrix have as yet been observed in myeloblasts maintained in tissue culture (Beard, 1963).

The formation of myeloblastosis virus in cytoplasmic inclusions or viroplasts of myeloblasts and in the viral matrix or viroplasm apparently are not the only mode of virus synthesis. Budding of the plasma membrane of myeloblastosis has been shown to be another way of myeloblastosis virus formation (Dmochowski, 1961; 1963; Dmochowski *et al.*, 1961, 1964). Recently in isolated instances, it has also been observed by Beard (1963). There is as yet no evidence of any connection between the budding of plasma membrane and virus formation in cytoplasmic inclusions or in viral matrix.

ERYTHROBLASTOSIS

Numerous electron microscope studies have been carried out on organs and tissues, such as spleen, liver, and bone marrow, of chickens with erythroblastosis induced by the virus of different strains of origin (Benedetti and Leplus, 1958;

FIG. 19 35—Budding of plasma membrane (arrow) of a myeloblast in the spleen of a chicken with myeloblastosis. ×90,000.
Benedetti and Bernhard, 1958; Iwakata and Amano, 1958; Iwakata, 1958), including strain R of Engelbreth-Holm and Rothe-Meyer (1935) (Dmochowski et al., 1958a, 1959a; Dmochowski, 1960a–c, 1961, 1963; Heine et al., 1961) and strain RPL-12 (Dmochowski et al., 1959b) The results of all these studies have been similar, although interpretation of the findings has differed. Studies have also been carried out on erythroblasts grown in tissue culture

and on those present in the circulating blood of chickens with erythroblastosis induced by strain R (Heine et al., 1961).

In some studies (Beard, 1963), few changes have been observed in the erythroblasts present in the spleen and bone marrow of leukemic chickens, except for occasional virus particles in vacuoles of the cytoplasm of erythroblasts. Greater changes such as vacuolization of the cytoplasm with virus particles present in these vacuoles,

FIG. 19.36— Part of the cytoplasm of a cell in the spleen of a chicken with erythroblastosis showing cytoplasmic inclusions in various stages of vacuolization, containing virus particles. ×15,000.

FIG. 19.37—Port of the cytoplasm of another cell in the spleen of a chicken with erythroblastosis showing vacuoles framed and marked A, containing virus particles. ×23,000.

and inside the cytoplasm of cells as well as budding of plasma membranes leading to the formation of virus particles have been observed in the circulating erythroblasts and in those grown in tissue culture (Heine et al., 1961). Characteristic virus particles (800 A) have also been observed in tissue culture fluids by electron microscopy and by biological tests (Heine et al., 1961). In addition, in a few cases a structure, the so-called viroplasm or viral matrix, has been observed in the erythroblasts grown in vitro. As already mentioned in the discussion on Rous sarcoma and myeloblastosis, this is a change in the cytoplasm, composed of particles of the size of ribosomes, but of greater electron density (Heine et al., 1961). Within this viroplasm or viral matrix particles have been found resembling the incomplete particles present in the cytoplasm of Rous sarcoma cells (Haguenau and Beard, 1962) and in nephroblastoma cells (Dmochowski, 1961, 1963; Dmochowski et al., 1961; Heine et al., 1962a). No evidence of adenosine triphosphatase activity has been observed in the
FIG. 19.37A—Part of Fig. 19.37 at higher magnification. Variation in the size of virus particles may be seen. ×90,000.

erythroblasts from the bone marrow of
normal chickens or those with erythro-
blastosis (Bonar et al., 1957; Beard, 1963).

Erythroblasts and cells of the erythroid
series, like myeloblasts and cells of the
myeloid series, present in the spleen and
liver of chickens with erythroblastosis
strain R, showing neoplastic involvement,
have been found to show changes similar

to those observed in myeloblasts (Dmo-
chowski, 1961, 1963). However, these
changes as in myeloblasts are not as fre-
quently encountered in the erythroblasts
as in the reticulo-endothelial cells or in
macrophages present in the spleen of chick-
ens with erythroblastosis (Benedetti and
Bernhard, 1958; Benedetti and Leplus,
1958; Dmochowski et al., 1958a, 1959a, b,

×46,000.

FIG. 19.39 — Cytoplasmic inclusion in erythroblastosis, showing in parts a double membrane, containing virus particles. ×90,000.

1961; Dmochowski, 1960a, c; Heine et al., 1961; Iwakata, 1958; Iwakata and Amano, 1958). Characteristic virus particles (800 A) have been found in the intercellular spaces and in cytoplasmic vacuoles with varying amounts of osmiophilic material (Figs.

19.36, 19.37, 19.37A), as well as in cytoplasmic inclusions of the size of mitochondria or larger (Figs. 19.38, 19.38A, 19.39). In addition, whorl-like formations have been observed in the erythroblasts. Occasionally, virus particles have been observed
FIG. 19.40 — Budding of plasma membrane of an erythroblast in the spleen of chicken with erythroblastosis. ×120,000.

FIG. 19.41 — Viral matrix or viroplasm (A) in the cytoplasm of an erythroblast, circular images in matrix marked by arrows. ×30,000.

to form by budding of plasma membrane (Fig. 19.40) of erythroblasts (Dmochowski et al., 1961, 1964). Equally rare are the structures, similar to viroplasm or viral matrix in the cytoplasm of myeloblasts, with circular images surrounded by dense osmiophilic particles which have been ob-

served in the cytoplasm of erythroblasts (Figs. 19.41 and 19.41A) present in the spleen of chickens with erythroblastosis strain R (Beard, 1963; Dmochowski et al., 1964).

Occasionally, structures have been observed with dense osmiophilic granules of

FIG. 19.41A — Part of Fig. 19.41 at higher magnification. Circular images (arrows) surrounded by dense osmiophilic granules. ×68,000.

FIG. 19.42 — Part of another cell in the spleen of chicken with erythroblastosis showing densely osmiophilic viral matrix (A). ×23,000.

FIG. 19.42A — Part of Fig. 19.42 at higher magnification showing fully formed typical virus particles in the viral matrix. ×68,000.

the size of ribosomes and with virus particles, fully formed or almost fully formed, lying on the periphery of the aggregates of the granules (Figs. 19.42 and 19.42A). It is quite possible that these structures constitute a further stage in the synthesis of erythroblastosis virus particles (Dmochowski et al., 1964). In addition, occasionally structures have been observed apparently in the nuclei of erythroblasts in the spleen of the infected chickens which give internal images forming among what at first sight appeared to be structures identical to viral matrix or viroplasm (Fig. 19.43). On close inspection Dmochowski et al. (1964) observed that these structures are composed not of granules but of strands, similar to those observed in the nuclei of other erythroblasts, and among them are circular images similar to those in the cytoplasmic viral matrix or viroplasm (Figs. 19.42 and 19.42A). They may be nuclear pores.

No indication of nuclear involvement has as yet been detected in Rous sarcoma tumor cells or in any cells of organs or tissues of chickens with avian leukosis except for hypertrophy of the nucleolus and small dense bodies in the nuclear sap

(Haguenau and Beard, 1962; Beard, 1963). Nevertheless, Rous sarcoma antigen has been found in the nucleus of virus-infected cells by means of labeled specific antibody before the appearance of the antigen in the cytoplasm of these cells (Malmgren et al., 1960; Mellors, 1960; Noyes, 1960). The connection between the immunological findings in Rous sarcoma cells and the electron microscope findings in erythroblastosis of chickens infected with erythroblastosis strain R virus is as yet unknown, but it may well constitute the first electron microscope observation of chicken tumor virus formation in the nucleus if the presence of Gallus adenolike virus of chickens (Burmester et al., 1960d), is excluded.

The cytoplasmic structures may be loci of virus synthesis, although the cytoplasmic inclusions have also been interpreted as the result of phagocytosis (Haguenau and Beard, 1962; Beard, 1963). This matter still remains to be resolved.

The described changes could not be as clearly and as frequently visualized in erythroblasts grown in vitro (Heine et al., 1961) as in myeloblasts grown in tissue culture (Bonar et al., 1960). The presence of

FIG. 19.43 — Nucleus of a cell in the spleen of a chicken with erythroblastosis. Arrows indicate circular images, similar to those found in cytoplasmic viral matrix in Figs. 17.41 and 19.41A. ×30,000.

numerous virus particles in the cytoplasmic vacuoles of erythroblasts grown *in vitro* was interpreted as the result of phagocytosis (Heine *et al.*, 1961). The budding phenomenon of the plasma membrane of erythroblasts grown *in vitro* has also been observed as in the case of erythroblasts grown in tissue culture (Heine *et al.*, 1961). While tissue culture has undoubtedly helped the electron microscope studies on Rous sarcoma and on myeloblastosis, it has been of particular help in the quantitative studies on these tumor viruses. Its great value is based on compelling investigators to re-examine the previously reported findings of electron microscope studies of Rous sarcoma and of leukemias of chickens. This re-evaluation of electron microscope examination has revealed changes in Rous sarcoma cells and in tissues of chickens with myeloblastosis and erythroblastosis, previously unobserved, and identical with those found in the respective tumor cells grown *in vitro*.

Virus particles and cytoplasmic inclusions have also been observed in macrophages and in reticular cells present in various tissues of chickens with erythroblastosis (Benedetti and Bernhard, 1958; Benedetti and Leplus, 1958; Dmochowski *et al.*, 1961). In these studies, cytoplasmic inclusions or viroplasts or gray bodies have been found more frequently than in the tumorous cells or erythroblasts. An analysis of the various changes observed in the cytoplasmic inclusions of reticular cells or of macrophages, as in the case of erythroblasts, indicates that they may be of mitochondrial origin, as originally suggested by Benedetti and Bernhard (1958). However, no budding of plasma membrane and no viroplasm (viral matrix) could be found in the reticular cells and macrophages. This does not necessarily indicate that such changes may not take place in these cells.

Alterations and changes observed in the erythroblasts or tumorous cells, reticular cells, and in macrophages present in the spleen and liver of chickens with erythroblastosis strain R (Dmochowski *et al.*,

1958a) are similar to those observed in the cells of the same origin present in the spleen and liver of chickens with erythroblastosis induced by strain RPL-12 (Dmochowski, 1960a-c, 1961, 1963; Dmochowski *et al.*, 1959b, 1961). The difference in the frequency of changes observed in the erythroblasts present in various organs and tissues of chickens with erythroblastosis, observed by different investigators may, at least in part, be due to the stage of disease at which these organs have been examined and to the extent of infiltration of the various organs by erythroblasts or tumorous cells.

Comment

The changes seen in myeloblastosis and in erythroblastosis have been described as of two types: nonspecific and specific with regard to pathological changes and to evidence of the relationship of the respective viruses to primary neoplastic cells (Haguenau and Beard, 1962).

As one of the nonspecific changes, the presence of characteristic virus particles has been considered in reticular cells and in macrophages in the spleen, liver, and bone marrow of chickens with myeloblastosis or erythroblastosis. Similarly, the presence of cytoplasmic inclusions containing virus particles in the cells of the spleen, liver, or bone marrow of chickens with myeloor erythroblastosis and with visceral lymphomatosis has been interpreted as a nonspecific change and attributed to phagocytosis (Haguenau and Beard, 1962). In other studies, macrophages have been considered as reservoirs of chicken tumor viruses and as sites of their intercellular proliferation (Iwakata, 1958; Iwakata and Amano, 1958). Whether the observed changes in reticular cells and macrophages can be attributed solely to phagocytosis of the respective viruses remains to be determined. In view of the presence of changes which can be interpreted as loci of virus synthesis in cells which do not participate directly in the neoplastic process such as those of the pancreas, thymus gland, and liver of chickens infected with

FIG. 19.44 — Low-power view of a cell in the spleen of a chicken with visceral lymphomatosis showing an inclusion with virus particles. ×15,000.

croscope, in response to viruses of myeloblastosis, erythroblastosis, and Rous sarcoma, and later found to be either nonexistent or only quantitative, are indeed quantitative or qualitative. Such studies may help to resolve the problem whether one or a number of viruses are involved in the induction of chicken leukosis and other tumors of birds.

LYMPHOMATOSIS

The lymphomatosis strain RPL-12 virus was isolated (Burmester, 1947) from a lymphosarcoma originally described by Olson (1941). The RPL-12 virus has been found to induce, besides "extravascular" visceral lymphomatosis and osteopetrosis, the so-called "intravascular" visceral lym-

croscope, in response to viruses of myelo-blastosis, erythroblastosis and Rous sarcoma, and later found to be either nonexistent or only quantitative, are indeed quantitative or qualitative. Such studies may help to resolve the question whether one or a number of viruses are involved in the induction of chicken leukosis and other tumors of birds.

LYMPHOMATOSIS

The lymphomatosis strain RPL-12 virus was isolated (Burmester, 1947) from a lymphosarcoma originally described by Olson (1941). The RPL-12 virus has been found to induce, besides "extravascular" visceral lymphomatosis and osteopetrosis, the so-called "intravascular" visceral lym-

FIG. 19.45 — Part of the cytoplasm of a lymphocyte showing cytoplasmic inclusion one micron in diameter.

FIG. 19.45 A – Part of Fig. 19.45 at higher magnification showing cytoplasmic inclusion, without a membrane, containing virus particles, ×90,000.

phomatosis, later reclassified as erythroblastosis (Burmester et al., 1959a, 1960a, c; Gross et al., 1959). The virus of visceral lymphomatosis, obtained from both natural and experimentally induced disease, as well as from livers of embryos of apparently normal birds, induces not only visceral lymphomatosis but erythroblastosis (Burmester et al., 1959a). Occasionally it also causes osteopetrosis, hemangiomas, fibrosarcomas, myxosarcomas, myelocytomas, neurolymphomatosis, ocular lymphomatosis, and granuloblastosis (myeloblastosis). Chickens, reared in contact with birds inoculated with strain RPL-12 lymphomatosis, have been observed to develop occasionally erythroblastosis or "intravascular" visceral lymphomatosis (Burmester et al., 1959a). As shown by Burmester et al. (1959b), "extravascular" visceral lymphomatosis which arises intra- or extramedullarly in which the cell type is a highly undifferentiated element of the lymphoid series (Gross et al., 1959) and hence described as tumorous (Dmochowski, 1960a, b, c; 1961; 1963) is also induced by strain R of erythroblastosis (originally described by Engelbreth-Holm and Rothe-Meyer, 1932). Pathologically, the "extravascular"

visceral lymphomatosis induced by RPL-12 strain does not differ from that induced by strain R, or from that induced by myeloblastosis BAI strain A virus (Burmester et al., 1959b). These observations may have some bearing on the results of electron microscope studies of organs and tissues from chickens with visceral or "extravascular" lymphomatosis.

Examination of the parts of spleen of chickens with visceral lymphomatosis showing neoplastic involvement revealed certain characteristic changes in cells, such as reticulo-endothelial cells, macrophages and lymphoblasts (tumorous cells), or cells of the lymphoid series (Dmochowski, 1960a, b, c; 1961; 1963; Dmochowski and Grey, 1958; Dmochowski et al., 1959a, c; 1964). In addition, virus particles have been found in the intercellular spaces. Alterations in mitochondria and endoplasmic reticulum have been observed, with nucleus and nucleolus, showing changes such as alteration in size and density, which need not necessarily indicate a specific effect of viral infection. Cytoplasmic inclusions of the size of mitochondria or larger, filled with dense osmiophilic material undergoing various stages of vacuolization with

FIG. 19.46 — Part of the cytoplasm of a cell present in the spleen of a chicken with visceral lymphomatosis. Numerous cytoplasmic inclusions (A) in various stages of formation, some with virus particles. ×15,000.
FIG. 19.46A — Part of Figure 19.46 showing a cytoplasmic inclusion with membranous structures and virus particles. ×75,000.

FIG. 19.47—Budding of plasma membrane of two lymphoblasts. ×90,000.

virus particles present in varying numbers, have been observed in all three types of cells apparently with least frequency in lymphoid cells (Fig. 19.44, 19.45, 19.45A, 19.46, 19.46A). In addition, occasional "budding" of plasma membrane (Fig. 19.47) and very occasionally structures composed of the formation of dense small osmiophilic particles with circular images

or viroplasm, similar to those present in Rous sarcoma, myeloblastosis, and erythroblastosis, have been found in the cytoplasm of cells which could only be described as cells of the lymphoid series. In addition, "whorl-like" formations have been observed in these cells as well as in the reticulo-endothelial cells and in macrophages.

FIG. 19.48—Low power view of cells in nephroblastoma. Budding of plasma membranes (arrows) and intercellular virus particles. ×45,000.

FIG. 19.49 — Cytoplasmic inclusions with virus particles in a cell of nephroblastoma. ×30,000.

The changes have been observed in the cells of spleen from chickens with visceral lymphomatosis, whether induced by strain RPL-12 or strain R virus (Dmochowski et al., 1964). The findings confirm and extend the original observations made on cells in the spleen from chickens with RPL-12 strain induced lymphomatosis (Dmochowski et al., 1959c; Dmochowski, 1960a-c, 1961; 1963).

NEPHROBLASTOMA

Burmester et al. (1959b) and Thorell (1958, 1960) demonstrated that myeloblastosis BAI-A strain virus induces myeloblastosis, visceral lymphomatosis, osteopetrosis, and renal adenocarcinoma, later described by Burmester as nephroblastoma. This original observation has been confirmed by Baluda and Jamieson (1961) and by Ishiguro et al. (1962).

FIG. 19.50 — Higher view of cytoplasmic inclusions in nephroblastoma, partly vacuolized and containing virus particles. ×68,000

FIG. 19.47 – Budding of plasma membrane of two lymphoblasts. ×90,000.

NEPHROBLASTOMA

Burmester et al. (1959b) and Thorell (1958, 1960) demonstrated that myeloblastosis BAI-A strain virus induces myeloblastosis, visceral lymphomatosis, osteopetrosis, and renal adenocarcinoma, later described by Burmester as nephroblastoma. This original observation has been confirmed by Baluda and Jamieson (1961) and by Ishiguro et al. (1962).

FIG. 19.50 — Higher view of cytoplasmic inclusions in nephroblastoma, partly vacuolized and containing virus particles. ×68,000.

FIG. 19.51 — Viral matrix or virus sum and budding particle in nephroblastoma cell. ×30,000.

FIG. 19.52 — High magnification of part of viral matrix showing circular images (arrows) and dense osmiophilic granules. ×117,00.

An electron microscope study (Dmochowski et al., 1960, 1961, 1964; Dmochowski, 1961, 1963) of nephroblastoma, both induced and transplanted, has revealed numerous intercellular and occasional cytoplasmic virus particles (Fig. 19.48). Cytoplasmic inclusions, similar to viroplasts in myeloblastosis (Bonar et al., 1960; Haddad et al., 1960; Weinstein et al., 1960; Dmochowski et al., 1958b; 1959a), filled with dense osmiophilic material, undergoing various stages of vacuolization with virus particles, either few or numerous, have been observed (Figs. 19.49 and 19.50). Budding of plasma membrane of cells leading to virus particle formation (Dmochowski et al., 1961) has been found more frequently (Dmochowski et al., 1964) than in erythroblastosis, myeloblastosis, or lymphomatosis or in Rous sarcoma cells (Figs. 19.48 and 19.51). Aggregates of dense osmiophilic particles of the size of ribosomes described as viral matrix, with various stages of virus particle formation more numerous than in other chicken neoplasias have been observed (Figs. 19.51 and 19.52). Frequently, cells have been found showing simultaneously the budding of plasma membrane, viral matrix, and cytoplasmic inclusions. If these changes are judged as sites of virus synthesis in cells of nephroblastoma, they have been found more numerous than in the cells of any other chicken neoplasia so far examined (Dmochowski et al., 1961, 1964).

These observations pertaining to the epithelial elements of nephroblastoma have been confirmed and extended to other cellular elements of this tumor (Heine et al., 1962a). Only occasional budding of plasma membrane but no other symptoms of viral synthesis have been found in the stromal cells, sarcomatous cells, and chondrocytes.

In these studies (Haguenau and Beard, 1962) no relationship could be established between the viroplasm or viral matrix and the formation of virus particles by nephroblastoma cells. In other studies (Dmochowski et al., 1961) formation or assembly of virus particles has been observed within the viroplasm or viral matrix in cells showing the formation of virus particles by plasma membranes, although this does not necessarily indicate a relationship between these two sites of virus formation.

The characteristic virus particles, while of the average size of 800 Å in cytoplasmic inclusions and in viral matrix or viroplasm, have been found to vary considerably in size, up to 1400 Å in diameter, when found in the intercellular spaces.

Adenosine triphosphatase activity was observed in nephroblastoma along the plasma membrane of cells of proximal and distal convoluted tubules and in the budding virus particles from these cells (de Thé et al., 1963c). However, sarcoma and cartilage plasma cell membranes and those of glomerular cells do not show the enzyme; virus particles which develop from these cells also do not show the enzyme (de Thé et al., 1963c). Virus particles from blood plasma of chickens with myeloblastosis show enzyme activity and are infective (Beard, 1963). It would be of interest to find out if virus particles can be obtained from nephroblastoma which do not show enzyme activity and are infective.

NONNEOPLASTIC CELLS AND TISSUES

As in other infections with the so-called ordinary or infectious viruses, cells and tissues which do not participate directly in the neoplastic process have been found infected with chicken tumor viruses. This is an important observation and may have an important bearing on the interpretation of the changes observed in reticular cells and in macrophages present in the spleen of chickens with erythroblastosis, myeloblastosis, visceral lymphomatosis, and also Rous sarcoma.

Thymus Gland

A study of the thymus gland of chickens with myeloblastosis (de Thé et al., 1963a) has demonstrated replacement of the lymphocytes of the cortex but not of the medulla by blast cells with the presence in the cytoplasm of these cells of spherical particles (650–850 Å) surrounded by a thin,

FIG. 19.51 — Viral matrix or viraplasm and budding (arrow) in nephroblastoma cell. ×30,000.
FIG. 19.52 — High magnification of part of viral matrix showing circular images (arrows) and dense asmiaphilic granules. ×117,00.

An electron microscope study (Dmochowski et al., 1960, 1961, 1964; Dmochowski, 1961, 1963) of nephroblastoma, both induced and transplanted, has revealed numerous intercellular and occasional cytoplasmic virus particles (Fig. 19.48). Cytoplasmic inclusions, similar to viroplasts in myeloblastosis (Bonar et al., 1960; Haddad et al., 1960; Weinstein et al., 1960; Dmochowski et al., 1958b; 1959a), filled with dense osmiophilic material, undergoing various stages of vacuolization with virus particles, either few or numerous, have been observed (Figs. 19.49 and 19.50). Budding of plasma membrane of cells leading to virus particle formation (Dmochowski et al., 1961) has been found more frequently (Dmochowski et al., 1964) than in erythroblastosis, myeloblastosis, or lymphomatosis or in Rous sarcoma cells (Figs. 19.48 and 19.51). Aggregates of dense osmiophilic particles of the size of ribosomes described as viral matrix, with various stages of virus particle formation more numerous than in other chicken neoplasias have been observed (Figs. 19.51 and 19.52). Frequently, cells have been found showing simultaneously the budding of plasma membrane, viral matrix, and cytoplasmic inclusions. If these changes are judged as sites of virus synthesis in cells of nephroblastoma, they have been found more numerous than in the cells of any other chicken neoplasia so far examined (Dmochowski et al., 1961, 1964).

These observations pertaining to the epithelial elements of nephroblastoma have been confirmed and extended to other cellular elements of this tumor (Heine et al., 1962a). Only occasional budding of plasma membrane but no other symptoms of viral synthesis have been found in the stromal cells, sarcomatous cells, and chondrocytes.

In these studies (Haguenau and Beard, 1962) no relationship could be established between the viroplasm or viral matrix and the formation of virus particles by nephroblastoma cells. In other studies (Dmochowski et al., 1961) formation or assembly of virus particles has been observed within the viroplasm or viral matrix in cells showing the formation of virus particles by plasma membranes, although this does not necessarily indicate a relationship between these two sites of virus formation.

The characteristic virus particles, while of the average size of 800 A in cytoplasmic inclusions and in viral matrix or viroplasm, have been found to vary considerably in size, up to 1400 A in diameter, when found in the intercellular spaces.

Adenosine triphosphatase activity was observed in nephroblastoma along the plasma membrane of cells of proximal and distal convoluted tubules and in the budding virus particles from these cells (de Thé et al., 1963c). However, sarcoma and cartilage plasma cell membranes and those of glomerular cells do not show the enzyme; virus particles which develop from these cells also do not show the enzyme (de Thé et al., 1963c). Virus particles from blood plasma of chickens with myeloblastosis show enzyme activity and are infective (Beard, 1963). It would be of interest to find out if virus particles can be obtained from nephroblastoma which do not show enzyme activity and are infective.

NONNEOPLASTIC CELLS AND TISSUES

As in other infections with the so-called ordinary or infectious viruses, cells and tissues which do not participate directly in the neoplastic process have been found infected with chicken tumor viruses. This is an important observation and may have an important bearing on the interpretation of the changes observed in reticular cells and in macrophages present in the spleen of chickens with erythroblastosis, myeloblastosis, visceral lymphomatosis, and also Rous sarcoma.

Thymus Gland

A study of the thymus gland of chickens with myeloblastosis (de Thé et al., 1963a) has demonstrated replacement of the lymphocytes of the cortex but not of the medulla by blast cells with the presence in the cytoplasm of these cells of spherical particles (650–850 A) surrounded by a fine

FIG. 19.51 — Viral matrix or viroplasm and budding (arrow) in nephroblastoma cell. ×30,000.
FIG. 19.52 — High magnification of part of viral matrix showing circular images (arrows) and dense osmiophilic granules. ×117,00.

dense ring, and enclosed by a less dense structure of 100–120 Å in thickness. Occasional budding of plasma membranes of the blast cells leading to virus particle formation has also been observed. Cytochemical studies have revealed the presence of adenosine triphosphatase activity of the plasma membranes and on the surface of individual virus particles. Similar studies of the thymus gland of chickens with erythroblastosis strain R have failed to reveal any specific changes. The blast cells may be a response of the reticular or lymphoid cells to BAI strain A virus (de Thé et al., 1963a). Cells of chickens with nephroblastoma which produce the same virus by "budding" apparently do not show these cytoplasmic changes (Heine et al., 1962a)

The enzyme adenosine triphosphatase first demonstrated in viroplasts or cytoplasmic inclusions of myeloblasts (Bonar et al., 1960) has also been found in the budding plasma membrane of the blast cells present in the thymus gland (de Thé et al., 1963a). It is also present, as already mentioned, in the plasma membrane of some epithelial cells of nephroblastoma and in their budding (Heine et al., 1962a). It is of interest that other cells of nephroblastoma apparently do not exhibit the same enzyme activity, although they appear to form virus by budding of their plasma membrane (de Thé et al., 1962).

Virus particles have also been found in the intercellular spaces of the thymus gland and in cytoplasmic vacuoles of cells described as of reticular origin.

Pancreas

Acinar cells of the pancreas of chicken embryos from supposedly normal hens and of apparently healthy chicks have been found to show budding of plasma membrane (Zeigel, 1961) similar to that observed in lymphoblasts, myeloblasts, erythroblasts, and in the epithelial cells of nephroblastoma (Dmochowski et al., 1960, 1961). The occurrence of the budding phenomenon has been found very frequently in the cells of the pancreas. It has not been found in the cells of the liver,

lung, kidney, spleen, small intestine, and heart, although characteristic virus particles (800 Å) composed of two concentric double membranes and a central dense nucleoid, have been observed in the intercellular spaces, in the cytoplasmic vesicles, and in vacuoles of cells, in all these organs as well as in the pancreas. The cells of the pancreas may be a site of tumor virus formation in latent or subclinical infections (Zeigel, 1961).

As yet there is no evidence that the characteristic virus particles in the pancreas of normal chickens are infectious particles, although their structure is identical with that of the particles found in Rous sarcoma, erythroblastosis, myeloblastosis, and visceral lymphomatosis ("extravascular"). This similarity gains in significance in view of the results of studies on the transmission of avian tumor viruses, such as visceral lymphomatosis (Burmester, 1957), Rous sarcoma, and erythroblastosis-lymphomatosis (Burmester et al., 1960a, b, c).

Characteristic virus particles in the spleen and in the bone marrow of normal chickens and apparently normal embryos have been described previously (Benedetti, 1957; Benedetti et al., 1956). They have also been described in tissue culture of such cells (Febvre and Benedetti, 1958). They have been found extracellularly in cytoplasmic vacuoles, or vesicles, and in cytoplasmic inclusions or viroplasm. Some of the structures in the different cells may be the result of phagocytosis, but at least some are due to the infectious process.

Similar evidence of the presence of virus in chick embryos has been obtained in another way (Rubin, 1960). An agent was found in cultures of tissues from some embryos which inhibited the infection of cells by Rous sarcoma. This agent was found to be the RPL-12 strain virus. Further extracts of apparently normal chick embryos have been found to transmit the neoplastic disease (Burmester, 1952). The recently reported RIF (resistance inducing factor) (Rubin, 1961) may be latent lymphomatosis virus, known to be present in many

matosis (Dmochowski *et al.*, 1959c). These cells appear to participate in virus synthesis more actively and more frequently than the respective tumorous cells of the erythroid, myeloid, or lymphoid series, but not exclusively, as reported by Beard (1963). Macrophagelike cells in Rous sarcoma cells grown *in vivo* or *in vitro* show changes (Beard, 1963) similar to those in macrophages studied in all forms of chicken leukosis. There is no need to accept the contention that macrophages or reticular cells have neoplastic traits, when concluding that these cells may also serve as seats of virus formation. It has indeed been proposed that macrophages may be the site of maturation of virus liberated in incomplete form by other cells in erythroblastosis (Iwakata and Amano, 1958).

The macrophages in the spleen of infected chickens are frequently seen in various stages of degeneration while there appears to be no lethal effect on myeloblasts grown *in vitro* (Beard, 1963). However, a comparison of the appearance of cytoplasmic inclusions or viroplasts in myeloblasts grown *in vitro*, as shown by Bonar *et al.* (1959, 1960) or in erythroblasts grown *in vitro* (Heine *et al.*, 1961) with that of cytoplasmic inclusions found in macrophages in the spleen of chickens with these diseases has failed to reveal any differences. Thus it appears that viral synthesis may take place in macrophages, while there is no doubt that some virus particles are phagocytized. If it is accepted that all cytoplasmic inclusions, contrary to morphological evidence, are phagocytized, the question of their origin arises. If macrophages do not synthesize the virus, then such inclusions must come from myeloblasts, erythroblasts, or lymphoblasts which would indicate that such cells also may degenerate in the spleen or liver of the affected chickens. The blast cells found in the spleen or liver of the diseased tissues have been designated "tumorous" (Dmochowski, 1960a–c, 1961, 1963; Dmochowski *et al.*, 1958a, b; 1959a, b, c) and not the reticular cells or macrophages (Beard, 1963). In these studies the term "tumorous" was used in preference to a specific designation such as myeloblasts or erythroblasts in view of the involvement of the myeloid or erythroid series of blood elements and therefore constituted a broader description of the specific types of cells encountered in the organs of the infected chickens.

PROPERTIES OF THE VIRUSES

An impressive amount of data is now available on the physical, chemical, and biological properties of the viruses involved in chicken neoplasia (Beard, 1963; Beard *et al.*, 1963). Considerable information has also been obtained on Rous sarcoma virus by the application of density gradient sedimentation (Crawford, 1960; Crawford and Crawford, 1961). There is no doubt that the virus particles observed in the neoplastic tissues or in the blood plasma of diseased chickens are the agents responsible for the various types of chicken neoplasia. Greater details of the evidence available in this respect are presented in a recent review by Beard (1963).

Particles (600–800 Å) with a characteristic appearance as already mentioned have been first observed in cells of Rous sarcoma grown *in vitro* (Claude *et al.*, 1947). Since then a considerable amount of impressive work has been carried out in pioneering studies on metal-shadowed virus particles present in the blood of diseased chickens (Beard, 1963). Electron microscopy of ultrathin sections of particles inside the cells extracellularly located and in the blood of chickens (Bernhard *et al.*, 1958), as well as in purified preparations has revealed the internal structure of these particles (Bernhard, 1960). Similar structure with even greater detail has been shown in Rous sarcoma virus particles by Epstein (1957, 1958, 1960), and by Epstein and Holt (1958). The particles are composed of a central dense nucleoid, surrounded by a zone of low electron density which in turn is surrounded by a membrane; this membrane is surrounded by an electron-lucent zone and two outer membranes.

The results of studies combining treat-

Only biological tests of the extracts of the pancreas, showing the described morphological changes in apparently normal embryos and chickens, and in chickens infected with the myeloblastosis virus can determine the type of virus involved. It remains to be ascertained whether in the particular findings (Zeigel, 1961) or in those with the pancreas of infected chickens (Heine *et al.*, 1963), the virus of visceral lymphomatosis (RPL-12) or myeloblastosis was involved.

It is now known that erythroblastosis and visceral lymphomatosis develop in chickens maintained in contact with chickens bearing Rous sarcoma virus (Burmester *et al.*, 1960b). In addition, as already mentioned, the RPL-12 strain of lymphomatosis virus induces erythroblastosis (Burmester, 1952) and the BAI strain A of myeloblastosis virus induces visceral lymphomatosis, osteopetrosis, and nephroblastoma (Burmester *et al.*, 1959b). It would be of interest to ascertain whether the virus particles can be identified with the BAI-A strain myeloblastosis virus by the adenosine triphosphatase reaction. This, however, may be difficult as apparently only some cells show production of this enzyme, while other cells of chickens infected with the myeloblastosis strain A virus, such as chondrocytes and cells which lead to collagen formation present in nephroblastoma, fail to show the enzyme production (Heine *et al.*, 1962a).

The failure to observe virus particles in the pancreas of chickens with erythroblastosis induced by either strain R or ES4, need not necessarily indicate that the particles are not present in this organ. It may, of course, be an outcome of cell-type response to these two particular strains of avian tumor viruses.

Liver

Chickens with extensive hepatic lymphomatosis (massive parenchymal infiltration with lymphoid cells) induced by BAI strain A myeloblastosis virus show virus particle formation by budding of plasma membrane of lymphoid cells and in microvilli of liver parenchymal cells at the bile canalicular border (de Thé *et al.*, 1963b). In chickens with myeloblastosis, virus particles have been found in the lumen of canaliculi but no budding has been observed. Budding and virus particles appeared to be related to virus concentration in the invading lymphoid tissue or in the circulating blood plasma of myeloblasts. No budding or virus particles could be found in the liver with extensive lymphomatosis induced by transplanted nephroblastoma (de Thé *et al.*, 1963b).

The myeloblastosis virus induces, as already mentioned, a broad spectrum of neoplasias in chickens (Burmester *et al.*, 1959b) and non-neoplastic response in the thymus gland (de Thé *et al.*, 1963a; Arvy *et al.*, 1963) and in the pancreas (Heine *et al.*, 1963) in the infected chickens. It appears that the liver cells reveal a similar phenomenon of budding to that observed in the cells of the pancreas of infected and of some normal chickens, and also in the cells of normal chick embryos (Zeigel, 1961).

It is of interest that the hepatic cells showing the budding phenomenon show no evidence of hyperplasia or any cytological alterations (de Thé *et al.*, 1963b). Thus, it is possible in the virus-host cell reaction to have virus synthesis with or without neoplasia.

RETICULAR CELLS AND MACROPHAGES

The presence of avian tumor viruses in the cells of the thymus gland and of the pancreas as well as in the cells of other organs has now been ascertained. These cells do not participate directly in the neoplastic process, but nevertheless they are the seat of tumor virus synthesis. Similarly, reticular cells and macrophages of the spleen, bone marrow, and other tissues contain the virus and apparently are the seat of virus synthesis in myeloblastosis (Dmochowski *et al.*, 1958b; Parsons *et al.*, 1959), in erythroblastosis (Benedetti and Bernhard, 1958; Benedetti and Leplus, 1958; Dmochowski *et al.*, 1958a, 1959b; Heine *et al.*, 1961; Iwakata, 1958; Iwakata and Amano, 1958) and in visceral lympho-

matosis (Dmochowski *et al.*, 1959c). These cells appear to participate in virus synthesis more actively and more frequently than the respective tumorous cells of the erythroid, myeloid, or lymphoid series, but not exclusively, as reported by Beard (1963). Macrophagelike cells in Rous sarcoma cells grown *in vivo* or *in vitro* show changes (Beard, 1963) similar to those in macrophages studied in all forms of chicken leukosis. There is no need to accept the contention that macrophages or reticular cells have neoplastic traits, when concluding that these cells may also serve as seats of virus formation. It has indeed been proposed that macrophages may be the site of maturation of virus liberated in incomplete form by other cells in erythroblastosis (Iwakata and Amano, 1958).

The macrophages in the spleen of infected chickens are frequently seen in various stages of degeneration while there appears to be no lethal effect on myeloblasts grown *in vitro* (Beard, 1963). However, a comparison of the appearance of cytoplasmic inclusions or viroplasts in myeloblasts grown *in vitro*, as shown by Bonar *et al.* (1959, 1960) or in erythroblasts grown *in vitro* (Heine *et al.*, 1961) with that of cytoplasmic inclusions found in macrophages in the spleen of chickens with these diseases has failed to reveal any differences. Thus it appears that viral synthesis may take place in macrophages, while there is no doubt that some virus particles are phagocytized. If it is accepted that all cytoplasmic inclusions, contrary to morphological evidence, are phagocytized, the question of their origin arises. If macrophages do not synthesize the virus, then such inclusions must come from myeloblasts, erythroblasts, or lymphoblasts which would indicate that such cells also may degenerate in the spleen or liver of the affected chickens. The blast cells found in the spleen or liver of the diseased tissues have been designated "tumorous" (Dmochowski, 1960a–c, 1961, 1963; Dmochowski *et al.*, 1958a, b; 1959a, b, c) and not the reticular cells or macrophages (Beard, 1963). In these studies the term "tumorous" was used in preference to a specific designation such as myeloblasts or erythroblasts in view of the involvement of the myeloid or erythroid series of blood elements and therefore constituted a broader description of the specific types of cells encountered in the organs of the infected chickens.

PROPERTIES OF THE VIRUSES

An impressive amount of data is now available on the physical, chemical, and biological properties of the viruses involved in chicken neoplasia (Beard, 1963; Beard *et al.*, 1963). Considerable information has also been obtained on Rous sarcoma virus by the application of density gradient sedimentation (Crawford, 1960; Crawford and Crawford, 1961). There is no doubt that the virus particles observed in the neoplastic tissues or in the blood plasma of diseased chickens are the agents responsible for the various types of chicken neoplasia. Greater details of the evidence available in this respect are presented in a recent review by Beard (1963).

Particles (600–800 Å) with a characteristic appearance as already mentioned have been first observed in cells of Rous sarcoma grown *in vitro* (Claude *et al.*, 1947). Since then a considerable amount of impressive work has been carried out in pioneering studies on metal-shadowed virus particles present in the blood of diseased chickens (Beard, 1963). Electron microscopy of ultrathin sections of particles inside the cells extracellularly located and in the blood of chickens (Bernhard *et al.*, 1958), as well as in purified preparations has revealed the internal structure of these particles (Bernhard, 1960). Similar structure with even greater detail has been shown in Rous sarcoma virus particles by Epstein (1957, 1958, 1960), and by Epstein and Holt (1958). The particles are composed of a central dense nucleoid, surrounded by a zone of low electron density which in turn is surrounded by a membrane; this membrane is surrounded by an electron-lucent zone and two outer membranes.

The results of studies combining treat-

ment with enzymes and electron microscopy have demonstrated that treatment with ribonuclease, under suitable conditions, leads to the removal of the core of virus particles present in Rous sarcoma tumors. A conclusion was therefore reached that this virus is an RNA-carrying virus (Epstein and Holt, 1958; Yamaguchi, 1962).

The virus particles, especially particles found outside the cells, vary in size and appearance, especially those found in nephroblastoma (Dmochowski, 1961, 1963; Dmochowski et al., 1960, 1961; Heine et al., 1962). This variation in size does not appear to be an artifact and may have some, as yet unknown, significance (Dmochowski et al., 1961). Nevertheless, virus particles present in the cytoplasmic inclusions or gray bodies (viroplasts) for the most part show a remarkable uniformity in size (800 Å) and spherical appearance, at least as far as can be judged by the techniques available at the present time. They are composed of a nucleoid, electron-lurent zone and outer double membrane. A quantitative correlation between the virus particles present in Rous sarcoma cells and tumor-inducing property has been obtained (Haguenau et al., 1958; Epstein, 1958, 1960). This is most encouraging as morphology alone can not serve as a criterion for the identification of a virus (Dmochowski, 1960b; Haguenau, 1960; Haguenau and Beard, 1962).

There is no doubt that too much emphasis cannot be placed on the sizes of virus particles as they appear in sections of tissues or high-speed centrifugal pellets of virus preparations. With this proviso, a comparison of the sizes and appearances of virus particles in tissues from different chicken neoplasms prepared in an identical manner can be made. Even in such uniformly prepared tissues or high-speed centrifugal pellets the particles of a certain strain may vary in size, shape, and internal structure. This is obviously not entirely the result of preparation procedures, but may indicate various stages in virus

particle formation and maturation. Calculations from sedimentation data of BAI strain A myeloblastosis virus (Sharp and Beard, 1954), indicate the size value of 1100 Å for the virus in hydrated state. It is of interest that at least some extracellular virus particles in the spleen of chickens with myeloblastosis (granuloblastosis) and in nephroblastoma are of the same size or are even larger. Therefore, the size and even the appearance of virus particles has to be taken with reservations. It is subject to revision as the various biophysical and electron microscope techniques of preparation of biological specimens are developed and improved.

The BAI strain A virus has been found to show strong activity to dephosphorylate adenosine and inosine triphosphates (Beard, 1963). The myeloblastosis virus particles in purified preparations also carry the enzyme (Green and Beard, 1955). This enzyme activity is proportional to the number of particles shown in the electron microscope study of the plasma of chickens with myeloblastosis or in tissue culture fluids from myeloblastosis grown in vitro (Beard, 1963). It is due to the inclusion of plasma membrane in the coat of the particles (Beard, 1963). Sedimentation, electrophoresis, and immunological studies (Beard, 1963) have demonstrated an intimate association of the enzyme activity with the virus. There is no evidence to suggest the possible biological significance of the association of the enzyme activity with the BAI strain A virus. Although probably not unique, this phenomenon nevertheless is of great interest, especially in view of the observation that loci of virus synthesis (viroplasts) in the neoplastic cells (myeloblasts) exhibit similar enzyme activity (Beard, 1963). This enzyme activity is also present in the budding plasma membrane of epithelial cells of nephroblastoma (de Thé et al., 1962) and of the thymus cells of chickens with myeloblastosis (Beard, 1963). Nevertheless, plasma membranes of the cartilage cells and chondrocytes do not show enzyme activity (de Thé et al., 1962)

and virus particles liberated by these cells do not show the enzyme (de Thé et al., 1962).

This enzyme activity is specific for the myeloblastosis virus (Beard, 1963). It is all the more of interest as the erythroblastosis virus and other chicken tumor viruses (Beard, 1963) have not shown a similar association with any enzyme activity. All previous studies which showed an association of enzyme activity with particles of other viruses were found to be erroneous, when improved purification procedures failed to confirm these studies.

In ultrathin sections of purified preparations of BAI strain A myeloblastosis virus, condensations of electron dense material have been observed with an appearance of either granules or filaments (Beard et al., 1963). A study of the appearance of myeloblastosis and of erythroblastosis virus (Beard et al., 1963; Bonar et al., 1963) following staining with potassium phosphotungstate (Brenner and Horne, 1959) has revealed an essential similarity in appearance betwen these two viruses and that of Rous sarcoma virus studied by the same technique (Dourmashkin et al., 1962; Dourmashkin and Simmons, 1961). The particles are spherical with knobs which surround the outer membrane. It is of interest that in some sections avian tumor viruses found in tissues of apparently normal chickens (Zeigel, 1961) and of infected chickens (Heine et al., 1963) appear surrounded by spines or protrusions which may correspond to those seen on particles stained negatively with potassium phosphotungstate.

Originally, virus particles of widely varying forms (spheroid, tadpole, spermlike) have been found present in shadow-cast preparations from the blood of chickens with BAI strain A virus (Sharp et al., 1952). They are similar to those of the Newcastle disease virus, observed under the same conditions (Cunha et al., 1947). Following the employment of a new technique based on drying of viruses on the surface of agar (Sharp et al., 1952) which led to the diffusion of water and salt, only spherical particles have been observed in shadow-cast preparations from the blood of chickens infected with BAI strain A virus. These studies have demonstrated that the tailed and pleomorphic forms of at least some viruses result from surface tension and salt concentration during drying of the virus particles (Beard et al., 1955). Similar conditions apparently result in a similar appearance of myeloblastosis BAI strain A virus (Beard et al., 1963), Rous sarcoma virus particles (Dourmashkin and Simmons, 1961), the mammary tumor virus (Dmochowski et al., 1963; Lyons and Moore, 1962), Gross mouse leukemia virus (Dmochowski et al., 1963) and presumably of other mouse leukemia viruses (Dalton et al., 1962; Zeigel and Rauscher, 1963). These tail-like and pleomorphic forms of the virus particles can largely be prevented by the resuspension in a proper diluent or by the employment of the sedimentation technique on agar (Sharp et al., 1952).

Treatment of BAI strain A virus particles with saponin leads to the disintegration of the outer membrane and to the appearance of structures 200–400 Å in size (Bonar et al., 1963) similar to those which have hemagglutinating properties in fowl plague (Waterson et al., 1961) and influenza virus (Horne and Waterson, 1960; Hoyle et al., 1961). Similar treatment of Rous sarcoma virus particles has revealed the structure of the outer membrane of the particles and of what may be the internal components of the virus (Dourmashkin and Simmons, 1961).

CONCLUSIONS

The electron microscope studies have demonstrated that the viruses of avian leukosis and other tumors cannot be distinguished morphologically from one another. Constantly accumulating evidence appears to indicate an essential similarity in the site of virus replication within the cells of all avian tumors and a considerable similarity in the relationship of these viruses to the constituents of cells of other

infected chicken organs, not directly involved in the neoplastic process, as well as to the constituents of cells of apparently normal chickens. The cells show viroplasm or viral matrix formation, cytoplasmic inclusions or viroplasts and the budding of plasma membrane. However, there appear to be quantitative differences in the type of response of cells of different origin to infection with the different virus strains. The apparent differences in the process of myeloblastosis virus synthesis in the thymus gland, kidney, and other cells may conceivably be only an expression of quantitative differences which may be revealed by further extensive electron microscope studies or they may be a real expression of the reaction of the different cell types to infection with the same virus. Nevertheless, some cells, such as macrophages, and reticular and epithelial cells apparently are capable of synthesizing avian tumor viruses in a manner similar to that of the cells (myeloblasts, erythroblasts, lymphoblasts) which respond by unrestricted proliferative growth. As some types of cells are capable of perpetuating the avian tumor viruses while other types of cells respond by neoplastic behavior, the level at which electron microscopy is now looking at virus infected cells is obviously not

capable of giving an indication of the morphological changes which lead to neoplasia. Electron microscopy with further improvements in specimen preparation and resolution may reveal even finer details of changes which occur in the cells infected with neoplastic viruses. It is apparent however that only if combined with other approaches electron microscopy may conceivably give some indication of the nature of the neoplastic process. While this may be a long-term goal, a more immediate aim appears to be the electron microscope study, preferably combined with cytochemical studies of suitably prepared specimens of one type of neoplasia induced by viruses of different strains, for example, a study of erythroblastosis induced by strains R, ES4, RPL-12, or by Rous sarcoma. Such studies may help to determine whether the morphological changes observed in erythroblastosis of the infected chickens will be similar or will reveal the quantitative differences characteristic of the particular virus strains. There is no doubt that correlative biological, cytochemical, and electron microscope studies will shed much light on virus-host cell relationship not only in avian neoplasia but in other types of cancer of viral origin.

Infectious Bronchitis

Avian infectious bronchitis is an acute, highly contagious, respiratory disease of chickens. The disease may occur in all age groups, but in the United States and Canada it is particularly a problem in adult laying flocks. Infectious bronchitis was first reported by Shalk and Hawn (1931), who had observed the disease in North Dakota in the spring of 1930. It soon became widespread, as indicated by the reports of others: namely, Beaudette and Hudson (1933), Bushnell and Brandly (1933), Beach (1934), and Beach and Schalm (1936). Infectious bronchitis has also been reported to occur in Israel (Komorov et al, 1941), the Netherlands (Swierstra, 1947; Richter, 1955; Bijlenga, 1956), England (Asplin, 1948), Germany (Fritzsche, 1952), Japan (Sato et al., 1955a; 1955b; Kawakubo et al., 1958), Italy (Galassi, 1956; Papparella et al., 1956; Petek, 1956; Petek and Corazzola, 1957), Greece (Ayfantis, 1956), Brazil (Hipólito, 1957),

France (Brion et al., 1959), and Hawaii (Raggi, 1960).

Etiology. The causative agent of infectious bronchitis is a filterable virus. The name *Tarpeia pulli* has been proposed for the virus (Merchant and Packer, 1956). Reagan et al. (1948) have estimated the virus to be about 65–135 mμ (millimicrons) in size. Filtration studies through gradocol membrane filters also placed the particle size within this range, 70–105 mμ (Hofstad, 1957). The virus passes the Seitz EK pad, all grades of Berkefeld filters, and the Selas 06 filter. It can be grown in the developing chicken embryo, where the virus causes stunting or death of the embryo after a few serial passages.

Infectious bronchitis virus has been grown in cell cultures of chicken embryo kidney cells and fibroblasts (Chomiak et al., 1958; Gunningham, 1960; Pette, 1960; and Kawamura et al., 1961). Only the embryo-adapted strains, such as the Beaudette

strain, will grow in cell cultures. Growth is detected by a cytopathic effect which can be neutralized by specific immune serum. Mallman and Cunningham (1963) found, in allantoic fluid infected with infectious bronchitis virus, a factor which enhanced the attachment and rapid formation of monolayers of chicken embryo cell cultures on glass surfaces. Carbo and Cunningham (1959) found infectious bronchitis virus to agglutinate chicken red blood cells after having been treated with 1 per cent trypsin for 3 hours at 37° C.; however, the reaction could be inhibited by normal as well as immune serum. Muldoon (1960) reported that the hemagglutinin could be released after treating the virus with 1 per cent trypsin for 30 minutes at 56° C. The treated virus could be stored for 3 weeks at −65° C. without loss of activity.

Infected tissues stored in 50 per cent glycerin retain their activity for at least 80 days in a refrigerator (Beach, 1918). In this medium, tissues can be shipped to a laboratory for diagnosis without refrigeration. Bronchitis virus in phosphate buffer at pH 7.79 remained active for 170 days at 4° C. and for 142 days at pH 8.2 in undiluted allantoic fluid (Cunningham and Stuart, 1947a). These authors (1946) found a laboratory strain of infectious bronchitis to be destroyed by common disinfecting agents such as 1 per cent phenol, 1 per cent liquor cresolis saponatus, 1:10,000 potassium permanganate solution, 70 per cent ethyl alcohol, and 1 per cent formalin within the three minute contact period. Quiroz and Hanson (1958) reported bronchitis virus to resist 1 per cent HCl or pH 2 for 1 hour at room temperature, a treatment which inactivated laryngotracheitis and fowl pox viruses. They also found 1 per cent phenol to have no effect on bronchitis virus exposed for 1 hour at room temperature, a treatment which inactivated the B_1 strain of Newcastle disease virus. Ether (20 per cent) reduced the titer but did not inactivate the virus, as was also found by Petek and Corazzola (1958). Most strains of bronchi-

tis virus, diluted 1:100 in 20 per cent horse serum broth, were destroyed after 15 minutes' exposure to 56° C.; however, there was considerable variation among the strains studied (Hofstad, 1956b). Singh (1960) studied the thermostability of bronchitis virus at 56° C. He found a bimodal inactivation at 56° C. indicating existence of two phases, an O (original) phase which was thermostable and a D (derivative) phase which was thermolabile. Virus strains in high embryo passage, such as the Beaudette strain, are in the D phase. The O phase was also found to be more resistant to formalin than the D phase. Cunningham and Stuart (1947b) found that freezing and thawing had no harmful effect on the virus. The virus has remained active for at least 19 years in the lyophilized state at 3° C. It has remained active for at least 7 years stored at −25° C. to −30° C. in the form of infective egg fluid (Hofstad, 1957). Buddha (1956) found 10 per cent glucose to give a stabilizing effect on bronchitis virus in the frozen and lyophilized state.

Transmission and incubation period. The incubation period of infectious bronchitis is 18 to 36 hours, depending on the dosage and route of inoculation. Chickens exposed to an aerosol of undiluted infective egg fluid regularly have tracheal rales within 18 to 24 hours. Natural spread requires about 36 hours or more. The disease spreads rapidly among birds in a flock. Susceptible chickens can be readily infected by intranasal or intratracheal inoculation of tracheal exudate or lung tissue suspension from an infected chicken. Air-borne transmission has been demonstrated experimentally (Levine and Hofstad, 1947), and field observations indicate that transmission through the air takes place readily. Hofstad and Kenzy (1950) found natural air-borne transmission a reliable means of exposing birds in challenge experiments.

The epizootiology of infectious bronchitis is not well understood. The recurrence of the disease year after year on the same farm may indicate that some re-

covered birds remain carriers of the virus, thus perpetuating the infection. However, attempts to demonstrate carriers under experimental conditions have not been successful. Following inoculation of a group of chickens with bronchitis virus, Fabricant and Levine (1951) were unable to detect the presence of virus in tracheal swabs and in the yolk of eggs collected from the recovered birds after 36 days. In nine trials where bronchitis-recovered birds were placed in contact with susceptible chickens, Hofstad (1947) was unable to demonstrate the presence of virus longer than 35 days after recovery. Pette (1959) has recovered bronchitis virus from the cloacal contents up to 24 days after experimental oral infection.

Symptoms. The most characteristic symptoms in young chicks are nasal discharge, gasping, rales, and coughing. The chicks tend to crowd under the hover to keep warm. Wet eyes are commonly seen, and swollen sinuses may be observed occasionally. As the disease progresses, many chicks become weak and depressed. Infectious bronchitis in chicks under 2 weeks of age may cause permanent damage to the oviduct, resulting later in false layers (Broadfoot et al., 1956). However, this is not the only cause of this condition according to Hutt et al. (1956). Mortality in very young chicks may be as high as 25 per cent, but in chickens over 6 weeks of age mortality is negligible. Prince et al. (1962) found feed consumption and weight gain significantly reduced by bronchitis infection.

In chickens over 6 weeks of age and in adult birds the outstanding symptoms are gasping, tracheal rales, and coughing. A nasal discharge is usually not observed. Blood counts taken during the course of the disease reveal a leukopenia during the
FIG. 20.1 — Thin-shelled, rough, and misshapen eggs laid by hens during an outbreak of infectious bronchitis. (Van Roekel, Univ. of Mass.)

first 2 days followed by a leukocytosis which declines after the seventh day to reach normal by the fifteenth day (Machado, 1951).

In laying flocks, production will decline, and misshapen, rough, and soft-shelled eggs (Fig. 20.1) may be found (Gordeuk and Bressler, 1950; Van Roekel et al., 1951; Hill and Lorenz, 1956; Sevoian and Levine, 1957). Broadfoot and Smith (1954) found egg production reduced 25 per cent, the number of unsettable hatching eggs increased 92 per cent, and hatchability reduced 7 per cent in outbreaks of bronchitis studied. Laying of poor quality eggs may continue in some flocks even after recovery of full production. Birds affected in the latter part of their laying year usu-

ally have a marked drop in egg production and some degree of molt. Such flocks require long periods of time to recover production. Pullets in good condition which have started to lay may suffer only a slight drop and regain normal production within a few weeks after recovery from respiratory symptoms. The course of the disease is usually one to two weeks, although it is not uncommon for a few birds in the flock to have symptoms for longer periods.

Pathology. On necropsy of affected chicks, a serous or catarrhal exudate is observed in the trachea. There is a catarrhal or a fibrinous inflammation of the air sacs. In chicks that die, yellowish, caseous plugs may be found in the lower trachea and bronchi. Small areas of pneumonia
FIG. 20.2 — Portion of trachea from an experimentally infected bird 72 hours following inoculation, showing thickened tracheal mucous membrane due to cellular infiltration and edema. ×450.

around the large bronchi may be present occasionally. Very young chicks also have a catarrhal inflammation of the nasal passages and sinuses, causing nasal discharge, wet eyes, and occasionally swollen sinuses. As chicks grow older, this lesion is less common, and in birds over two months of age there is seldom gross involvement of the upper nasal passages and sinuses.

Hofstad (1945) found a thickening of the tracheal mucosa and submucosa due to edema and diffuse cellular infiltration as the principal microscopic lesions in the respiratory tract (Figs. 20.2 and 20.3). There was no interruption of the continuity of the tracheal epithelium, and the lumen contained an exudate in which cellular elements were usually sparse or absent (Fig. 20.4). No inclusion bodies have been observed. On necropsy of infected chickens that are in production, fluid yolk material is found in the abdominal cavity. This is a nonspecific

change and is found in other diseases causing a marked drop in production. Sevoian and Levine (1957) studied the gross and microscopic pathology of the reproductive tract of infected chickens and chickens subjected to physiological stress (removal of feed and water). Oviduct length and weight were markedly reduced in both groups, but return to normal required 21 days for the infected group but only 11 days for the group under stress. Ovarian regression was similarly affected. Microscopically the height of the cellular epithelium lining the oviduct was sharply reduced and the cells became cuboidal in shape with some loss of cilia. Dilation of the glands occurred in half the oviducts studied. In the lamina propria and intertubular stroma of the oviducts, lymphocytic foci and cellular infiltration were present. Significantly fewer changes of a similar nature were seen in the group under stress.

Immunity. Chickens that have recovered

FIG. 20.3 — Portion of trachea from a field case of infectious bronchitis, showing cellular infiltration and edema of the mucosa and submucosa, vascular congestion, vacuolation of the epithelium, and hemorrhage in the submucosa.

from infectious bronchitis are resistant to intratracheal inoculations as soon as symptoms have subsided. It requires about 3 weeks for most birds to have a high level of antibodies following exposure to bronchitis virus (Fabricant, 1951). After recovery, antibodies can be demonstrated for one year or longer. Most flocks that have experienced an outbreak of bronchitis are immune for at least 12 months. Observations by Van Roekel *et al.* (1950), however, have suggested that immunity to the disease may decline sufficiently for reinfection to occur in some flocks following exposure to the virus. Jungherr and Terrell (1948) have demonstrated that eggs laid by recovered hens will carry antibodies which will later be absorbed by the hatched chick. Antibodies were found in the serum of the chick for 3 weeks. Such passive antibodies, however, did not serve to completely protect the chicks against

natural exposure to infectious bronchitis (Hofstad and Kenzy, 1950).

Diagnosis. The diagnosis of infectious bronchitis must be based upon isolation of the virus or by demonstrating an ascending antibody titer against a known strain of bronchitis virus.

It is difficult to attempt even a presumptive diagnosis in the early stage of the disease because its clinical manifestations are similar to those of Newcastle disease and laryngotracheitis. After the disease has progressed sufficiently, knowledge of the symptoms, mortality, and duration makes possible a presumptive diagnosis. Fabricant (1950) has found that a typical clinical history of infectious bronchitis coupled with a negative hemagglutination inhibition test for Newcastle disease justifies a presumptive diagnosis of infectious bronchitis. This would be valid in areas
FIG. 20.4 — Portion of trachea from a field case of infectious bronchitis, showing exudate containing scattered cellular elements in the lumen of the lower trachea. ×100.

where these two respiratory diseases were the only ones commonly found.

Virus isolation. Infectious bronchitis virus may be isolated by intratracheal inoculation of susceptible chicks with a broth suspension of lung and trachea collected from an infected bird during the early stages of the disease. Symptoms of tracheal rales will follow an incubation period of 18 to 36 hours. This short incubation period is characteristic of infectious bronchitis. Inoculation of both susceptible and immune chickens would give definite information for a diagnosis. However, this procedure is not commonly carried out.

Isolation of the virus is most frequently done in the embryonating chicken egg. This is achieved by inoculating a suspension of lung and trachea into the allantoic cavity of 9- to 11-day-old embryonating eggs. The virus may also be found in other tissues to a lesser extent, such as the aqueous humor (Flowers et al., 1957) and spleen, kidney, bursa, air sac, and pancreas (Hofstad, 1962). Contaminating bacteria in the inoculum are controlled by either filtering through a bacteriological filter or by adding a mixture of antibiotics. The presence of infectious bronchitis virus in the embryonating egg following inoculation is somewhat difficult to discern in the initial passage since there is little change in the majority of the embryos inoculated. Dwarfing of a few embryos by some strains and survival of most of the embryos in the initial passage is characteristic of bronchitis virus. Its presence can be definitely detected, however, by the intratracheal inoculation of susceptible chicks with allantoic fluid collected after a postinoculation period of 48 to 96 hours. If bronchitis virus is present, the chicks will have tracheal rales after a period of 18 to 36 hours.

The information obtained following the above procedures, together with a typical flock history and symptoms, will permit a diagnosis of infectious bronchitis within 3 or 4 days. Results of further egg passages of the isolated virus and the detection of antibodies in the serum collected from the inoculated chicks three weeks after recovery would positively confirm the diagnosis.

The effect of infectious bronchitis virus on the embryo has been studied in detail by Beaudette and Hudson (1937), Delaplane and Stuart (1939, 1941), Fabricant (1949), Loomis et al. (1950), and Raggi et al. (1960). While some strains may produce dwarfing of a few embryos during the initial egg passage, stunting, curling, and death of the embryo can be seen more frequently in the second, third, and succeeding passages. The typical dwarfed embryo (Fig. 20.5) will be seen more consistently as the number of passages increases. Simpson (1958) found the incubation temperature to markedly alter the virus growth, virulence, and population stability in embryonated eggs. One strain of virus reached the same maximum titer in eggs incubated at 34° C. or 38° C., but it required at least 30 hours longer to attain this level at 34° C. The virus was lethal for embryos at 38° C., but only 20 per cent were killed at 34° C.

The characteristic embryo changes are seen several days after inoculation of the virus. During candling, only slight movement of a dwarfed embryo may be observed. In opening the air-cell end of the egg, the embryo is seen curled into a spherical form with the thickened amnion closely adherent to the embryo. The yolk sac appears shrunken, and an increased volume of usually clear allantoic fluid is present. A consistent internal lesion of the bronchitis-infected embryo is the persistence of the mesonephros containing urates. This lesion appears to be associated with the stunting of the embryo and is not specific for bronchitis infection. Another lesion found in embryonating eggs inoculated with nonlethal isolates of bronchitis virus is the thickened amnion and adjacent layer of the allantois covering the stunted embryo. The beginning of this lesion can usually be detected on the third day after inoculation. It likewise is not a pathognomonic lesion since it can also be observed following inoculation of

eggs with lentogenic strains of Newcastle disease virus.

The microscopic lesions in the embryo have been studied by Loomis *et al.* (1950) They found perivascular cuffing in the livers of about one-third of the infected embryos. Extensive necrosis and congestion of the kidneys were also prominent. Edema was present in the amnion and chorioallantoic membrane.

The embryo mortality following inoculation of bronchitis virus increases with the number of serial passages. Beaudette and Hudson (1937) observed very few dead embryos during the first six passages when inoculations were made on the chorio-allantoic membrane. However, in the seventh and later passages the majority of embryos died. Delaplane and Stuart (1941), likewise making the inoculation on the chorio-allantoic membrane, observed a greater mortality with each succeeding egg transfer. In early passages

the mortality occurred late, but in subsequent transfers the embryos died by the end of the second day. Hofstad (1952) observed an average mortality, following inoculation into the allantoic sac, of less than 10 per cent during the first passage, 61 per cent by the fifth serial passage, and 83 per cent by the ninth serial passage in a study of field strains of bronchitis virus.

Infectious bronchitis virus propagated in the embryonating egg gradually loses its ability to infect chickens. This loss of pathogenicity for chickens occurred after 89 egg transfers with a Rhode Island strain mentioned by Delaplane and Stuart (1941). Hofstad (1952) confirmed these findings with another strain propagated via the allantoic sac route. Hoekstra and Rispens (1960b) found their strain of bronchitis virus to possess some pathogenicity after 120 embryo passages. Larose and Van Roekel (1961) observed strain 42 (Beaudette) to be pathogenic for chickens
FIG. 20.5 — Comparison of normal 16-day-old embryos (above) and dwarfed, infected embryos of same age (below). (Hofstad and Bauriedel, Iowa State University.)

after 300 serial transfers in embryos. The loss of pathogenicity for the chicken is accompanied by a loss of immunogenic properties.

The distribution of the virus of infectious bronchitis in the embryonating egg has been studied by Cunningham and El Dardiry (1948). Following inoculation into the allantoic sac, the highest concentration of virus is recovered from the chorio-allantoic membrane followed in order by the allantoic fluid, amnionic fluid, and the liver. The highest concentration of 10^7 embryo lethal doses was detected 36 hours after inoculation. A decrease of titer resulted if eggs were left in the incubator after death of the embryo. Groupé (1949) detected an interfering substance in the allantoic fluid of such eggs. The substance was not present when infected eggs were removed immediately or not more than two hours after death of the embryo. Hitchner and White (1955) studied the growth curve of a vaccine strain (20–30 embryo passages) of infectious bronchitis virus in eggs and found maximum virus concentration 24 to 30 hours after allantoic route inoculation. The embryo lethal (Beaudette) strain of virus was found to reach its maximum titer in 12 hours.

Detection of antibodies against bronchitis virus. Infected chickens are bled in the initial stages of the disease and again in 3 weeks. Both samples of sera are tested for antibodies against bronchitis virus. Demonstration of a low antibody titer in the serum collected during the initial stage, followed by a high titer after recovery, constitutes a diagnosis of infectious bronchitis.

The usual method of detecting antibodies is to set up ten-fold dilutions in broth of a known embryo-adapted bronchitis virus, such as the Beaudette strain. The virus titer is determined by inoculating each ten-fold dilution into a group of four or five 9- to 12-day-old embryonating eggs. Each egg receives 0.05 ml. When the virus dilutions are being made, a portion of each dilution of virus is

mixed in a separate tube with an equal amount of suspect serum. The two portions are mixed by shaking the tubes. Each mixture of virus dilution plus serum is then inoculated into a set of four or five embryonating eggs, using 0.1 ml. Most of the neutralization occurs immediately with maximum neutralization in 15 minutes (Cunningham, 1957). Neutralization of the virus is exponential (Page and Cunningham, 1962).

Following inoculation, the eggs are incubated and candled daily for one week to remove eggs containing dead embryos. The 50 per cent end point of embryo mortality in each series can then be determined by the method of Reed and Muench (1938). The difference between these end points represents the neutralizing capacity of the serum. For example, if the mortality end point of the virus titration was in the 10^{-6} dilution and the end point of the serum-virus mixture was in the 10^{-3} dilution, then the neutralizing capacity of the serum would be 1,000 neutralizing doses in 0.05 ml. of serum. The neutralizing capacity of normal chicken serum may range from 0 to a maximum of 36 neutralizing doses (Cunningham, 1951), while serum of a bronchitis-recovered bird should have 100 or more neutralizing doses (Fabricant, 1951). Woernle (1959) and Woernle and Brunner (1960) have demonstrated bronchitis antibodies by the agar gel precipitation technique. This test is done by placing antigen (chorio-allantoic membrane suspension from infected embryos) in one well in an agar, and suspected antiserum in an adjacent well and observing the precipitin lines between the two wells. Woernle (1960) found no difference between German strains, the Beaudette strain, and the Connecticut and Massachusetts strains by the agar gel precipitin test.

Brumfield and Pomeroy (1957) have applied the direct complement fixation test to infectious bronchitis diagnosis. Jeon (1962) has standardized the details of the test and studied the principal mechanism involved in the technique. Brown and Schminle

(1962) have described an indirect hemagglutination test for infectious bronchitis. The virus is adsorbed onto tannic acid-treated, horse red blood cells and after washing are mixed with the suspected serum. If the serum has antibodies it reacts with the antigen and causes clumping of the red cells. Vazington (1962) also described a similar indirect hemagglutination test; however he used sheep erythrocytes instead of horse red cells.

Treatment. There is no specific treatment for infectious bronchitis. In flocks of young chicks it is helpful to increase the temperature of the room as well as of the brooder. Overcrowding should be corrected. In laying flocks drafts should be eliminated, and warm, moist mashes should be given to encourage the birds to eat. Anything the poultryman can do to keep up feed consumption in the flock should be encouraged to avoid excessive loss in weight in the birds. Dusting or spraying so called cold remedies are not worth their cost. Recovery takes place as the birds acquire an immunity to the virus. If the disease is complicated with chronic respiratory disease or air-sac infection, treatment with the broad-spectrum antibiotics may be indicated. (See Chapter 13.)

Prevention and control. The best preventive is strict isolation of the flock, along with sound management practices, such as adding only day-old chicks as replacement stock and rearing them in isolation. The poultry house should be properly ventilated. Even on farms with sound management practices, infectious bronchitis may occur, particularly in heavily populated areas. This has brought on the necessity of using immunization procedures in the control of the disease.

The first immunization procedure used was started about 1941 in the New England states (Van Roekel et al., 1950). It consisted of inoculating a small portion of the birds in a flock with a field strain of virus and allowing natural spread to the rest of the flock. This was usually done at 7 to 15 weeks of age when the disease would produce the least economic loss to the poultryman. After recovery from the infection, the flock would be immune to bronchitis through the laying year.

This type of vaccination procedure using pathogenic field strains has been replaced with modified live virus vaccines (Brandt et al., 1952; Luginbuhl and Jungherr, 1952; Crawley, 1953, 1955; Hofstad, 1954, 1956; Hoekstra, 1960; and Hoekstra and Rispens, 1960a). These modified vaccines use strains of virus that have undergone 25 or more embryo passages to reduce their pathogenicity and spreading ability. It should be emphasized that while these modified strains at present are safer to use, they are still capable of spreading, and in the very young chick without passive antibodies and in laying flocks in high production they may produce undesirable results.

The replacement flock should be vaccinated during the growing period preferably at 3 to 4 months. In broilers it is necessary to immunize at an early age. If the chicks possess passive antibodies derived from the yolk, they can be inoculated at a few days of age. These antibodies lessen the severity of the infection but Raggi and Lee (1958) found that the young age and passive antibodies were important factors in preventing a satisfactory immune response to live virus vaccine. Chicks which do not possess passive antibodies will tolerate the vaccine best after three weeks of age.

Several methods of administration of bronchitis vaccines have come into use—the spray or aerosol (Crawley, 1953; Hofstad, 1954), the dust (Markham et al., 1955; Price et al., 1955), and drinking water (Luginbuhl et al., 1955) procedures. These mass vaccination techniques have become very popular with the poultryman because they are labor saving. The bronchitis vaccines have also been combined with Newcastle disease vaccines as an added convenience and apparently without interference in the immune response from each vaccine (Markham et al., 1956). However, interference has been demonstrated between these two viruses in certain combinations (Luginbuhl and Jung-

herr, 1953; Hanson *et al.*, 1956), and it would seem advisable that whenever possible and practical the bronchitis immunization should be administered separately.

The immunity which can be expected from commercial bronchitis vaccines is variable (Raggi and Bankowski, 1956). There is definite loss of immunogenicity with increased attenuation of bronchitis virus (Crawley, 1955; Hofstad 1956c). Raggi and Lee (1957) found a direct relationship between SN titers and response to challenge in only one of three vaccines studied. There was a noticeable difference with the other two vaccines. This tended to confirm the reports of Jungherr *et al.* (1956), Hofstad (1956a, 1958) who found strain differences using reciprocal serum neutralization tests. Hofstad (1961), however, later found that cross-challenge results did not agree with serum neutralization results. There was some cross-immunity between isolates which had previously been found antigenically different by reciprocal serum neutralization tests. The field prevalence of variant bronchitis strains is not known; however, the Massachusetts type or the typical field strain apparently will induce the best immunity to challenge with heterologous strains (Raggi, 1960; Hofstad, 1961). In general, infectious bronchitis is being satisfactorily controlled.

Complications resulting from the use of infectious bronchitis vaccines in flocks free of *Mycoplasma gallisepticum* are rare. However, when this organism is present either in active or latent form, immunization with bronchitis virus may kindle the infection, resulting in so-called air-sac disease. The end result is that the bronchitis vaccine "take" is extended in an exaggerated form beyond the 10- to 14-day period seen in uncomplicated cases. In the case of broilers this means cull birds, mortality, a delay in marketing the flock, and a grading down of the carcasses. In replacement flocks it may mean a delay in coming into production and an increased number of culls. The effects of both bronchitis virus and *Mycoplasma gallisepticum* in chickens have been studied by Adler *et al.* (1962) and Blake (1962).

Attempts to produce an inactivated virus vaccine have resulted in loss of immunogenic properties following inactivation by formalin (Delaplane and Stuart, 1939) and ultraviolet light (Hofstad, 1952). Christian and Mack (1957) used beta-propiolactone to inactivate bronchitis virus. A concentration of 0.25 per cent at 37° C. for 60 minutes was minimum treatment for inactivation. Some protection to challenge and a slight rise in serum antibodies resulted in birds receiving 1 and 2 ml. doses. Woernle (1961) reported some success with an adsorbed bronchitis vaccine inactivated by 0.2 per cent formalin. Evaluation of the vaccine was based on the agar diffusion precipitin test. Embryo-adapted strains of bronchitis virus which have lost their infectivity for chickens have been of no practical immunizing value. Beaudette *et al.* (1956) were unable to demonstrate immunity in the 18 days following intramuscular inoculation of the 24th embryo passage of a live bronchitis strain of virus.

QUAIL BRONCHITIS

Quail bronchitis, an acute respiratory infection of quail (*Colinus virginianus*, Linné), was reported by Olson (1950). The disease occurred on a state game farm in West Virginia during the 1949 hatching season. In 1956 a similar disease was noted in Texas by DuBose et al. (1958).

The symptoms of the disease were tracheal rales, sneezing and coughing, but no nasal discharge was observed. Nervous symptoms were occasionally observed. Mortality was from 50 to 80 per cent in the field outbreaks, however neither Olson (1950) nor DuBose and Grumbles (1959) was able to demonstrate much mortality in the experimental cases. The incubation period was reported to be from 4 to 7 days and the course of the disease, from 1 to 3 weeks.

Olson (1950) found that Chukar Partridges were not susceptible, however he was able to reisolate virus from chickens and turkeys after experimental inoculation. DuBose et al. (1958) found pheasants and "Japanese Quail" to be resistant to infection.

The etiology of quail bronchitis is a filterable virus which can be grown in thicken embryos, where it causes dwarfing of the embryo and a thickening of the amnion similar to that produced by infectious bronchitis virus of chickens. The tious bronchitis virus can be differentiated from infectious bronchitis virus by its ability to withstand 56° C. for 90 minutes whereas most strains of infectious bronchitis virus are inactivated after 15 minutes at 56° C. and all of them after 30 minutes (DuBose et al., 1960). It has also been demonstrated to be serologically distinct from infectious bronchitis virus.

Quail bronchitis virus can be stored for as long as 4 years at −20° C. (DuBose et al., 1958). The virus passes through the Seitz EK filter pad. Virus has been isolated from the brain from a few cases having nervous symptoms. DuBose and Grumbles (1959) also isolated virus consistently from the aqueous humor and they found it to be as good a source of virus as tracheal exudate.

Yates and Fry (1957) studied the relationship between quail bronchitis virus and an agent which they had isolated and described as a chicken embryo lethal orphan (CELO) virus. They found that CELO antiserum neutralized 10⁷ e.l.d. of quail bronchitis virus, thus establishing the similarity between these two agents. DuBose and Grumbles (1959) confirmed the similarity between the two agents and were able to reproduce the disease in quail by inoculation of either agent, and also demonstrated contact transmission with both agents. Yates and Fry (1957) have demonstrated neutralizing antibodies from the major poultry producing areas in the United States, and thus these viruses apparently are widespread among avian species.

Infectious Laryngotracheitis

The first outbreak of infectious laryngotracheitis, an acute, contagious, respiratory disease of chickens, was reported by May and Tittsler (1925). They first observed the disease in a flock of chickens in Rhode Island in October of 1923. Beach (1925) reported outbreaks of the disease occurring in California in 1924. In a survey by Hinshaw (1931a), reports of observations indicated that the disease may have existed some years prior to 1924; however, the disease became of economic importance in the United States in 1924. Some experiments by Gwatkin (1925) indicated that infectious laryngotracheitis was present in Canada. Seddon and Hart (1935, 1936) identified the disease in Australia in 1935. The first outbreak in Great Britain was recorded by Dobson (1935). Van Heelsbergen (1929) stated that the disease had been observed in Holland. Later the disease was reported from Sweden (Magnusson, 1940) and from Poland (Marek, 1948).

Some of the early investigators called the disease infectious bronchitis; however, the more appropriate name infectious laryngotracheitis was later recommended by the Special Committee on Poultry Diseases of the American Veterinary Medical Association, and this nomenclature was adopted (1931).

Etiology. The causative agent of infectious laryngotracheitis is a filterable virus (Beaudette, 1930; Beach, 1930, 1931a, 1931b; Gibbs, 1931a; Graham *et al.*, 1931). The virus has been named *Tarpeia avium* (Holmes, 1948). It is retained by the Berkefeld W filter but passes through the N filter with irregularity and through the Berkefeld V filter readily. Variable results have been reported using the Seitz filter pad. Filtering a 1:50 broth dilution of infected chorio-allantoic membrane suspension through a series of Selas filters, it was found that it passed through the 03 filter but irregularly passed the 04 filter. Bakos *et al.* (1962) found the virus to pass

through all grades of the Berkefeld candles and through gradacol membranes of 450 μ pore size. Watrach et al. (1959) found the virus to have an average diameter of 180 μ when purified preparations were studied by electron microscopy. In tissue sections they found the virus to be morphologically similar to the herpes group. Laryngotracheitis virus can be propagated in the embryonating chicken egg, where it causes primarily proliferative and necrotic lesions on the chorio-allantoic membrane (Burnet, 1934; Brandly, 1935, 1936).

The virus has been grown in cultures of respiratory epithelial cells, in fibroblast cells, and in kidney cells. (Atherton and Anderson, 1957; Chang et al., 1960; Chomiak et al., 1960; and Pulsford, 1960). The virus produces a cytopathic effect in which the cells undergo a granular degeneration into sharply limited masses. The eclipse phase is relatively long, particularly with the low virulent strains. Atherton and Anderson (1957) were unable to demonstrate virus in the fluid of growing cultures; however, Pulsford (1960) did demonstrate release of virus into the fluid of cell cultures with the strains of virus he used. Inclusion bodies were observed in cultures of respiratory epithelium but not in fibroblast cell cultures.

The resistance of the virus to certain physical and chemical factors has been studied by Schalm and Beach (1935). Virus in tracheal exudate exposed to 55° C. survived from 10 to 15 minutes. When infective tracheal exudate was suspended in 50 per cent glycerine in buffer at pH 7.4 and held in the dark, the infectivity was retained from 7 to 14 days at 37° C., from 35 to 42 days at 16° to 24.5° C., and as long as 217 days at 4° to 10° C. Virus in the trachea of dead fowls survived from 22 to 44 hours at 37° C., and from 30 to 60 days at 4° to 10° C. The infectivity of the virus is well preserved when dried from the frozen state (Goldhaft, 1961; Hofstad and Yoder, 1963). Beaudette et al. (1948) reported active virus in dried preparations stored almost 10 years in the refrigerator. The virus is destroyed by one-

half-minute exposure to 3 per cent cresol disinfectant and to 1 per cent solution of lye.

There is evidence of differences among strains of laryngotracheitis virus. Burnet (1936) found an enzootic Australian strain (Victorian) to be less readily neutralized by immune serum and to produce smaller lesions on the chorio-allantoic membrane than the more virulent, epizootic United States and New South Wales isolates. However, there appeared to be no qualitative antigenic difference between them. Pulsford (1953, 1954) confirmed the observations of Burnet when he found a strain of laryngotracheitis virus which was resistant to neutralization by antiserum, although it was capable of producing the disease with resulting antibodies against a classical strain. Cover and Benton (1957) and Satriano et al. (1957) have isolated strains of laryngotracheitis virus of low pathogenicity for chickens.

Susceptible hosts. The virus of laryngotracheitis has a distinct host specificity. Chickens are the usual host, but pheasants are also susceptible to the virus by inoculation or natural exposure (Kernohan, 1931a; Hudson and Beaudette, 1932a). The following species of birds have been found refractory to the virus: turkeys, starlings, quail, sparrows, ducks, pigeons, guinea fowl, doves, and crows. White rats, guinea pigs, mice, and rabbits are likewise resistant (Beach, 1931b; Brandly and Bushnell, 1934; Seddon, 1936). The embryonating eggs of the turkey and chicken are susceptible to the virus, while those of the duck, guinea fowl, and pigeon are refractory (Brandly, 1936).

Transmission and incubation period. Following natural exposure, the incubation period of laryngotracheitis varies from 6 to 12 days (Kernohan, 1930; Seddon and Hart, 1935). After intratracheal inoculation of infective material, symptoms occur in 2 to 4 days.

The natural route of infection is by way of the respiratory tract. Gibbs (1931b) was unable to produce the disease by feeding capsules of dried material, but when

the dried infective powder was placed in the litter, the chicks soon developed the disease. Laryngotracheitis can be produced by intravenous, subcutaneous, and intraperitoneal inoculation, although not consistently (Gibbs, 1933a). Bakos et al. (1962) were unable to produce symptoms following intracutaneous and intramuscular inoculation.

It is well established that carriers of the virus exist for long periods after a natural outbreak of the disease (Gibbs, 1931a, 1931b, 1932; Komarov and Beaudette, 1932). Only a few birds in each flock remain carriers, but these serve to perpetuate the disease whenever they come in contact with susceptible chickens. The method of detecting carriers is to swab the tracheas of recovered birds and to inoculate susceptible chickens. By this method, carriers have been found to eliminate virus for as long as 16 months after an outbreak.

Transmission of the disease indirectly by way of contaminated poultry crates and other equipment and by flying birds is possible, although it is probably of minor importance in the spread of laryngotracheitis. Kingsbury and Jungherr (1957) reported evidence of indirect transmission in fifteen outbreaks by means of rat, man, crow, and dog. Brandly and Bushnell (1934) were unable to demonstrate virus on the surface of eggs which were laid during an outbreak of the disease.

Symptoms. The acute, epizootic form of the disease usually spreads rapidly in a flock, and all or most of the birds become affected. Hinshaw (1931b) has recorded histories of some outbreaks where lacrimation in a few birds along with sudden death of one or two chickens occurred prior to the onset of respiratory symptoms throughout the flock. Jordan (1958) found panophthalmia in addition to respiratory symptoms, and Raggi and Armstrong (1960) reported hemorrhagic conjunctivitis in outbreaks of laryngotracheitis.

The outstanding symptoms are gasping, rales, and coughing. Many of the birds are depressed, sitting on the floor or on the roosts (Fig. 21.1). Some exhibit symptoms of gasping with the head extended and the beak open (Fig. 21.2). Wheezing or whistling sounds may be heard as the bird gasps. In these severely affected individuals coughing is frequent and often results in the expulsion of bloody mucus from the trachea. The head of the bird may be cyanotic. Many chickens will have less severe symptoms, consisting only of tracheal rales, mouth breathing, and occasional coughing. There may be lacrimation and occasionally a serous exudate from the nares. An accumulation of excessive amounts of inflammatory exudate and blood in the lumen of the larynx, and trachea, or syrinx frequently results in death by asphyxiation.

In laying flocks a variable drop in production occurs. Hinshaw (1931) observed an average drop of 12 per cent in California flocks affected with the disease. The decline began 4 days after the onset and continued until the eighteenth day. Normal production was reached again after 30 days. In colder climates and in chickens affected late in their laying year, the decline in production may be much greater. Beach (1925) observed a drop of 62 per cent in one flock.

A mild, enzootic form of the disease has been reported by Pulsford (1953, 1954), and by Simmons et al. (1954) as occurring in certain areas of Australia. More recently, Cover and Benton (1957) in the United States have recognized a mild form of the disease in broilers in which symptoms are slight coughing and rales with little or no mortality.

Course and Mortality. The average course of the disease is about 2 weeks with extremes of 1 to 4 weeks (Hinshaw, 1931a). The mortality is variable, depending upon a number of factors. Inadequate housing in winter, parasitism, and unfavorable weather conditions might influence the severity of the disease. Hinshaw et al. (1931) found an average mortality of 15 per cent in 25 outbreaks of the disease in California. The greatest mortality occurred on the eleventh day, and 85 per cent of
FIG. 21.1 — An advanced case of laryngotracheitis. Attitude during expiration. (Beach and Freeborn, Univ. of Calif.)

FIG. 21.2 — Laryngotracheitis. Same fowl as Figure 21.1. Attitude during inspiration.

losses were recorded 15 days after onset of the disease. Kernohan (1931b) reported a mortality of 72 per cent in one flock. Brandly and Bushnell (1934) reported a mortality of 14 per cent and 48 per cent respectively in two outbreaks. Graham *et al.* (1930) reported a subacute disease with low mortality even in artificially induced cases.

Pathology. When dead birds are presented for necropsy, the beak and mouth of the birds may be stained with blood and mucus. The mucous membrane of the trachea and larynx may be covered with a film of bright, blood-stained exudate. In some cases the lumen of the trachea may be partially or entirely occluded with exudates composed largely of blood (Fig. 21.3). A yellowish, caseous exudate, with little or no blood, may cover the mucosa

FIG. 21.3 — Hemorrhagic tracheitis in chicken caused by laryngotracheitis virus. (Hofstad and Baurfedel, Iowa State University.)

in other birds. Chickens in the early stages or with mild symptoms frequently do not have a hemorrhagic tracheitis when killed and necropsied

The microscopic pathology of laryngotracheitis has been studied in detail by Seifried (1931). Between 24 and 72 hours after inoculation there is edema and cellular infiltration of the mucosa and submucosa. Hemorrhage may separate the mucosa and submucosa. After the third day, dense cellular infiltration with a loss of epithelial structure characterizes the lesion. Inclusion bodies of the intranuclear type are found in the early stages of the disease. Seifried describes them as homogeneous structures which occupy a large part of the nucleus. The area immediately around the inclusion remains unstained and these bodies usually occur in groups of epithelial cells rather than in single isolated cells (Fig. 21.4).

The pathology in the embryonating chicken egg following inoculation of laryngotracheitis virus has been studied by Burnet (1934) and Brandly (1935). Following inoculation of the virus upon the chorio-allantoic membrane, small areas of gray thickening are visible by the third day. The lesions become larger up to the fifth or sixth day when the embryo usually dies (Fig. 21.5). There is edema of the chorio-allantoic membrane, and the allantoic fluid takes on the consistency of thick egg albumen. Embryos that live to the sixth day are stunted. Microscopically the membrane has areas of cellular proliferation and edema. Intranuclear inclusion bodies are observed in groups of ectodermal epithelial cells between the first and third days. As the lesion progresses, the epithelium undergoes necrosis and is gradually replaced by inflammatory tissue of the mesoderm.

Diagnosis. The acute, epizootic form of laryngotracheitis can be recognized frequently by the flock history, mortality record, and necropsy findings. A typical flock history is one revealing an acute, rapidly spreading, respiratory disease with symptoms of rales, mouth breathing or

gasping, fits of coughing with expulsion of bloody mucus, and some mortality. Hemorrhagic tracheitis is a typical necropsy finding It is important to choose several dead birds for necropsy rather than live, sick birds, since the latter frequently do not show the extensive tracheal lesions.

In the mild form of the disease a field diagnosis is difficult and laboratory aid is required.

Other diseases which may be confused with laryngotracheitis are infectious bronchitis and Newcastle disease. A few differences between the three diseases aid in the diagnosis. Laryngotracheitis is rarely observed in young brooder chicks, although they are fully susceptible to the virus. Of the three diseases Newcastle disease has the most adverse effect on egg production, fol-

lowed in order by infectious bronchitis and laryngotracheitis. A complete cessation of production is not unusual in outbreaks of Newcastle disease.

A greater mortality is usually experienced in the acute, epizootic form of laryngotracheitis than in outbreaks of Newcastle disease, although mortality in the latter disease can be extremely variable. As a rule, no mortality is experienced in outbreaks of infectious bronchitis in chickens over 2 months of age. The hemorrhagic tracheitis found frequently in birds dying from laryngotracheitis is not usually observed in Newcastle disease and infectious bronchitis.

Laboratory diagnoses of laryngotracheitis are made by intratracheal inoculation of susceptible and immune chicks with a

FIG. 21.4 – Tracheal mucosa from chick killed on fifth day following intratracheal inoculation. Arrow points toward a group of nuclei containing inclusion bodies characteristic of infectious laryngotracheitis. ×1,200.
FIG. 21.5 — Lesions on chorioallantoic membrane produced by laryngotracheitis virus following inoculation into the allantoic sac. Normal membrane shown in lower left. (Hofstad and Bauriedel, Iowa State University.)

broth suspension of tracheal exudate from a suspected case, by isolation of the virus in embryonating chicken eggs, or by microscopic finding of inclusion bodies in tracheal sections. Armstrong (1959) has found smears of tracheal and conjunctival cells stained with Giemsa's stain to be a satisfactory method of examining for inclusion bodies. Woernle and Brunner (1961) and Jordan and Chubb (1962) have used the agar diffusion technique in the diagnosis of laryngotracheitis. It is possible to detect either virus antigen or antibody. In chick inoculations, consideration is given to the incubation period, the lesions produced, and the finding of inclusion bodies in tracheal sections. Inclusion bodies can be found between the first and fifth day after inoculation. The time at which inclusions are found may depend on the concentration of virus in the inoculum and the method and route of inoculation. Following intratracheal inoculation of laryngotracheitis virus by swab, inclusions were found only on the second and third days (Hanson, 1957). The inclusions may be found in tracheal sections from the original birds if presented for diagnosis in the early stages of the disease. Inclusion bodies may be demonstrated from tracheal and conjunctival cells smeared on a slide and stained with Giemsa's stain. Keller and Hebel (1962) attempted tracheal smears in 60 specimens, and 34 samples were positive for inclusions while virus was isolated 43 times. Inclusions were demonstrated 4 times when no virus was isolated. Hanson (1957) has emphasized the necessity of using Zenker's fixative with acetic acid. Pirozok et al. (1957) have described a rapid method, using a water soluble wax to eliminate dehydration and clearing processes, for the histological diagnosis of laryngotracheitis. Sevoian (1960) has used simultaneous fixing and dehydration of tissues for rapid demonstration of inclusion bodies.

A common method of making a laboratory diagnosis is to inoculate embryonating chicken eggs at 9 to 12 days of age. A broth suspension of tracheal exudate, treated with antibiotics or filtered through a suitable filter, may be inoculated upon the chorio-allantoic membrane or into the

allantoic sac. While allantoic sac inoculation is satisfactory for propagation of laryugotracheitis virus, inoculation on the dropped chorio-allantois of 12-day-old embryos is preferred for original isolation. Webster (1959) found that virus could not be isolated after the seventh day following experimental infection. Hitchner and White (1958) have observed that titration of the virus on the dropped chorio-allantoic membrane gave a two log higher titer than four other methods of inoculation, including the allantoic sac route. Laryngotracheitis virus produces areas of grayish thickening on the chorio-allantoic membrane by the third day (Fig. 21.5). Inclusion bodies can be observed between the first and third days in sections of the membrane. (See Pathology.)

Following inoculation of laryngotracheitis virus into the sinus of chickens, there develops a sinusitis with swelling, a nasal discharge, and lacrimation (Hanson, 1957). The sinus is very sensitive to the virus, and this method can be useful for diagnosis and for titration of the virus.

Burnet (1936) and Pulsford (1953, 1954) have used a serum neutralization test for studies of the epizootiology of the disease. Burnet's test makes use of the pock counting technique. The undiluted serum is mixed with 10-fold dilutions of virus and the mixture allowed to stand for one hour at room temperature. The mixture is then inoculated on the dropped chorio-allantoic membrane of 12-day-old embryos, and after 3 days' incubation the eggs are examined for pocks. A marked reduction of the pock count over the virus control is indicative of a positive serum. Hitchner et al. (1958) used the serum neutralization test and found that a 1:5 dilution of serum gave satisfactory results and found no difference between heated and unheated serum in the test; however, Hanson (1957) has found it important to heat-inactivate serum immediately after collection and before storage in the freezer to stabilize the neutralizing capacity of the

serum to be used in the serum neutralization tests. Shibley et al. (1962) found no correlation between serum-virus-neutralizing indices and resistance to challenge.

Treatment. The birds will recover rapidly as soon as an immunity develops. No medicinal treatment has been found to relieve the dyspnea of affected birds. Occasionally a veterinarian might relieve some chickens by removing the caseated casts of exudate from the larynx and upper trachea with a forceps. In outbreaks where only part of the flock is affected, it might be possible to vaccinate those groups not yet affected and render them immune before the disease spreads. Vaccination should not be carried out, however, unless a diagnosis is reasonably certain.

Prevention and control. Sound management practices have been used with success in the prevention of laryngotracheitis (Gibbs, 1933b). The introduction of the disease on the farm can be avoided by adding new stock only from clean sources, preferably as day-old chicks, by using only clean equipment, and by applying strict isolation practices.

When the disease has occurred on a farm, prevention of recurrence may be accomplished without vaccination. The recovered birds should be marketed, preferably before new stock is brought on the farm. After all chickens are gone, the house and all equipment are thoroughly cleaned and disinfected. If possible, the house, yard, and equipment used by the infected birds should be left unused for two months after disinfecting as an added assurance that the virus has been inactivated.

Prevention by vaccination is used to immunize unexposed groups of birds when the disease has just appeared in one pen on a farm, to immunize flocks on farms where the disease has occurred and where the recovered birds must be kept for breeding stock, and to immunize flocks in areas where the disease is prevalent.

Vaccination. The ability of the virus of laryngotracheitis to multiply in the mucous membrane of the cloaca was first demonstrated by Hudson and Beaudette (1932b). They found it possible to make serial passages of the virus from the cloacal mucous membrane of one bird to that of another. Later these chickens were found to be immune to intratracheal inoculation of the virus. This finding led to a practical method of immunizing flocks against laryngotracheitis. Extensive field trials with the vaccine proved its effectiveness in the prevention of laryngotracheitis (Beaudette and Hudson, 1933; Beach et al., 1934; Gibbs, 1933a, 1934).

Following vaccination the birds resist an intratracheal challenge by the ninth day (Beaudette and Hudson, 1933). During the first nine days virus can be detected in swabs from the cloaca, but the virus does not persist for longer periods (Gibbs, 1933a; Beach, 1935). That carriers did not exist after the vaccination reaction had subsided was an important consideration in using the vaccination procedure for the control of laryngotracheitis. The duration of immunity is not been determined, although results indicate that birds are protected for at least a year. Hitchner and Winterfield (1960) found chickens which had been vaccinated in the vent by the drop or brush method at 1, 4, or 8 weeks were susceptible to a challenge virus when given in the infraorbital sinus at 16 weeks of age. Revaccination by the vent method failed to give a "take" or secondary antibody response, although dropping vaccine in the eye induced a good serological response. Shibley et al. (1963) have found immunity to heterologous strains to persist for at least one year when the avirulent strain (Cover and Benton, 1957) was dropped into the conjunctival sac of 10-week-old chickens.

Dried tracheal exudate from infected chickens was originally used as the vaccine. However, egg-propagated virus was later utilized because of its greater safety,

more uniform potency, and decreased cost of production. Brandly (1936) found that as many as 36 serial transfers of the virus in embryos did not decrease its virulence or immunizing ability. It was further observed by Beaudette (1939) that egg-propagated laryngotracheitis virus, when dried and held in a vacuum under refrigeration, retained its immunizing power for as long as 421 days. Goldhaft (1961) found laryngotracheitis vaccine held for 24 years at 40° F. protected all chickens vaccinated.

In the vaccination procedure the operator exposes the mucous membrane of the upper wall of the cloaca and brushes the vaccine on the exposed mucous membrane. The brush should be dipped into the vaccine before each application. Growing chickens may be vaccinated into the bursa of Fabricius, using a blunt curved hypodermic needle, but the method is seldom used. Since the bursa undergoes atrophy during the latter part of the growing period, the method cannot be used in vaccinating adult birds. Inoculation into the bursa of Fabricius results in a larger percentage of "takes" than does the brushing method (Gibbs, 1933a; Beach et al., 1934). The best age for prophylactic vaccination of layers and breeders is between 2 and 4 months of age. Pulsford and Watts (1961) have shown that chicks from endemic areas had strong passive immunity to laryngotracheitis. This might influence the response to vaccine if vaccination is done at an early age.

Following vaccination the birds should be examined for takes. Gibbs (1934) found that the best time to do this was on the fourth or fifth day, although the reaction could be detected from the third to the eighth day. A take is evidenced by an edematous swelling of the lips of the cloaca and a catarrhal, hemorrhagic, or fibrinous inflammation of the infected mucous membrane (Fig. 21.6). When chickens are found with no visible reaction to the vaccine, they should be re-

vaccinated immediately and, if possible, segregated until they can be re-examined for takes 4 or 5 days later. It is important to revaccinate chickens with no takes, be-

cause the chickens may acquire the natural disease from the virus being eliminated from the cloaca of the vaccinated birds.

FIG. 21.6 — Taken from laryngotracheitis vaccination: (A) swelling of cloacal lips, (B) reddening of mucous membrane. (Beach and Freeborn, Univ. of Calif.)

Newcastle Disease

An infectious, highly contagious and de-
structive malady, Newcastle disease (ND)
attacks chiefly chickens and turkeys.
Various other birds as well as certain mam-
mals, including man, may also contract the
disease. ND is caused by a virus which is
classified as a myxovirus and resembles the
viruses of influenza and mumps in certain
properties.

Occurrence

First recognized in the middle 1920's,
Newcastle disease has become a major
menace to the world's poultry industry.
Kraneveld, in 1926, reported a highly dif-
fusible and fatal infection of poultry prev-
alent in the Dutch East Indies, and in the
same year, Doyle saw the disease near New-
castle-on-Tyne, England. Doyle named it
after the locality and demonstrated it to be
distinct from the dreaded fowl plague or
fowl pest.

The outbreak in England was promptly
stamped out by quarantine of the premises,

slaughter of infected and exposed flocks,
and disinfection of contaminated equip-
ment and premises. Eradication of the
Oriental outbreaks was not attempted, and
the malady is now present in every poultry
producing area of the world.

During the decade following recognition
of what is now generally termed ND, the
malady was reported also from India, the
Philippine Islands, Korea, Japan, Australia,
Ceylon, and Kenya. Subsequently, it ap-
peared in Palestine, Syria, and the middle
Congo, and, with World War II, it spread
to Europe by way of Sicily and Italy. It was
first identified in the United States in 1944
(Brandly et al., 1944, 1946a; Beach, 1944)
although, according to Beach, it apparently
had been present in California as early as
1935. Beaudette and Hudson (1956) refer
to isolation of ND virus (NDV) in Illinois
and New Jersey in 1938.

In the initial appearance of the malady
in these and later foci, its identity with
Newcastle disease of Doyle (1927) was

[633]

seldom recognized, and at least 15 synonyms, e. g., pseudo-fowl pest, *Pseudovogelpest, atypische Geflügelpest*, pseudo-poultry plague, avian pest, avian distemper, *Ranikhet*, avian pneumoencephalitis, have been recorded (Brandly *et al.*, 1946a). By 1918, the malady had spread throughout this country and to Hawaii and Canada, and, by 1951, it had become disseminated widely in Europe and in various parts of Africa. It was also recognized in Madagascar, Mexico, and Central and South America (Beaudette, 1943, 1949, 1950, 1951). Following later reports of its proved occurrence in China (Ma *et al.*, 1947) and Indo-China, Liao (1951) observed that a disease known as chicken pest, which may have been ND, had been known in China for many generations. A mild outbreak in Japan (Kawashima *et al.*, 1953), the occurrence of mild strains in France (Lissot, 1956), persistence of milder forms in England (Reid, 1955), and reintroduction of a fatal form in Kenya (Scott *et al.*, 1956) have been recorded more recently.

In the absence of land or sanitary barriers between adjacent areas or across water and air routes, the eventual wide diffusion of ND was inevitable. First reports of the disease during the early 1960's including several from South American and African countries (Monteverde *et al.*, 1962; Kaschula, 1961a) reaffirmed its high diffusibility and current prevalence in all major poultry producing areas. Reappearances of frequently severe epidemics of ND also continue to be reported: Kaschula, 1961a in Africa; Brion and Fontaine, 1960 in France; Divo, 1961 in Venezuela.

The early lack of definite diagnostic procedures together with the differences in certain clinico-pathologic features manifested on the appearance of ND in new areas have frequently delayed its recognition and the eventual development of more effective control measures.

Absence of the virus from the blood stream of birds was a confusing feature of certain earlier outbreaks in the Orient. The considerable delay in suspecting and

identifying ND after it invaded the U.S.A. can be chiefly ascribed to features previously not ascribed to the malady, namely, relatively low mortality and predominance of nervous and respiratory manifestations. With recent substantial improvements of immunologic and other diagnostic methods, long delays and failures in recognition of the milder as well as more severe outbreaks should be largely avoidable.

Doyle (1935) recognized the shortcomings of the eponymic term, Newcastle disease, but, in view of prevalent usage rather than priority, believed its use warranted until further clarification could be accomplished. The proposal that the task of selecting a more suitable name be referred to a duly constituted body on nomenclature (Brandly, 1947) may still warrant consideration.

IMPORTANCE

Newcastle disease represents a serious economic challenge to all segments of the poultry industry. The proclivity of NDV to attack not only poultry and birds, but man and other mammals as well, magnifies its potential as well as actual threat. The high resistance of NDV to adverse environment and the facility with which it may spread, especially by air, further contribute to the gravity of the problem.

The high mortality described in the initial reports (Kraneveld, 1926; Doyle, 1927) has characterized many early as well as later outbreaks: Crawford in Ceylon, 1930; Sahai in India, 1937; Albiston and Gorrie in Australia, 1942; Coronel in the Philippines, 1947; Kaschula in Africa, 1961b; Reid in Great Britain, 1961. More recent outbreaks in Mexico and an exotic introduction in California were likewise highly fatal (Report of Chief of Bureau of Animal Industry, 1950). Absence of mortality among adult chickens has been reported from various parts of the world, e.g., Dobson from England (1939), Beach (1942), Bankowski (1961), and others from the United States, and Komarov from Palestine 1947), while, following the 1947 epizootic in England, a low or subclinical

form of the disease was recognized except for occasional mild signs in chicks (Anonymous, 1948). Highly variable mortalities from ND have been encountered in the United States (Beach, 1942; Barber, 1947; Goldhaft and Wernicoff, 1948). The latter workers saw both low (10 per cent) and high (90 per cent) fatalities in adjacent poultry flocks in New Jersey. Binns *et al.* (1949) reported a relatively fatal epizootic in Utah with losses up to 86.5 per cent and an average mortality of 48.6 per cent in eight flocks, totaling 13,639 birds of various ages.

The losses from the nonfatal outbreaks, while less spectacular, may be equal to or greater than those where the death loss is high. Crippling as well as impaired growth and feed utilization among surviving birds follow outbreaks of ND. An increase of two or more weeks in finishing surviving broiler chickens for the market is not uncommon. The mortality among turkey poults is usually not as great as among chicks but may reach 15 to 20 per cent of a brood. The greatest loss among layers frequently results from reduced production and impaired eggshell and albumen quality. ND also reduces the fertility and hatchability of eggs. The virus has produced teratogenic defects and early mortality among experimentally infected embryos (Blattner and Williamson, 1951; Williamson, *et al.*, 1956).

A survey of ND prevalence in an intensive poultry farming area in 1947 (Byerly, 1948) showed a 30 per cent infection rate. Soon after ND became widespread in the United States, the livestock sanitary officials of twenty-seven states listed ND as their foremost problem in poultry production (Linn, 1948). An additional loss exacted by ND comes from restrictions upon exports of eggs, both hatching and other, and of baby chicks, of breeding and other stock, and of dressed poultry. Risk of NDV contamination of various vaccines for poultry and other animals reduces the demand for such exports to other countries.

In the United States alone, about 2.69 billion chickens and 99 million turkeys were hatched in 1962. An estimated 1 per cent mortality from ND would represent 27 million chickens; a comparable heavy loss from the other effects of the disease would raise the annual total to 35 million dollars. An additional toll in the struggle against ND as it prevails in the United States is the cost of vaccination against it. A conservative estimate of the annual cost of vaccinating one billion birds against ND is 15 million dollars. This would raise the estimated yearly toll of ND in the United States to more than 50 million dollars. On an equal basis, the annual tribute exacted from the world's poultry industry would conservatively double this figure.

The grouping and designation, as practiced in England (1936 Fowl Pest order) and European countries, of Newcastle disease and fowl plague or pest while perhaps having some merit from the regulatory control aspect, tend to becloud the problem of specific diagnosis and of prophylactic intervention. Furthermore, on the matter of obtaining reliable data on occurrence, prevalence, and incidence of ND and diseases resembling it becomes more complicated.

Newcastle disease has been recognized in man as almost entirely a localized eye infection yet pulmonary and generalized infections have been reported. While infection of one person from another has not been recognized, the possibility that ND may become a more serious public health problem must be recognized (Burnet, 1943; Brandly, 1950, 1951; Cunningham, 1952; Hanson and Brandly, 1958).

NATURE OF THE VIRUS

The agent of Newcastle disease was recovered in 1926 by T. M. Doyle (1927) from diseased birds, and shown to be filterable and distinguishable antigenically from the virus of fowl plague. Burnet and Ferry (1934), by filtration data, estimated the size of the viral particles to be 80 to 120 millimicrons. On the basis of electron micrographs, Bang (1948) later calculated the

diameter to be 112 mμ. The present and much more detailed picture of the morphology of Newcastle disease virus is based upon several methods of purification and on examination by negative staining (Waterson, 1964; Rott and Schäfer, 1961; Schäfer, 1963). The virion, or mature virus unit which varies in size from 150 to 200 mμ (Waterson and Cruickshank, 1963) consists of an envelope and an internal component. The either-sensitive and osmotically deformable envelope (Bang, 1946) has a pattern of projections or spikes (80 A° long) and contains the antigenic components that stimulate the host to produce hemagglutinin-inhibiting and virus-neutralizing antibodies (Rott, 1964). The internal component, or nucleocapsid, also known as the G-antigen or NP-antigen, consists of a long and much coiled tube which has a diameter of 180 Angstroms (Schäfer and Rott, 1959). The protein structural units of the tube are arranged in a helix around the central hollow axis. Within them and determining the entire configuration is ribonucleic acid.

The Newcastle disease virion is morphologically similar to but antigenically distinct from other viruses of the parainfluenza group and, like them, it is inactivated by hydroxylamine (Rott and Schäfer, 1962). With the exception of myxovirus Yucaipa which was isolated in California and produces a mild respiratory disease in chickens (Bankowski and Corstvet 1961; Dinter et al., 1964) and fowl parainfluenza 2 of Ruckle-Easters (Waterson, 1964), the other parainfluenza viruses produce disease in mammals. Among them are parinfluenza of cattle, respiratory syncytial virus and mumps virus of man, and the antigenically related group of measles, distemper, and rinderpest (Chanock and Coates, 1964).

The true influenza viruses have a smaller virion, 80 to 120 mμ, and a smaller nucleocapsid, 90 Angstroms in diameter. Influenza viruses affecting birds include fowl plague, virus N, Czechoslovakian and British duck influenzas, and tern disease (Dinter, 1964). The avian influenzas share an antigenic component with influenza A of man, swine, and horses. Influenza B, which affects man, is antigenically distinct.

Newcastle disease virus possesses a number of biological and physical characteristics by which it may be distinguished from other myxoviruses and by which strains of NDV may be distinguished from each other. Among these properties are the ability to agglutinate and to lyse erythrocytes, to induce toxic changes without accompanying multiplication, to enter cells and to replicate, to infect and to incite various signs and lesions in certain hosts and to cause the death of some hosts, to be specifically neutralized by antibodies, and to be inactivated by selected agents under defined conditions. If the procedures used are properly standardized and controlled, all the actions can be quantitated and the results obtained can be repeated with considerable degree of exactness.

From the standpoint of economics, the most important property of NDV is its ability to produce disease and death of chickens: a property in which the strains of virus differ markedly. All strains may be grouped for convenience into three classes of differing virulence for chickens: velogenic, mesogenic, and lentogenic (Hanson and Brandly, 1955). Irrespective of the route of exposure, chickens receiving velogenic strains develop severe disease which often terminates in death. Embryos, after receiving a minimal lethal dose, die within 50 hours. When introduced by peripheral routes mesogenic strains usually produce a mild disease which rarely results in death of the chicken. If the virus is introduced directly into the central nervous system, severe disease and death result. Chicken embryos are killed within 50 to 60 hours after receiving a minimum lethal dose. Lentogenic strains produce a mild or inapparent disease irrespective of method of exposure. If the lentogenic virus is introduced directly into the central nervous system, it does not multiply and it does not result in death of the bird. Embryos are

killed 100 hours after receiving a minimal lethal dose.

Foremost among the biological properties of NDV is its ability to adsorb to the surface of red cells and to induce their aggregation. Hemagglutination of NDV was first described by Burnet (1942) who also found this action to be inhibited by specific antiserum. The hemagglutinin is structurally identified with projections on the envelope of the virus (Rott, 1964) and it has been chemically determined to be the enzyme, neuraminidase. Hemagglutination may be measured by the sedimentation rate of agglutinated red cells (Hirst and Pickels, 1942) or by the pattern which the aggregated cells form on a curved glass surface (Salk, 1944). The latter means of detection has been found to be the most practical method of quantitating the hemagglutinating activity of the virus. The process of hemagglutination consists of two stages: the attachment of the virus to the receptor substance on the cell surface (agglutination) and the destruction of the receptor substance by the enzyme neuraminidase (Ackerman, 1964). The second stage (Sagik and Levine, 1957; McCollum and Brandly, 1955a) is associated with the release of the virus from the surface of the cell (elution). While erythrocytes of all amphibia, reptiles, and birds are agglutinated to some degree by NDV (Clark and Nagler, 1943), some mammalian erythrocytes are inagglutinable. Man, mouse, and guinea pig erythrocytes are agglutinated by all strains of NDV; those of cattle, goat, sheep, swine, and horses are agglutinated by some but not all strains of NDV (Winslow et al., 1950b). The erythrocytes of some individual cattle are agglutinated by one Newcastle strain while cells of another individual are not agglutinated by the same strain. The sensitivity of all cells to agglutination, but particularly so variably reactive cells as those of cattle, is dependent upon ionic concentration of the salts and the pH of the suspending solution. Erythrocytes are not the only type of cell to which the virus absorbs and which may be agglutinated as a result of this absorption. Chu (1953) demonstrated that sperm cells may be agglutinated by the action of Newcastle disease virus. The absorption of NDV to brain cells may be demonstrated by the reduction it induces in the ability of the virus preparation to subsequently agglutinate avian erythrocytes (Piraino and Hanson, 1960).

Approximately 100,000 virus infective units equal an hemagglutinating unit. The number of viral particles in a preparation may be approximated on the basis of its hemagglutinin activity. However, the rate of inactivation of the hemagglutinating activity of the virus is not necessarily proportional to the rate of the inactivation of the infectivity of the virus preparation (Hanson et al., 1949; Tolba and Eskarous, 1962). Some strains of Newcastle disease virus which lose their hemagglutinative activity on treatment at 56° C. within 5 minutes, remain capable of infecting embryonated eggs or other suitable hosts even after a further period of 25 minutes of inactivation. Other strains of NDV retain their ability to hemagglutinate after treatment at 56° C. for 180 to 240 minutes although their ability to produce infection was lost within the first 90 minutes. In this respect, NDV differs from the influenza viruses, all of which lose their ability to infect embryonated eggs before they lose their ability to hemagglutinate. The difference in the rate at which the hemagglutinin is destroyed by heat is a characteristic by which NDV strains may be differentiated.

Like other parainfluenzas, NDV possesses a hemolysin. The virus is capable of lysing those erythrocytes that it can agglutinate (Kilham, 1949; Burnet, 1950; Burnet and Lind, 1950). The hemolytic activity of virus preparations is enhanced by freezing and thawing, by dialysis, by sonic vibration, and by osmotic shock (Granoff and Henle 1954; McCollum and Brandly, 1955b). The salt concentration and pH of the suspending solution and the temperature at which the reaction takes place are important (Granoff and Henle, 1954). Picken (1964)

diameter to be 112 mμ. The present and much more detailed picture of the morphology of Newcastle disease virus is based upon several methods of purification and on examination by negative staining (Waterson, 1964; Rott and Schäfer, 1961; Schäfer, 1963). The virion, or mature virus unit which varies in size from 150 to 200 mμ (Waterson and Cruickshank, 1963) consists of an envelope and an internal component. Lentogenic strains produce a mild or inapparent disease irrespective of method of exposure. If the lentogenic virus is introduced directly into the central nervous system, it does not multiply and it does not result in death of the bird. Embryos are

killed 100 hours after receiving a minimal lethal dose.

Foremost among the biological properties of NDV is its ability to adsorb to the surface of red cells and to induce their aggregation. Hemagglutination by NDV was first described by Burnet (1942) who also found this action to be inhibited by specific antiserum. The hemagglutinin is structurally identified with projections on the envelope of the virus (Rott, 1964) and it has been chemically determined to be the enzyme, neuraminidase. Hemagglutination may be measured by the sedimentation rate of agglutinated red cells (Hirst and Pickels, 1942) or by the pattern which the aggregated cells form on a curved glass surface (Salk, 1944). The latter means of detection has been found to be the most practical method of quantitating the hemagglutinating activity of the virus. The process of hemagglutination consists of two stages: the attachment of the virus to the receptor substance on the cell surface (agglutination) and the destruction of the receptor substance by the enzyme neuraminidase (Ackerman, 1964). The second stage (Sagik and Levine, 1957; McCollum and Brandly, 1955a) is associated with the release of the virus from the surface of the cell (elution). While erythrocytes of all amphibia, reptiles, and birds are agglutinated to some degree by NDV (Clark and Nagler, 1943), some mammalian erythrocytes are inagglutinable. Man, mouse, and guinea pig erythrocytes are agglutinated by all strains of NDV; those of cattle, goat, sheep, swine, and horses are agglutinated by some but not all strains of NDV (Winslow et al., 1950b). The erythrocytes of some individual cattle are agglutinated by one Newcastle strain while cells of another individual are not agglutinated by the same strain. The sensitivity of all cells to agglutination, but particularly such variably reactive cells as those of cattle, is dependent upon ionic concentration of the salts and the pH of the suspending solution. Erythrocytes are not the only type of cell to which the virus absorbs and which may be agglutinated as a result of this absorption. Chu (1953) demonstrated that sperm cells may be agglutinated by the action of Newcastle disease virus. The absorption of NDV to brain cells may be demonstrated by the reduction it induces in the ability of the virus preparation to subsequently agglutinate avian erythrocytes (Piraino and Hanson, 1960).

Approximately 100,000 virus infective units equal an hemagglutinating unit. The number of viral particles in a preparation may be approximated on the basis of its hemagglutinin activity. However, the rate of inactivation of the hemagglutinating activity of the virus is not necessarily proportional to the rate of the inactivation of the infectivity of the virus preparation (Hanson et al., 1949; Tolba and Eskarous, 1962). Some strains of Newcastle disease virus which lose their hemagglutinative activity on treatment at 56° C. within 5 minutes, remain capable of infecting embryonated eggs or other suitable hosts even after a further period of 25 minutes of inactivation. Other strains of NDV retain their ability to hemagglutinate after treatment at 56° C. for 180 to 240 minutes although their ability to produce infection was lost within the first 90 minutes. In this respect, NDV differs from the influenza viruses, all of which lose their ability to infect embryonated eggs before they lose their ability to hemagglutinate. The difference in the rate at which the hemagglutinin is destroyed by heat is a characteristic by which ND strains may be differentiated.

Like other parainfluenzas, NDV possesses a hemolysin. The virus is capable of lysing those erythrocytes that it can agglutinate (Kilham, 1949; Burnet, 1950; Burnet and Lind, 1950). The hemolytic activity of virus preparations is enhanced by freezing and thawing, by dialysis, by sonic vibration, and by osmotic shock (Granoff and Henle, 1954; McCollum and Brandly, 1955b). The salt concentration and pH of the suspending solution and the temperature at which the reaction takes place are important (Granoff and Henle, 1954) Picken (5-

638   C. A. BRANDLY and R. P. HANSON

has suggested that the hemolytic capability of NDV can be separated from its hemagglutinative activity by chemical procedures.

The ability of the viral preparation to provoke a pathologic change in a host system in the absence of multiplication has been designated toxicity. Burnet (1942) first reported that NDV possesses this capability. The toxic response is elicited following intracerebral, intranasal, and intravenous administration of the virus in mice and intravenous injection of rabbits. When introduced into the brain of a mouse, the virus incites central nervous system disturbance with paralysis within two days and death in three days (Upton et al., 1953; Groupe and Dougherty, 1956). Following nasal instillation, it may induce pneumonia and death of mice (Ginsberg, 1951), and following intravenous injection, it may cause lymphocytopenia (Evans and Melnick, 1950) and fever (French, 1952) of rabbits. Toxic capability of the virus is rapidly reduced by dilution and readily destroyed by treatments that destroy infectivity. Following inoculation of the virus into the brain of a mouse, it is absorbed by and penetrates the cells. The virus may even initiate a partial replication process as has been suggested by Cairns (1951). However, infective virus is not produced. The toxicity of NDV for mice following inoculation by any route varies among strains (Hanson et al., 1951; Upton et al., 1953). Those strains that have a high degree of neurotoxicity for mice are also highly pathogenic for chickens. No relationship has been found between toxicity measured in other ways and pathogenicity for chickens.

Replication of NDV has been studied in cell culture systems. The virion, on reaching a cell surface, presumably attaches by processes that are involved in agglutination of erythrocytes. The virion then passes through the cell wall probably by viropexis (Silverstein and Marcus, 1964). At this point the virion loses its integrity, the envelope disappears, and it is supposed that the nucleoprotein core is released as a long filament (Fig. 22.1). Infective virus cannot be found for the next three hours. During the eclipse period, NDV specific antigen can be demonstrated by complement fixation and by fluorescent antibody reactions. First detected is the NP antigen in the cytoplasm near the nucleus (Rott, 1964). Then the HA antigen and neuraminidase can be found throughout the cytoplasm. The specific antigens accumulate and structures identical with the mature virion appear just within the cell membrane 3 to 4 hours after infection (Wheelock, 1963; Kingsbury, 1962). Sometimes these particles pack the microvilli. If the cell is destroyed by sonic disruption, its particles are found to be infectious. In the usual course of events the virions are liberated as small parts of the cell membrane, much as microvilli are sloughed (Bang, 1952). Liberation of virus starts four hours after infection and can continue for another four hours without destruction of vital processes of the infected cell. An excess of virus specific substances, external NP antigen, viromicrosomes, and released HA are produced that are not incorporated into the infective virus particles, the virions (Rott, 1964).

There is some evidence that the virion may be produced either at the cell surface and incorporate cell membrane substance, or within the cytoplasm and incorporate endoplasmic reticulum substance (Rott and Schäfer, 1962). The first class of particles is sensitive to hydroxylamine and is usually avirulent for chickens. The second class is resistant to hydroxylamine treatment and is usually virulent for chickens.

NDV interferes with the multiplication and pathologic expression of certain other viruses and, in turn, it is interfered with by certain viruses (Raggi et al., 1963; Chanock, 1955; Morimoto et al., 1962). Mixed infection in chickens can result in aborted disease and immunologically reduced response (Hanson et al., 1956). In cell cultures, interference has been utilized in the development of procedures to detect noncytopathic viruses (Shimizu et al., 1964). Mixed infections of NDV strains and of

ND and influenza viruses sometimes result in production of combined forms, a kind of recombinant (Granoff and Hirst, 1954; Granoff, 1962).

Newcastle disease virus is capable of producing changes in many tissue culture systems. These changes are of two primary types: necrosis of the cell and alteration in form or physiology of the cell. The alterations may be characterized by increased permeability to dyes or by formation of giant cells. Many types of primary cells, particularly of chicken embryo origin (Rubin et al., 1957; Morehouse et al., 1963), and certain cell lines of mammalian origin are readily infected by NDV (Brandt, 1961; Bankowski, 1964; Gelenczei and Bordt, 1960). On cell monolayers, many strains of NDV induce the formation of plaques (Granoff, 1964; Schloer, 1964). In these circumscribed areas of a sheet of cells, the virus has multiplied and destroyed or altered the cells in such a manner that an area of change or plaque is evident to the naked eye. The plaques produced by NDV can be grouped into several size classes, ranging from 0.5 to 2.4 mm. in diameter. The degree of the cell destruction within these plaques varies in such a way that most plaques can be described as clear if most or almost all of the cells are destroyed, or turbid if only a few of the cells have been destroyed. Some strains of the virus produce plaques with sharp margins and other strains produce plaques with a faint margin. In the latter instance, it is difficult to distinguish the boundary between the plaque and the monolayer. In the red plaques first described by Thiry (1963), there is no evidence of cell destruction. The plaque is apparent because of change in ability of infected cells to absorb dye. Syncytial formation is sometimes evident in red plaques (Schloer, 1961). Depending on temperature and nature of the monolayer, plaques develop within 2 to 4 days fol-

lowing inoculation of the virus. Since the size and clarity of a plaque increase with time, the description of a plaque must always refer to its age.

Velogenic and mesogenic strains are cytopathic and produce plaques; lentogenic strains are sometimes cytopathic but appear to be unable to produce plaques in chicken embryo fibroblasts and in HeLa cells. With these exceptions, most laboratory strains of NDV as well as new isolates contain more than one type of plaque and, sometimes, as many as five types differing in size, margination, degree of cell destruction, or type of cell alteration. It is possible to differentiate strains according to the types of plaques that they produce. It is possible to carry them as pure lines which will continue to produce under suitable conditions of serial transfer plaques that are similar to the one that was initially picked (Baron, 1964; Schloer, 1964).

All strains of NDV induce infection of chicken embryos which lead, with few exceptions, to death of the embryo. The lentogenic strains may fail to induce death of the embryo when antibodies are present in the yolk. Velogenic and mesogenic strains produce such rapid infection that the yolk antibody is incapable of modifying it. The route of infection, the temperature at which the incubated egg is held, the age of the embryo, and the quantity of virus introduced modify the infectious process. Infection is more rapidly fatal when the inoculated embryos are young, when the quantity of virus introduced is large, and when incubation is above, as contrasted to below, 37° C. (Sinha, 1958). Yolk sac and intravenous inoculation result in more rapid fatalities than do allantoic and chorioallantoic membrane inoculation (Hanson et al., 1947). The route of the infection modifies the order in which tissues become infected and the rate at which the virus titer increases. High titers of virus are found in the extra-embryonic fluids from 24 to 48 hours before the death of the embryo. The differences in time vary among strains. However, development

of high titers in the lung and spleen of the embryo itself precede death by only 2 to 6 hours. Presumably, the presence of virus in these tissues is associated with changes that result in death. Consequently, the rapidity with which these sites in the embryo are reached by the virus following its introduction probably determines the length of the period between infection and death. A measure of the virulence of a strain of NDV for the chicken embryo can be based on the number of hours that elapse between introduction of the minimal infective dose and death of the embryo (Hanson and Brandly, 1955). Lentogenic strains take over 100 hours; mesogenic and velogenic strains, 50 hours or less. The gross lesions induced by ND in the embryo include petechial hemorrhage on the skin of the embryo over the extremities and, with some strains, particularly over the cranial area (Bang, 1964).

The pathogenicity of NDV for chickens is determined largely by the strain of the virus, but also in part by the dose, the route of administration, the age of the chicken, and certain environmental conditions (Sinha et al., 1952). The younger the chicken, the more virulent is the virus. Breed or genetic stock of chicken has only a slight effect upon susceptibility to the virus. At high ambient temperatures, chickens appear to be more susceptible and to more frequently develop neurologic signs (Sinha, 1957). Some of the velogenic strains are capable of producing death following the introduction of only a few infective particles; other strains require a million or more infective units to induce death; some strains are nonfatal even in enormous doses. The route of infection modifies the action of the pathogenic process. Natural routes of infection, such as intranasal, oral, and ocular, including aerosol forms, are most frequently associated with development of respiratory disease. Intramuscular, intravenous, and intracerebral administrations usually enhance the neurovirulence of the virus.

A sequence of events following introduc-

tion of NDV into the chicken is initiated by multiplication of the virus at the site of introduction (Asdell and Hanson, 1960). There follows liberation of virus into the blood stream, a second cycle of multiplication in visceral organs, a second release into the blood stream, and passage into the central nervous system in some instances. Signs of disease and liberation of virus into the environment are associated with the second release of the virus into the blood stream. The course of the disease is determined by the defense mechanisms that come into play at this time. The pathogenicity of NDV for chickens can be measured by the ability of the virus to produce death, to produce central nervous system signs such as paralysis, tremor, and torticollis, and to produce respiratory signs which may be marked or so slight as to become evident only upon a disturbance of the birds. Degree of pathogenicity is expressed by the effect of the virus upon the ability of the bird to lay and to maintain weight gains. The virulence of NDV for susceptible chickens presents a complete continuum from very rapid fatal infection to an inapparent disease.

All NDV strains are capable of provoking an antibody response in chickens, rabbits, and in other species into which they are introduced. Newcastle disease virus has several antigens. The antigen that induces the virus neutralizing antibody and the hemagglutinating antigen are associated with the envelope of the virus; the NP antigen or soluble antigen is associated with the nucleoprotein portion of the virus. The NP antigen is detected in the complement-fixation test and in the gel-diffusion test. The hemagglutinating antigen, the virus neutralizing antigen, and the NP antigen form distinguishable lines in the gel-diffusion test (Rott, 1964). The ability of the virus to fatally infect embryonated eggs and to infect cells in culture is inhibited by the virus-neutralizing antibody. The virus also induces the production of protective antibodies in the chicken which enables it to resist reinfection. The various

serologic procedures do not necessarily detect the same antibody and antigenic reactivities. When the hemagglutinating antigen is destroyed by ether, the preparation no longer agglutinates erythrocytes and one of the lines in the gel-diffusion test is eliminated (Coleman, 1959). The difference between the virus neutralizing antibody, the hemagglutination-inhibiting antibody, and the refractivity of chickens to challenge become apparent on a temporal scale. In the serum of convalescent chickens, antibody as measured in these ways appears to increase and decrease in an independent manner (Coleman, 1959). Hemagglutination-inhibiting antibodies will become undetectable while virus-neutralizing antibody is still very high. Refractivity of chickens to reinfection often cannot be related to a circulating antibody. Antigenic differences exist among NDV strains. Strains can be distinguished on the basis of the gel-diffusion test, the hemagglutination-inhibition test, and the virus-neutralization test. These are differences that are both qualitative and quantitative in nature (Schloer, 1964).

The stability of NDV can be measured on the basis of alterations in the ability of the virus to infect, to agglutinate cells, and to induce an immunogenic response. These abilities can be destroyed at varying rates by such physical and chemical treatments as heat, light, ultra-violet, X-ray, oxidation processes, pH changes, and cresolic compounds. The rate at which the reactivity of the virus is destroyed varies with the strain of virus. It is also dependent upon the time of exposure to treatment, the quantity of virus which is initially exposed, the nature of the suspending medium, and by interactions among treatment variables. The sensitivity of the virus to thermal changes has been studied in greater detail than has any other environmental factor (Foster and Thompson, 1957; Hanson et al., 1949). All activity of the virus is destroyed at 100° C.—within a minute. At 56° C. the destruction of infectivity, hemagglutinative activity and immunogen-

lowing inoculation of the virus. Since the size and clarity of a plaque increase with time, the description of a plaque must always refer to its age.

Velogenic and mesogenic strains are cytopathic and produce plaques; lentogenic strains are sometimes cytopathic but appear to be unable to produce plaques in chicken embryo fibroblasts and in HeLa cells. With these exceptions, most laboratory strains of NDV as well as new isolates contain more than one type of plaque and, sometimes, as many as five types differing in size, margination, degree of cell destruction, or type of cell alteration. It is possible to differentiate strains according to the types of plaques that they produce. It is possible to carry them as pure lines which will continue to produce under suitable conditions of serial transfer plaques that are similar to the one that was initially picked (Baron, 1964; Schloer, 1964).

All strains of NDV induce infection of chicken embryos which lead, with few exceptions, to death of the embryo. The lentogenic strains may fail to induce death of the embryo when antibodies are present in the yolk. Velogenic and mesogenic strains produce such rapid infection that the yolk antibody is incapable of modifying it. The route of infection, the temperature at which the incubated egg is held, the age of the embryo, and the quantity of virus introduced modify the infectious process. Infection is more rapidly fatal when the inoculated embryos are young, when the quantity of virus introduced is large, and when incubation is above, as contrasted to below, 37° C. (Sinha, 1958). Yolk sac and intravenous inoculation result in more fatal fatalities than do allantoic and chorioallantoic membrane inoculation (Hanson et al., 1947). The route of the infection modifies the order in which tissues become infected and the rate at which the virus titer increases. High titers of virus are found in the extra-embryonic fluids from 24 to 48 hours before the death of the embryo. The differences in time vary among strains. However, development

of high titers in the lung and spleen of the embryo itself precede death by only 2 to 6 hours. Presumably, the presence of virus in these tissues is associated with changes that result in death. Consequently, the rapidity with which these sites in the embryo are reached by the virus following its introduction probably determines the length of the period between infection and death. A measure of the virulence of a strain of NDV for the chicken embryo can be based on the number of hours that elapse between introduction of the minimal infective dose and death of the embryo (Hanson and Brandly, 1955). Lentogenic strains take over 100 hours; mesogenic and velogenic strains, 50 hours or less. The gross lesions induced by ND in the embryo include petechial hemorrhage on the skin of the embryo over the extremities and, with some strains, particularly over the cranial area (Bang, 1964).

The pathogenicity of NDV for chickens is determined largely by the strain of the virus, but also in part by the dose, the route of administration, the age of the chicken, and certain environmental conditions (Sinha et al., 1952). The younger the chicken, the more virulent is the virus. Breed or genetic stock of chicken has only a slight effect upon susceptibility to the virus. At high ambient temperatures, chickens appear to be more susceptible and to more frequently develop neurologic signs (Sinha, 1957). Some of the velogenic strains are capable of producing death following the introduction of only a few infective particles; other strains require a million or more infective units to induce death; some strains are nonfatal even in enormous doses. The route of infection modifies the nature of the pathogenic process. Natural routes of infection, such as intranasal, oral, and ocular, including aerosol forms, are most frequently associated with development of respiratory disease. Intramuscular, intravenous, and intracerebral administrations usually enhance the neurovirulence of the virus.

A sequence of events following introduc-

of incubation of naturally infected eggs. The chicken embryo is susceptible to the virus of ND and other diseases during its successive stages of development, yet the effects produced at each stage are markedly different due to differentials in specific enzyme and humoral activities (Blattner and Williamson, 1951; Buddingh, 1952). However, some of the lentogenic vaccine strains (B_1, LaSota, F) inoculated in 10-day embryonating eggs may require 90 to 150 hours to produce death, and by direct intracerebral inoculation may kill less than 10 per cent of susceptible day-old chicks (Hanson and Brandly, 1955).

An outbreak of ND may be so acute and severe as to kill all, or nearly all, of the birds in a flock within 3 or 4 days. At the other extreme, the disease may be so mild that symptoms are scarcely noticeable or they may be absent and the disease subclinical in nature. Natural and acquired differences in both the virus and the host, as well as known dosage and various environmental factors, appear largely to explain differences in the nature and course of the disease.

The incubation period of ND after natural exposure has been reported to vary from 2 to 15 days, or even longer, with an average of 5 to 6 days. The incubation time, as well as severity of the disease, decreases gradually from hatching to maturity. The response of offspring of immune hens may be altered favorably by the passive protection afforded by antibodies derived from the yolk. With heavy exposure to virulent NDV, rapidly developing prostration and early death may be observed to the exclusion of other signs.

Signs Among Baby Chicks and Growing Chickens

The most common signs of ND in chicks are respiratory in nature—gasping (Fig. 22.2), coughing, and hoarse chirping. Sometimes there is complete aphonia. Depression, partial or complete inappetence, and increased thirst in the early stages, and huddling are common expressions. Nervous

signs, including partial or complete paralysis of the extremities, muscular tremor, and rhythmic, clonic spasms, usually follow but sometimes accompany the respiratory signs. Peculiar attitudes, including torticollis (Fig. 22.3), opisthotonus, emprosthotonus, and lateral deviation of the head, are associated with a variety of abnormal movements, e.g., rearing, somersaulting, walking in circles, falling.

Partial or complete motor paralysis of one or both legs was the only sign observed in several outbreaks of ND among turkey flocks (Gray et al., 1954).

Whereas respiratory involvement is common, all chicks of an affected brood may not show this sign; a few individuals may develop nervous manifestations only, and occasionally neither sign may be entirely absent in a brood. The respiratory symptoms usually persist in the brood for 2 to 3 weeks. Temporarily delayed growth or permanent stunting of development is a variable consequence of ND. Recovery rarely occurs after prominent nervous signs develop. Other clinical signs, at times obviously modified by complicating factors, have been described in young and old birds of other avian species as well as chickens affected with ND. In younger birds the mortality may range from zero to 100 per cent according to reports from various parts of the world.

Signs in Laying Flocks

The disease usually appears suddenly and spreads quickly through fully susceptible flocks. Respiratory distress of varying severity, with coughing and gasping by a few or virtually all of the birds, is generally the first sign. In some flocks and outbreaks, respiratory involvement may be so mild as to be scarcely detectable, or it may be absent. These manifestations are identical with signs of bronchitis and closely resemble those of laryngotracheitis. Depression and impaired appetite accompany the respiratory difficulty. The flock may virtually cease eating within the week following onset. Concurrently, egg production may

icity occurs within periods of 5 minutes to 6 hours. At 37° C., hours or even days are required to induce these changes. At 20° C. and 8° C., months or years pass before all reactivity of the virus is lost.

NDV is destroyed by exposure to ultraviolet light rays in a similar fashion to other myxoviruses (Oppenheimer *et al.*, 1944). It has a rather broad stability in the presence of varying hydrogen ion concentrations. The infectivity is retained for many hours at a pH as low as 2 and as high as 10 (Moses *et al.*, 1947).

The inactivating effect of chemicals is very much dependent upon substances in the suspending medium, large quantities of protein reducing the effect of chemicals and delaying the inactivation of the virus. Formalin, beta-propiolactone (Mack and Chotisen, 1955), and phenol are useful in destroying the infectivity without severely damaging the immunogenicity of the preparation. At low temperatures, dilute formalin will destroy the infectivity without markedly affecting the hemagglutinin and without any measurable effect upon the immunogenicity of the preparation. Most known viricidal chemicals will destroy NDV (Tilley and Anderson, 1947; Beamer and Prier, 1950; Cunningham, 1948).

Destruction of the stability of NDV in nature is greatly dependent upon the medium in which the virus is present, e.g., decaying carcasses, feces, drying or fermenting matter, or mucous droplets in air (Zakomirdin, 1963; Walker *et al.*, 1953; Olesiuk, 1951; Mickalov and Vrtiak, 1963; Boyd and Hanson, 1958). The proteinacious matter may not only be protective but it may nullify the action of the disinfectant. Environmental conditions, particularly warm temperature and solar radiation, facilitate the destruction by chemicals. Freezing temperatures suspend most inactivating procedures. Disinfection should follow physical cleaning and, in winter, should be carried out only in the presence of supplemental heat.

A strain of NDV is a culture that has been recovered from a chicken or other host by inoculation of a suitable laboratory system such as embryonated eggs or tissue culture. Such a culture or isolate can be called a strain without signifying that it is necessarily distinct or different from any other culture or isolate (International Rules of Nomenclature). Almost all strains of NDV that have been characterized on the basis of their physical stability and their biological properties have been shown to differ slightly or markedly from one another (Hanson and Brandly, 1955). From such strains, one can isolate sublines which are differentiable from the parent culture on the basis of plaque morphology (Granoff, 1964; Schloer, 1964). These lines are usually differentiable also on the basis of their virulence for selected host systems and selected physical characteristics, and they may differ in their antigenicity. Sublines may also be separated by selective properties such as ability of a portion of a viral population to resist thermal shock (Goldman and Hanson, 1955). A subline may be separated from a culture by its ability to propagate in a given host system (Brueckner *et al.*, 1950; Romarov and Goldsmit, 1946). With few exceptions, strains are composed, on initial isolation, of heterogeneous populations that are separable on bases of plaque type and ability to surmount physical or biological hurdles. These population segments presumably arise through mutation (Granoff, 1964) and persist with varying degrees of success so that the population is the sum of the surviving mutants at any one time.

The heterogenicity of Newcastle strains suggests a built-in adaptability which has survival value to the virus in nature. It also suggests the desirability of formulating vaccines by selection of the most antigenically competent viral lines.

NATURE AND COURSE OF THE DISEASE

Proof is lacking that NDV, within an egg laid by an infected hen, may survive in and permit hatching of an infected embryo. Nevertheless, infection and death of embryos may occur during the first 4 or 5 days

FIG. 22.3 — Nervous symptoms of Newcastle disease.

from zero to 100 per cent among laying flocks have been reported from various parts of the world (Brandly, 1950).

Effect on Egg Quality and Production

The laying of soft or imperfectly shelled eggs early during attacks of ND in laying flocks may be followed after recovery by temporary and permanent abnormalities of egg quality. Lorenz and Newlon (1944), Berg et al. (1947), and later others reported on the basis of field findings and observations of trap-nested hens of absent or tremulous air cells, watery albumen, and rough, discolored, and chalky shells, and of abnormally shaped eggs. A high percentage of the hens laid abnormal eggs up to 45 days after an outbreak of ND (Lorenz and Newlon, 1944). The loss of albumen quality and shell abnormality tended to be permanent. Parnell (1950) found that eggs from hens that had experienced an attack of ND had low albumen indexes

when fresh and at successive periods up to 64 weeks in cold storage. Such eggs, as compared to those from hens not previously affected, did not keep as well in storage and the loss from inedible eggs was greater. Stuck yolks, which usually accompany watery albumen, accounted for most of the loss. The yolk quality was not altered. Parnell observed that during active ND infection some hens seem to lose their ability to secrete thick albumen while others do not. Knox (1950) reported on the effects of an epizootic of ND among crossbred and standardbred Rhode Island Reds. Comparisons of egg production and size over a 2- and 3-year period, including the outbreak, indicated the epizootic probably had a 12 weeks' effect on egg production before normal percentage production was attained for that time of year. Egg production decreased from an expected 60 per cent to 17 per cent for outbred Rhode Island Reds, to 40 per cent for incrossbreds

FIG. 22.2 — Respiratory symptoms of Newcastle disease.

drop precipitously to a low level or to zero Respiratory signs may recede or disappear entirely within 2 to 3 weeks, although apparent spread and persistence of ND may be prolonged, especially in flocks partially resistant as a result of prior infection or vaccination. Nervous involvement may appear as in chicks, although the proportion of cases is usually lower among the older stock. In the absence of complications, the appetite may return to normal after several weeks, and egg production has been reported to reach preinfection levels 1 to 8 weeks after an outbreak (Beach, 1917; Biswal and Morrill, 1954). If molt is induced, especially after production is well started in the pullet flock, return to production may be further delayed. In other instances, the egg yield as well as egg quality of the flock is permanently impaired.

In the more severe outbreaks, depression and "septicemialike" prostration are early prominent signs. The entire flock may sit huddled on the roosts and floor, eating little or nothing. A number of yard or floor eggs, mostly with soft or imperfect shells, are usually laid. A profuse fluid diarrhea often accompanies the early febrile reaction which, with rapid dehydration of the body, soon becomes sparse and almost exclusively urate in composition. Even in such outbreaks, the less severely affected birds may recuperate rapidly, marked improvement being apparent within 24 to 48 hours. The central nervous system is involved in a variable number of birds. Clonic spasms and partial or complete paralysis of one or several extremities, the head and neck, or the entire body, especially combinations of spasms and paralysis, are quite characteristic of ND. The consequence of these and other signs, e.g., torticollis and incoordination, may not be early death, but individuals so affected may be classed as "mortality" since recovery is rare. Mortality rates ranging

FIG. 22.3 — Nervous symptoms of Newcastle disease.

from zero to 100 per cent among laying flocks have been reported from various parts of the world (Brandly, 1950).

Effect on Egg Quality and Production

The laying of soft or imperfectly shelled eggs early during attacks of ND in laying flocks may be followed after recovery by temporary and permanent abnormalities of egg quality. Lorenz and Newlon (1944), Berg et al. (1947), and later others reported on the basis of field findings and observations of trap-nested hens of absent or tremulous air cells, watery albumen, and rough, discolored, and chalky shells, and of abnormally shaped eggs. A high percentage of the hens laid abnormal eggs up to 45 days after an outbreak of ND (Lorenz and Newlon, 1944). The loss of albumen quality and shell abnormality tended to be permanent. Parnell (1950) found that eggs from hens that had experienced an attack of ND had low albumen indexes

when fresh and at successive periods up to 64 weeks in cold storage. Such eggs, as compared to those from hens not previously affected, did not keep as well in storage and the loss from inedible eggs was greater. Stuck yolks, which usually accompany watery albumen, accounted for most of the loss. The yolk quality was not altered. Parnell observed that during active ND infection some hens seem to lose their ability to secrete thick albumen while others do not. Knox (1950) reported on the effects of an epizootic of ND among crossbred and standardbred Rhode Island Reds. Comparisons of egg production and size over a 2- and 3-year period, including the outbreak, indicated the epizootic probably had a 12 weeks' effect on egg production before normal percentage production was attained for that time of year. Egg production decreased from an expected 60 per cent to 17 per cent for outbred Rhode Island Reds, to 40 per cent for incrossbreds

and 34 per cent for crossbreds. The decrease in per cent of egg production for all groups during the epizootic was sufficient to lower the annual egg production, but to a lesser extent than was anticipated from the decrease observed during 12 weeks of low production. Average egg weights for the 3 months, as well as the annual egg weights of all groups, were decreased to a small but appreciable extent. A considerable time elapsed before birds were able to overcome the effects of ND on egg weight.

Upon infection with ND, some pullets laid imperfect and soft-shelled eggs (Biswal and Morrill, 1954). The eggs from certain pullets had a definite reduction in shell weight and thickness which persisted at least through the 56 days after infection.

Clegg and Mueller (1951) concluded that eggshell abnormalities resulting from ND infection were due to malfunction of the shell-producing uterus of the previously infected hen.

EPIDEMIOLOGY

Important in the ecology of ND virus and, hence, in the epidemiology of ND are the high resistance of the virus to adverse environment, the facility of its spread by various means, including air-borne routes or mechanisms, and its relatively broad and apparently expanding host spectrum (Beaudette, 1943, 1949; Brandly, 1950, 1953; Brandly et al., 1946a).

From the standpoint of the hosts' ecology, various states from complete refractivity to ready susceptibility to infection and, therewith, the occasional development of a balanced, though highly insecure, host-virus relationship are of major consequence. Environmental factors, especially husbandry and industry practices, obviously influence the ecology of the host, and these, together with other factors not already referred to in previous sections, may be considered briefly in the epidemiology of ND.

Season

Earlier reports indicate that ND prevailed mainly during the fall and winter seasons, tending to disappear largely during the warmest weather in enzootic areas (Beaudette, 1943; Brandly et al., 1946a). Davis et al. (1950) observed from a field survey that the reaction to living ND vaccine, mild and satisfactory in the summer of 1948, became so severe during the following winter that vaccination was discontinued as a practice in the area. "Breaks" after vaccination, regardless of the type of living or inactivated vaccine used, were greater during the winter season. Sinha et al. (1957) studied the severity of ND in 6- to 7-week-old chickens acclimatized to different environmental temperatures. After infection with viral aerosols, the mortality at 85°–90° F. was 100 per cent; at 70°–75° F., 95 per cent; at 50°–55° F., 75 per cent, and at 32°–35° F., 55 per cent. The incubation period was shortest at the warmer temperatures. Nervous signs of ND predominated at warmer temperatures; the respiratory signs were more pronounced at the colder temperatures.

While climatic factors may mediate susceptibility to ND infection, it would appear that husbandry practices which provide successive broods of susceptible chicks on contaminated premises throughout the year inordinately favor perpetuation of the infection.

On the basis of various evidences of prior unrecognized, mild, or subclinical ND in the United States, Beaudette (1952) believed that the obvious clinical disease may have been provoked by cold, adverse weather.

Age

More recent reports substantiate earlier observations which indicated that birds of all ages and breeds are susceptible although substantially less so with advancement to maturity (Beaudette, 1943; Brandly, 1953; Brandly et al., 1946a; Crawley, 1954). Earlier compilations of well-

documented evidence (e.g., Brandly, 1953) emphasize the much greater hazards of severe vaccination-induced ND among chicks one to several days of age than among older birds. Congenital immunity as a modifying factor of susceptibility and epidemic behavior has already been alluded to.

Host Range

Recent evidence of ND infection in several previously unreported species indicates that the host range or spectrum of ND is expanding, perhaps in part the result of adaptative mutation. Aside from the wider distribution of the infection and increased opportunity for exposure which favor its extension to new hosts, there is a greater awareness of the prevalence and adaptability of ND virus. It seems logical that the paucity of recorded observations of mild and subclinical ND in chickens and other susceptible as well as more refractory species may be largely accounted for by superficial and incomplete observations and the inadequacy of earlier diagnostic techniques.

A number of additions can be made to the species reported earlier as affected during natural outbreaks, namely, chickens, turkeys, guinea fowls, ducks, geese, parrots, pigeons, pheasants, partridges, crows, sparrows, mayas, and martins as well as unidentified species of free-flying birds (Beaudette, 1948, 1950; Brandly et al., 1946a). Nevertheless, the evidence of susceptibility of several wild species was not isolated. Initially reported isolations of ND virus from other species include: a natural case of the disease in a nestling European starling (Sturnus vulgaris) in New York (Gillespie et al., 1950); recovery from the bone marrow of a gannet (Sula bassana) in the Orkneys (Wilson, 1950); from a great horned owl (Bubo virginianus virginianus) in Ohio which showed nervous involvement (Ingalls et al., 1951); from an osprey (Pandion haliaetus) and three parakeets

(Palcornia) in Holland (Zuijdam, 1952a); and from the jackdaw (Corvus monedula) (Keymer, 1961). Naturally infected in an outbreak in a zoological garden were the little owl (Athene noctua), raven (Bucorvus sp.), white-tailed eagle (Haliaetus albicilla), and giant kingfisher (Dacelo gigas) (Schoop et al., 1955). Vrtiak (1958) reported recovery of the virus from a swan by Shah and Johnson (1959), from a nestling koel (cuckoo), and from a canary by Monda et al. (1961).

Avian species reported susceptible to inoculation infection are quail, sparrows (Beach, 1942; Pomeroy and Fenstermacher, 1948), grouse (Pomeroy and Fenstermacher, 1948), and the laughing dove (Kaschula, 1950).

Possibly indicative of the predictable behavior in species considered to be relatively resistant is the infection in ducks and geese. Earlier reports record both death and incomplete susceptibility of these species during outbreaks in fowl on the same premises and areas. Asplin's findings (1947), while supporting the substantial refractivity of ducks and geese to contact ND infection, revealed only temporary subclinical infection. Macpherson (1956b) infected a fledgling cormorant by feeding tissues of a hen dead of Hertfordshire strain ND infection. It remained well and its blood showed a high HI titer 7 days later; at 5 weeks following feeding, the titer was waning and became negative at 6 weeks. This author stated, "The short duration of immunity in the cormorants under experiment, as measured by the antibody content of their serum, indicates the possibility of repeated infection in this species analogous to repeated influenza in man. The low morbidity in comparison to the high morbidity in cormorant species may indicate a long established biological adaptation of ND virus to these birds and that the domestic fowl may, in fact, be only the secondary host."

Further experimentation tends to confirm earlier observations that few, if any,

species of birds are refractory to massive exposure with various strains by all routes. However, Placidi and Santucci (1956) state that carnivorous birds are apparently entirely resistant.

Determination of susceptibility to infection by feeding or aerosol exposure should afford a better indicator of liability to natural infection than parenteral inoculation would. Both pigeons and doves were found susceptible to severe and frequently fatal infection with strain GB (Boney, 1951) administered as an aerosol (Hanson and Sinha, 1952). Moses (1951) infected cowbirds, grackles, starlings, and English sparrows by aerosols of strain 11914. Sparrows were also subjected to aerosols of strain GB and contracted infection.

Recognition of the infectivity of NDV for man by direct and indirect contact and for various other mammals, naturally and artificially, is a recent significant development. Since Burnet in 1942 recorded the first human case, which resulted from accidental introduction of infected allantoic fluids into the conjunctival sac, a number of human cases have been recorded. To those summarized by Keeney and Hunter (1950), and among which 11 were verified by virus isolation, have been added many reports including those of the Minnesota group (Pomeroy, 1951; Quinn et al., 1952; and Lippmann, 1952), and the summary report of more than 100 cases throughout the world recorded in 53 papers during the period 1943 to 1955 (Hanson and Brandly, 1958). The Minnesota outbreak involved 40 of a total of 90 persons employed in evisceration of poultry at a slaughtering plant. Virus was recovered from 4 of 10 individuals examined while showing acute symptoms. Quinn et al. (1952) record 2 cases with ocular signs and a third with only general symptoms. The latter yielded virus from the nasal secretions and one of the others from the urine as well as the blood, nasal secretions, and saliva. Generalized infection without ocular involvement and recovery of the virus from the saliva had been recorded previously by Mitchell and Walker (1951) while the presence of the virus in the urine of man had not. Recognition of ND as an occupational hazard, especially to poultry eviscerators and to persons preparing ND vaccines and administering the living vaccines in the form of sprays and dusts (Dardiri et al., 1962), and of its potential human-to-human spread should serve as a major impetus for the poultry industry and the veterinary medical profession to suppress the malady at its source and eventually to eradicate it. Conjunctival reinfection of man within 4 weeks (Freymann and Bang, 1949) and after 4½ years (Jacotot et al., 1955) has been recorded.

A number of species of mammals including mice, hamsters, monkeys, dogs, guinea pigs, rabbits, ferrets, swine, calves, cats, bats, shrews, hedgehogs, and chinchillas have developed clinical manifestations after artificial exposure to NDV chiefly by parenteral routes. In several species, e.g., swine and sheep (Hofstad, 1950; Brueckner et al., 1950) and monkeys (Meyer and Mack, 1946; Wenner and Lash, 1949; Reagan et al., 1947), morbidity or death, or both, resulted only after intracerebral inoculation, not by intravenous and other routes. Six strains of NDV identified only according to the state of origin, were infective for cave bats (Myotis lucifugus) by intranasal instillation as well as by intracerebral, intraperitoneal, and intradermal injection (Reagan and Brueckner, 1951).

The reported capacity of certain strains of NDV to infect various mammals including man, experimentally, or in nature, i.e., cats (Bolin, 1948; Giltner, 1950; Report of Director, Purdue Agr. Exper. Sta., 1950), and man further stresses the real and potential range of infectivity of the virus.

Modes of Spread

Various reports and surveys (Beaudette, 1943, 1950, 1951; Brandly et al., 1946a; Kaplan, 1949; Blood, 1950; Brandly, 1950, 1953; and others) indicate that natural spread of ND has been chiefly through the media of exudates, excreta, and offal of infected birds. The digestive and respiratory routes obviously constitute the major chan-

nels of natural infection, although entry of NDV by the ocular and cloacal routes may be quite common.

Traffic in live birds, including inapparent cases and recovered birds as well as clinical cases, has often accounted for dissemination of infection, frequently over long distances (Beaudette, 1943). Initiation of the 1947 epizootic of ND in England (Gordon and Asplin, 1947) like the 1942 outbreaks in Düsseldorf and Arnsberg, Germany (Brandly et al., 1946a) was ascribed to the importation of market poultry. In the English outbreak, uneviscerated infected carcasses from Hungary were incriminated. In 33 per cent of 540 outbreaks there was a history of access to swill or butcher's waste, the former being found in some cases to contain the offal of imported carcasses. Traffic in live poultry accounted for 42 per cent of the first outbreaks. During later outbreaks, Gordon et al. (1948) observed that less than 5 per cent of the outbreaks arose from contaminated swill, while those originating from traffic in live birds increased to over 70 per cent. Dobson and Simmins (1951) demonstrated NDV in 50 of 135 samples of skin from eviscerated, imported poultry carcasses including chickens, turkeys, ducks, and geese. The fact that the isolants appeared to have been of a highly pathogenic type and that infectivity of survivors of severe ND is usually of short duration suggested to Asplin (1952) that these findings could be explained by surface contamination of the skin or by subclinical infection of partially resistant fowls with the virulent virus in the packing stations of the country of origin. Koser (1942) believed that certain flock outbreaks resulted from contamination introduced by irrigation of meadows.

Introduction of ND into the Hawaiian Islands and South America was attributed to the importation of infected chicks (Adler et al., 1951; Divo, 1950). Importations of ND have been ascribed to game or other birds (Report of Chief, B.A.I. 1950; Jansen et al., 1949; Zuijdam, 1949).

The previous evidence of air-borne spread of ND was substantiated by the work of DeLay et al. (1948) who recovered the virus from the air of a poultry house harboring an infected flock. Artificially created aerosols of the virus have been shown by Hanson and Sinha (1952), Sinha et al. (1952, 1954), and others to serve as a ready means of transmitting the virus.

More recent reports affirm the respiratory tract (Kohn, 1955, 1959) to be the most important and susceptible to ND infection yet an ND epidemic in Nigeria has been described that did not spread from pen to pen via the air, nor rapidly in the feed, but readily via infected drinking water (Kaschula, 1961b).

The presence of NDV in eggs laid during the preclinical and early acute stages of the disease (Van Roekel, 1946; Jungherr, 1946; Prier et al., 1950) may permit, through breakage, the contamination of crates, incubators, and other objects as well as the surrounding atmosphere. The virus, which has been found in about a third of the eggs laid during the acute phase of a flock outbreak or after live virus vaccination (Beaudette, 1948), would appear to prevent development or kill the embryo of fertile eggs (Doll et al., 1950a; Hofstad, 1949b). The report of DeLay et al. (1947), suggesting parent-to-offspring transmission as a result of finding virus in 4-day-old chicks from eggs laid during an outbreak, is interesting but requires confirmation. Living ND vaccines, especially those of relatively high pathogenicity, may serve to introduce infection into or upon premises from which it may spread directly via vaccine-infected birds or indirectly by contamination of air, water, and various objects. Fowl pox, laryngotracheitis, or other vaccines contaminated with ND virus (Zargar and Pomeroy, 1950; Hanson, 1953) have spread ND.

Carriers and Vectors

While the fowl in the early incubative and frank stages of ND is recognized as the most potent source of infection, it has become evident that the convalescent or recovered individual may sometimes harbor

and eliminate the virus for substantial periods. Several investigators have reported detection of NDV in recovered chickens or in eggs laid during periods of 2 to 4 months following exposure or clinical recovery (Beach, 1912; Jungherr and Terrell, 1946; Schoening and Osteen, 1948; Walker and McKercher, 1954). Pomeroy (1948) reported NDV recovery from a chicken showing illness 17 months after having undergone recognizable ND infection. Beaudette (1948) reported isolation of NDV from a flock at 5 weeks of age and again when it was in 10 per cent production. The possibility of reinfection in both these instances was, however, not excluded. Walker and Powell (1950) reported that normal hens, placed in contact with a rooster infected 6 months previously, developed infection after 5 weeks' exposure. Brandly (1945) observed that susceptible hens, placed with an immune cockerel that had been inoculated with virus several days previously apparently contracted the disease from the cockerel. Prier et al. (1950) failed to recover NDV from eggs laid by immune hens 1 to 26 days after heavy challenge. However, Zuijdam (1952b) found that flocks of chickens partly immune, as a result of vaccination with a killed or living vaccine, excreted virus for 33 and 19 days after a subsequent challenge with virulent virus. Virus was not shed after vaccination with two other living vaccines and subsequent challenge. Asplin (1952) found that fowls vaccinated with strain F, of low virulence, failed to show signs on challenge but they excreted virus. Dinter and Bakos (1953) and Woernle and Brunner (1957) reported similar results, the former of transfer of NDV to pen contact birds. Schmidt and Bindrich (1956) observed virus excretion in clinically immune fowl after Hertfordshire virus vaccination only when the HI serum titer fell below 1:16 or 1:20 and the SN titer was lower than the HA.

Numerous other observations indicating failure of infection to occur, even after frequent or prolonged contact of susceptible and recovered birds, suggest a low rate of recovered carriers. Nevertheless, with the development of predominantly pneumotropic strains of virus and the occurrence of largely nonfatal infections or of natural reinfections, the possibility of an increase in carrier rate may be anticipated.

Gordon et al. (1948) concluded that the introduction of healthy turkeys from affected areas apparently accounted for the origin of some ND outbreaks. Other birds, especially free-flying species (sparrows; turtle, striped, and laughing doves; and cormorants) appear to have been incriminated as vectors or carriers by the observations of Kraneveld and Mansjoer (1950), Mansjoer (1961), Kaschula (1950), Gustafson and Moses (1953), Hartwigk and Nitschke (1957), Hanson and Sinha (1952), and Macpherson (1956b).

The presence of virus in the feces of various mammals, e.g., mice, rats, dogs, foxes, or cats for periods up to 8 days after they had eaten NDV-infected embryos or fowl carcasses has been demonstrated (Polci and Silvagni, 1954; Zuijdam, 1951; Walker et al., 1954; Baczynski, 1959; and others).

Arthropods have not been incriminated as vectors of ND. Komarov (1940) found ticks (Argas persicus) abundant in an infected flock, but allowing them to feed on a healthy fowl did not transmit the disease. By inoculation of susceptible fowl with ticks from a diseased bird, the virus was found to survive in or on the tick for 7 but not 10 or 13 days. Bolin (1948) isolated NDV from common chicken lice collected from hens 33 days after subcutaneous injection with the virus. Hofstad (1919a) obtained negative results by transfer of mites (Liponyssus sylviarum) from infected chickens, but inoculation with washed mites that had fed on infected birds caused infection.

Mansjoer (1961) found that the virus remained viable in the Indonesian giant snail for several weeks and, hence, could be a source of infection.

DIAGNOSIS

A combination of means or methods is usually required for definitive diagnosis of Newcastle disease. These may embrace clinical examinations, gross and histological observations, isolations of the virus, virus-serum neutralization tests, hemagglutination, hemagglutination inhibition, hemadsorption, and specific immunity tests (Beaudette, 1943, 1951; Brandly et al., 1946b; Jungherr et al., 1946; Cunningham, 1952; Bankowski et al., 1959; and others).

Clinical Examination

The signs of ND described under "Nature and Course of the Disease" obviously closely resemble or are identical with those of a number of infectious diseases. Bronchitis, laryngotracheitis, coryza, leukosis, mycosis, pullorum disease, and the so-called chronic respiratory disease (Delaplane and Stewart, 1943) and infectious sinusitis of turkeys cause gasping and other respiratory signs indistinguishable from those frequently seen in birds and flocks affected with ND. The common nervous expressions of ND—lameness, paralysis, incoordination, torticollis, etc.—are often similar to or identical with those seen in the following diseases; neurolymphomatosis (fowl paralysis), avian encephalomyelitis (epidemic tremor), riboflavin deficiency (curled toe paralysis), vitamin E deficiency (encephalomalacia or crazy chick disease), and sometimes vitamin D (rickets) and vitamin A deficiencies; also botulism, heavy metal poisoning, and, according to Placidi (1954), corn cockle (Lychnis githago) poisoning.

Distinction between ND and respiratory diseases such as bronchitis, laryngotracheitis, and chronic respiratory disease (mycoplasmosis) is particularly difficult in flocks of growing and laying birds where the rather typical nervous manifestations of ND are lacking. Nervous signs may be absent or fail to appear until late in the course of the outbreak, thus complicating or preventing a clinical diagnosis. A pre-cipitous drop or cessation of production among layers and the development of nervous signs following respiratory involvement, especially in chicks, often suggest ND.

Gross Lesions

The pathologic changes of ND, chiefly hemorrhagic and inflammatory in nature, vary greatly in location, severity, and extent from bird to bird and among flocks and outbreaks (Beaudette, 1943; Jungherr et al., 1946). The variability in tropisms and pathogenicity among and within strains of NDV, as already mentioned, has been the cause of much confusion and delay in diagnosis and in the search for a satisfactory name for the disease. Likewise, variation in the response of the host animal associated with such factors as age and partial immunity often contributes materially to differences in lesions. Peracute or acute cases may show predominantly hemorrhagic pictures with severe and extensive involvement of the proventricular submucosa and the lymphoid patches and follicles of the intestine and, to a lesser extent, the gizzard (Doyle, 1927; Beaudette, 1943; Jungherr et al., 1946; Kaschula, 1961b). Hemorrhagic necrotic involvement adjacent to the lymphoid plaques of the intestine, including the so-called cecal tonsils, is a significant feature of infection by the more pathogenic strains with endotheliotropic properties (Jungherr et al., 1946).

Focal hemorrhages of the serous membranes, while occasionally described, are not as prominent or constant as in fowl plague and pasteurellosis. The markedly hemorrhagic conjunctivitis sometimes seen in man (Shimkin, 1946), the occasional congestion and hemorrhage of the conjunctiva in fowl (Bankowski, 1946; Crook, 1951; Santoni and Bonaduce, 1932), as well as the hemorrhagic encephalitis occasionally encountered in inoculated chicken embryos (Burnet, 1942; Jungherr et al., 1946) are further expressions of the endothelial

affinity of NDV. In acute forms of ND, the spleen may be mottled or quite pale and shrunken, the latter an apparent consequence of hemorrhage into the body tissue.

Cloudiness of the air sacs, with a film of grayish or yellowish exudate, is a frequent but not constant lesion of infection with distinctly pneumotropic strains (Beach, 1912) and has been commonly seen with various strains proposed for use as ND living virus vaccines. The serositis of the pulmonary air sacs has a marked tendency to progress to the pericardium and visceral epicardium with consequent pericarditis and resultant marked thickening, opacity, and caseous exudates. The subacutely or chronically affected air sacs may be thickened and show fibrotic "scarring."

Congestion and mucous exudation, generally quite mild, are often present in the tracheas of birds which have shown respiratory signs, but these changes do not serve for differentiation of ND from other respiratory infections

Biswal and Morrill (1954) found that ND infection of laying pullets may result in oophoritis, with marked degeneration or atresia, and lymphocytic hyperplasia. In the pullets studied, there followed arrest of ovulation and subsequent oviposition.

Clouding or graying of the eyes, as described in a few cases, may result from suspension of inflammatory cells in the fluid of the anterior chamber. In rare cases, vesicles form on the wattles and comb and these may indicate a dermotropic character of the ND virus (Brandly, 1945; and others)

Newcastle disease infection of the embryonating chicken egg, by chorioallantoic membrane inoculation, first described by Burnet and Ferry (1934), frequently results in the development of minute, fine, gray foci in the exposed portion of the membrane or of plaquelike gray thickenings with satellite foci. Congestion of the feet and skin varies from slight to moderate. Distinct petechial, or slightly larger, hemorrhages of the skin of the embryo occur quite commonly with some strains, less often with others. Infrequently, the embryos may show marked cranial hemorrhage or "hemorrhagic encephalitis." Gross congestive and hemorrhagic involvement of the yolk sac is present in a considerable proportion of specimens. This change has not been seen in fowl plague, pox, bronchitis, and laryngotracheitis infections of the chicken embryo (Jungherr et al., 1946).

Microscopic Lesions

Lesions considered to be characteristic of infection with NDV vary with the organ, virus strain, and other factors involved. They are essentially necrotizing in nature in the spleen, liver, gallbladder, intestine, and heart, and of a proliferative character in the lung, iris, and central nervous system. The serous membranes of the thoracic and abdominal cavities manifest secondary changes of inflammation and cellular infiltration.

Characteristic gross hemorrhagic, necrotic foci of the lymph follicles, patches, and cecal tonsils were found to occur near or in the normal lymphoid aggregates. Recent foci have been observed also in the interfollicular tissue of intact lymphoid follicles. Well-developed foci are usually situated in the subepithelial region of the mucosa and frequently bulge into the lumen, virtually occluding it. Complete cell necrosis and conspicuous hemorrhage are found at the center of the focus while the border shows capillary congestion and extravasation. The foci tend to produce a partial sloughing of the affected mucosa overlaid by serous exudate containing bacterial clumps; the foci usually extend to, but rarely beyond, the muscularis mucosa. Most of the intestinal wall is involved, but the serosa is left intact, although the adjacent mesentery sometimes shows capillary congestion and extravasation. The tissues of and adjacent to the lymphoid aggregates of the heart, liver, gallbladder, and proventriculus occasionally also show necrotizing and hemorrhagic lesions.

The lung lesions are primarily proliferative and secondarily exudative in chat-

acter. Hyperplasia of the alveolar wall cells, i.e., the epithelial covering, the endothelial lining of the capillaries, and the connective tissue septa, is indicated by the relatively numerous mitotic figures present. The proliferative process may partially or completely obliterate the alveolar space with consequent consolidation and interstitial pneumonia. The exudative coronary changes consist of cellular and serous accumulations in the peribronchial alveoli with extension into the regional tertiary bronchus. The pulmonary and abdominal air sacs reveal secondary inflammatory changes characterized by edema and mononuclear and some heterophil cell infiltration accompanied by metastatic thickening of the mesothelium. Fibroblastic proliferation is a common sequel of chronic infection. The iris also occasionally shows cellular infiltration. An interstitial pancreatitis has been observed with a few viral strains (Jungherr et al., 1946).

Both the ovary and various sections of the oviduct of laying pullets may show inflammatory reaction to NDV. Oophoritis was characterized by marked degeneration and subsequent lymphocytic hyperplasia. In the earlier stages, heterophilic infiltration, edema, and capillary hemorrhage were prominent; later there was lymphocytic hyperplasia. However, only the shell-secreting portion appeared to suffer functionally upon return to production (Biswal, 1954; Biswal and Morrill, 1954).

Among birds which survive challenge inoculation following vaccination, a considerable proportion may show gross residual lesions such as scattered gray foci of the spleen and liver and, particularly, focal fibrosis of the air sacs. Histologically, there are discrete areas of consolidation of the lung often associated with fibrosis; exudative lesions are more common than in normal birds. There seems to be an increase of noncircumscribed lymphocytic aggregates, particularly of the liver and kidneys. Evidence of stress on the renal function during immunization may be seen in the considerable areas of tubular de-

generation and regeneration (Jungherr et al., 1946).

The central nervous system lesions of ND have been described by various authors. Only thickening and proliferation of the vascular endothelium accompanied by early neuronal changes are usually seen in recent lesions, while characteristic glial clumps are more common in the older ones. Loci of predilection are the lumbar cord, medulla, and cerebellar nuclei. The glial foci of the cerebellar molecular layer may be indistinguishable from those occurring in avian encephalomyelitis, although they occur unassociated with marked perivascular cuffing and axonal reaction of the neurons characteristic of the latter disease.

Virus Isolation

As with other infectious diseases, the unequivocal method of diagnosing ND is the isolation and identification of the causative agent. Serologic and pathologic examinations may suffice to confirm suggestive histories and signs in areas where ND is enzootic, but new foci or extensions of the disease usually require recovery and identification of the virus. Likewise, ND infection of avian and mammalian hosts, including man, may induce typical or previously unidentified signs and symptoms. Signs or serologic evidence may be lacking entirely (Quinn et al., 1952), or the serologic findings, as either mumps in man where the serum may neutralize ND virus, may be misleading (Kilham et al., 1949; Evans, 1955; Bang and Foard, 1956).

Specimens for attempting isolation of the virus should be selected from cases in the incubative and early clinical stages of the disease (Brandly et al., 1946b). Younger individuals are more likely to yield virus (Brandly et al., 1946b; Beaudette et al., 1948, 1949a), and one should utilize suitable specimens of tissues most likely to have a high viral content, e.g. spleen, lungs, respiratory exudate. The more pathogenic and invasive strains are more widely distributed and present in greater

concentration in the various tissues and organs (Hofstad, 1951; Karzon and Bang, 1951; Sinha et al., 1952; Baskaya et al., 1952; Report of the Poultry Disease Subcommittee, 1963). The rapid disappearance from, or masking of the virus in the tissues of the host usually follows or coincides with the development of demonstrable circulating antibodies and detectable immunity to ND (Brandly et al., 1946b; Hofstad, 1951; Report of the Poultry Disease Subcommittee, 1963). Yet the virus may be isolated from the brain and excreta when circulating antibodies are present (Walker and McKercher, 1954).

Interference phenomena, e.g., of NDV by bronchitis virus after simultaneous exposure, may lead to erroneous results (Hanson et al., 1956). The recovery of NDV from the urine of an occupationally acquired human case emphasizes its wide distribution in the body and excretions and the necessity for adequate sampling in the search for it (Quinn et al., 1952).

The embryonating chicken egg is, for obvious reasons, preferred to the chicken or other animal for isolation of NDV. Details of the procedures of isolation, as described by various workers, point out the essential steps, precautions, and pitfalls (Bureau of Animal Industry, 1916a, 1916b; Brandly et al., 1946b; Beach, 1948; Beaudette et al., 1948; Thompson and Osteen, 1948; Report of the Poultry Disease Subcommittee, 1963).

As a rule, fertile eggs, preferably from healthy nonimmune hens, which have been incubated for 9 to 11 days at 37°–38° C., are injected in the allantoic chamber with suspensions of suspected tissues, free of bacteria. Antibiotic agents, usually either penicillin or streptomycin or more commonly a mixture of the two, are added to the inoculum to suppress or destroy bacteria which may be present (Brandly et al., 1946b; Thompson and Osteen, 1948; Beaudette et al., 1948). The injected and suitable control eggs are returned to the incubator, candled once or twice daily for the subsequent 5-day period or until death

of all or a large part of the embryos. Embryonic deaths during the first day are considered to be due to trauma or nonspecific causes. Examination of embryos dying subsequently may reveal some or all of the changes described under "Lesions," although congestive or hemorrhagic changes may be poorly defined or absent during initial or early egg passages of NDV. Clear, bacteria-free, allantoic fluids may then be tested for agglutinative activity for chicken erythrocytes and, if positive, it should be determined whether the phenomenon is inhibited by known ND immune serum. Identification of NDV may be accomplished, also, or confirmed by means of specific virus neutralization trials of the suspected egg fluids, or more directly, of the tissue suspensions, by employing mixtures of the ND immune serum and the unknown tissue for inoculating the embryonating egg as the test organism.

The use of susceptible chickens for isolation and identification of NDV may be expedient and desirable under certain circumstances where adequate isolation can be maintained. Much larger inocula may be employed than with eggs and possible difficulty in adaptation of the virus to the latter avoided (Beach, 1942; Brandly et al., 1946b; Geurden et al., 1950; Report of the Poultry Disease Subcommittee, 1963).

Interest in and recent progress with culture of NDV and other viruses in different types of tissue cultures of various cells, e.g., chicken embryo and adult cells, monkey kidney, Ehrlich ascites tumor, HeLa, and others suggest their further use for diagnostic isolation and differentiation (Topacio, 1951; Bankowski and Boynton, 1948; Pereira and Gompels, 1954; Seiffert, 1955; Chanock, 1955; Scott et al., 1953; Flanagan et al., 1955; Levine and Sagik, 1956; Bankowski, 1957; Bankowski et al., 1959; Goldwasser and Kohn, 1957; Rubin et al., 1957; and others). Epithelial cells of chickens, whether or not in tissue culture, may show normal as well as abnormal microvilli, the latter after infection, and from which virus is eliminated (Bang, 1952). Particles small-

stable, nonspecific inhibitors (Karzon, 1956) must be recognized and guarded against. Aliquots of suspected tissues, triturated, if necessary, and processed for inoculation, are admixed with suitable quantities of antibiotic preparations, of ND immune serum and of normal serum, respectively. The suspected tissues alone may be inoculated also in an effort to detect bacterial or other pathogens, or contamination which was suppressed by the antibiotic substances.

Hemagglutination (HA) and Hemagglutination-Inhibition (HI) Tests

The finding by Burnet (1942) and Lush (1943) that NDV, like influenza, agglutinated the red blood cells of chicks and that such hemagglutination was specifically inhibited or neutralized by ND immune serum provided a simple and useful diagnostic method. The test for HA may serve as a rapid method for detecting NDV in the fluids or extracts of infected tissues of fowl as well as in the fluids of infected eggs (McClurkin et al., 1954). Monti (1952). Mitscherlich and Gürtürk (1952), Clark et al. (1955, 1957), Gardner et al. (1954), and Geurden and Devos (1955) demonstrated HI activity in the sera of ND infected chickens by adding NDV-treated chicken erythrocytes as a means of early and rapid diagnosis. The latter state that the serum-sensitized erythrocytes may be lyophilized and stored indefinitely for use. Hanson et al. (1947) showed that minimal NDV titers, at least of 10^6, are required if the infected allantoic or amniotic fluids are to induce hemagglutination. Bronchitis and laryngotracheitis viruses, while infective for the chicken embryo, do not cause hemagglutination, thus providing a means of differentiation from the HA-positive NDV (Brandly et al., 1946b).

As with the test for neutralization of NDV infectivity by specific immune serum, the test for inhibition or neutralization of the hemagglutinative activity of the virus (HI) gives quantitative as well as qualitative information. In the alpha procedure,

the virus suspension in serial twofold dilutions beginning with 1:5 is mixed with equal volumes of the serum under test and a 0.5 per cent suspension of chicken red cells. In the beta procedure, the serum is serially diluted and admixed with the red cell suspension and a constant quantity, e.g., 10 HA units of the virus (Brandly et al., 1947). The test, with adequate control tubes, is incubated at room temperature for 30 minutes and the results read on the basis of the degree or titer of HI. Typical, complete HA $(+ + + +)$ is represented by a continuous layer of cells covering the entire rounded bottom of the tube; a thicker layer, irregular in outline, covering a portion of the bottom is a partial or $+ + +$ reaction; a small central disk with a narrow granular fringe of agglutinated cells is a $+ +$ reaction; and a larger button, or disc, of cells with a narrow ring of agglutinated cells is classed as a $+$ reaction. Complete inhibition of the HA reaction, like the normal unimpaired settling of cells as in the control tubes, leaves a central compact button with regular edges. The highest dilution of virus giving a $+ +$ or higher reaction represents the titer of the virus, and the quantity of virus involved is considered a unit. Elution of virus from the cells and their subsequent release from the agglutinated layer causes a cascading or sliding of the cells to the bottom of tube and the formation of a disc, or button, as occurs when erythrocytes sediment normally. Rapid serum and whole blood HI tests have been devised and used with satisfactory results (Luginbuhl and Jungherr, 1949; Zargar and Pomeroy, 1949; Walker, 1952; and others).

The variables, both quantitative and qualitative, inherent to the HI test prompted efforts toward standardization (Report of Poultry Disease Subcommittee, 1963).

The HI test, although somewhat simpler and less protracted than the VN test, is usually considered less reliable than the latter. Neither the antibody nor the mechanism of reaction is the same in the HI and VN test as indicated by the sub-

stantially longer persistence of the VN principle or antibody and results of serum fractionation studies (Brandly et al., 1947; Hanson et al., 1950). An HI titer value of 10, according to the beta procedure, has been considered as of questionable diagnostic significance, one of 20 or higher definitely indicating prior infection of the bird. On the basis of their studies, Doll et al. (1950b) concluded that the HI response may differ according to strain of virus in time of development, titer, persistence, and with respect to route of infection and other factors. After several routes of infection, the HI titer rose to 10 or 20 in 5 to 6 days, indicating that complete inhibition at these titers was of diagnostic value. More than 90 per cent of the experimentally exposed thickens showed positive titers at the tenth day and were positive on the twelfth day. Direct and indirect complement-fixation tests have been utilized and found highly specific for serologic diagnosis of ND (Boulanger and Rice, 1953; Nitzschke, 1954; Brumfield and Pomeroy, 1957). Since specific anti-ND substances are demonstrable only after a period of 7 to 10 days following NDV infection, the use of serologic tests for earliest definitive diagnosis should be supplemented with appropriate HA tests using tissues of suspected birds, or fluids of embryonizing eggs or tissue cultures inoculated with them (Valado, 1955; and others).

Immunity Tests of Living Birds

Definitive diagnosis of prior ND infection may be accomplished by inoculating with fully virulent NDV, suitable specimens from flocks suspected of having been infected at least a week previously. Susceptible controls are simultaneously inoculated with the previously titrated challenge virus. Serum samples should be tested prior to inoculation by SN or HI tests.

Other Tests

Superiority from the standpoint of sensitivity and economy of time and materials has been claimed for isolation or hemadsorption or both of NDV in HeLa, monkey

kidney, or chicken embryo (Bankowski et al., 1959; Matewa, 1960; André and Audebau, 1960; Jakubik, 1962) or other cells in tissue culture according to the procedure of Vogel and Shelikov (Shelikov et al., 1958). The fluorescent antibody procedure allowed more rapid detection of NDV infection than did HI or regular egg inoculation according to Maestrone and Coffin (1961). Raggi (1960) reported a rapid plate agglutination test for ND.

PREVENTION AND CONTROL

The simplest and most logical measure against Newcastle disease and other infections is to prevent contact of the virus with the susceptible bird or mammal. A second and indirect method, applicable against certain diseases, is vaccination. The latter gives the animal a greater or lesser degree of protection against infection in case of exposure. The third and least satisfactory and least economical procedure is to attempt treatment of the animal after it is exposed or has become affected.

A combination of sanitary management, to reduce or prevent exposure, and of vaccination is often required to combat highly contagious diseases, such as ND, that have become widely established in a community, region, or country. However, both measures must be systematically carried out on an area, regional, state, or larger basis if control is to be reasonably and permanently effective. A minimum of 70 per cent of the flocks in an area must be included at the outset in the rigid sanitary program, combined with a satisfactory twice-a-year, or oftener, vaccination program.

Restriction of exposure to and spread of ND generally increases in proportion to expansion of the size of the flock, the rearing and maintaining birds of different ages on the premises, and the proximity of the housing units.

General compliance with a rigid sanitary program prevents ND where the poultry population is relatively small and flocks are some distance apart. Vaccination may be required as a supporting measure to sanita-

stable, nonspecific inhibitors (Karzon, 1956) must be recognized and guarded against. Aliquots of suspected tissues, triturated, if necessary, and processed for inoculation, are admixed with suitable quantities of antibiotic preparations, of ND immune serum and of normal serum, respectively. The suspected tissues alone may be inoculated also in an effort to detect bacterial or other pathogens, or contamination which was suppressed by the antibiotic substances.

Hemagglutination (HA) and Hemagglutination-inhibition (HI) Tests

The finding by Burnet (1942) and Lush (1943) that NDV, like influenza, agglutinated the red blood cells of chicks and that such hemagglutination was specifically inhibited or neutralized by ND immune serum provided a simple and useful diagnostic method. The test for HA may serve as a rapid method for detecting NDV in the fluids or extracts of infected tissues of fowl as well as in the fluids of infected eggs (McClurkin et al., 1954). Monti (1952), Mitscherlich and Gürtürk (1952), Clark et al. (1955, 1957), Gardner et al. (1954), and Geurden and Devos (1955) demonstrated HI activity in the sera of ND infected chickens by adding NDV-treated chicken erythrocytes as a means of early and rapid diagnosis. The latter state that the serum-sensitized erythrocytes may be lyophilized and stored indefinitely for use. Hanson et al. (1947) showed that minimal NDV titers, at least of 10^6, are required if the infected allantoic or amniotic fluids are to induce hemagglutination. Bronchitis and laryngotracheitis viruses, while infective for the chicken embryo, do not cause hemagglutination, thus providing a means of differentiation from the HA-positive NDV (Brandly et al., 1946b).

As with the test for neutralization of NDV infectivity by specific immune serum, the test for inhibition or neutralization of the hemagglutinative activity of the virus (HI) gives quantitative as well as qualitative information. In the alpha procedure,

the virus suspension in serial twofold dilutions beginning with 1:5 is mixed with equal volumes of the serum under test and a 0.5 per cent suspension of chicken red cells. In the beta procedure, the serum is serially diluted and admixed with the red cell suspension and a constant quantity, e.g., 10 HA units of the virus (Brandly et al., 1947). The test, with adequate control tubes, is incubated at room temperature for 30 minutes and the results read on the basis of the degree or titer of HI. Typical, complete HA (+ + + +) is represented by a continuous layer of cells covering the entire rounded bottom of the tube; a thicker layer, irregular in outline, covering a portion of the bottom is a partial or + + + reaction; a small central disc with a narrow granular fringe of agglutinated cells, a + + reaction; and a larger button, or disc, of cells with a narrow ring of agglutinated cells is classed as a + reaction. Complete inhibition of the HA reaction, like the normal unimpaired settling of cells as in the control tubes, leaves a central compact button with regular edges. The highest dilution of virus giving a + + or higher reaction represents the titer of the virus, and the quantity of virus involved is considered a unit. Elution of virus from the cells and their subsequent release from the agglutinated layer causes a cascading or sliding of the cells to the bottom of tube and the formation of a disc, or button, as occurs when erythrocytes sediment normally. Rapid serum and whole blood HI tests have been devised and used with satisfactory results (Luginbuhl and Jungherr, 1949; Zargar and Pomeroy, 1949; Walker, 1952; and others).

The variables, both quantitative and qualitative, inherent to the HI test prompted efforts toward standardization (Report of Poultry Disease Subcommittee, 1963).

The HI test, although somewhat simpler and less protracted than the VN test, is usually considered less reliable than the latter. Neither the antibody nor the mechanism of reaction is the same in the HI and VN test as indicated by the sub-

stantially longer persistence of the VN principle or antibody and results of serum fractionation studies (Brandly *et al.,* 1947; Hanson *et al.,* 1950). An HI titer value of 10, according to the beta procedure, has been considered as of questionable diagnostic significance, one of 20 or higher definitely indicating prior infection of the bird. On the basis of their studies, Doll *et al.* (1950b) concluded that the HI response may differ according to strain of virus in time of development, titer, persistence, and with respect to route of infection and other factors. After several routes of infection, the HI titer rose to 10 or 20 in 5 to 6 days, indicating that complete inhibition at these titers was of diagnostic value. More than 90 per cent of the experimentally exposed chickens showed positive titers at the tenth day and were positive on the twelfth day. Direct and indirect complement-fixation tests have been utilized and found highly specific for serologic diagnosis of ND (Boulanger and Rice, 1953; Nitzschke, 1954; Brumfield and Pomeroy, 1957). Since specific anti-ND substances are demonstrable only after a period of 7 to 10 days following NDV infection, the use of serologic tests for earliest definitive diagnosis should be supplemented with appropriate HA tests using tissues of suspected birds, or fluids of embryonating eggs or tissue cultures inoculated with them (Valado, 1955; and others).

Immunity Tests of Living Birds

Definitive diagnosis of prior ND infection may be accomplished by inoculating with fully virulent NDV, suitable specimens from flocks suspected of having been infected at least a week previously. Susceptible controls are simultaneously inoculated with the previously titrated challenge virus. Serum samples should be tested prior to inoculation by SN or HI tests.

PREVENTION AND CONTROL

The simplest and most logical measure against Newcastle disease and other infections is to prevent contact of the virus with the susceptible bird or mammal. A second and indirect method, applicable against certain diseases, is vaccination. The latter gives the animal a greater or lesser degree of protection against infection in case of exposure. The third and least satisfactory and least economical procedure is to attempt treatment of the animal after it is exposed to or has become affected.

A combination of sanitary management, to reduce or prevent exposure, and of vaccination is often required to combat highly contagious diseases, such as ND, that have become widely established in a community, region, or country. However, both measures must be systematically carried out on an area, regional, state, or larger basis if control is to be reasonably and permanently effective. A minimum of 70 per cent of the flocks in an area must be included at the outset in the rigid sanitary program, combined with a satisfactory twice-a-year, or oftener, vaccination program.

Restriction of exposure to and spread of ND generally increases in proportion to expansion of the size of the flock, the rearing and maintaining birds of different ages on the premises, and the proximity of the housing units.

General compliance with a rigid sanitary program prevents ND where the poultry population is relatively small and flocks are some distance apart. Vaccination may be required as a supporting measure to sanita-

tion in less concentrated production areas, and if so, it should be employed as a means toward eradication of ND.

Such a goal was projected (Report of the Subcomm. on Plans for Eradication of Newcastle Disease, 1959) but not implemented in the United States where the disease is endemic yet infrequently clinically acute or peracute. A regional program to eliminate NDV has been implemented in Maine (Chute and O'Meara, 1963). Continuous application of the slaughter policy against ND in Great Britain in the face of reintroduction of infection and the prevalence of mild or subclinical infection has fallen short of success while imposing serious financial burdens on breeding and research stock perpetuation (Report of the Committee on Fowl Pest Policy, 1962). Vaccination with inactivated vaccines or with living lentogenic strains of low or limited diffusibility must be considered essential components of eradication programs especially where ND is widespread in an area or country (Osteen et al., 1961; Levine, 1962).

If it is not used properly and wisely, vaccination will engender among poultrymen an entirely disproportionate or false sense of security while constituting an appreciable year-after-year expense.

Natural selection toward development of greater genetic resistance is a consequence when ND becomes enzootic in a poultry population (Knox, 1950; Francis and Kish, 1955; Placidi and Santucci, 1956; Takamatsu et al., 1956; Cole and Hutt, 1961; and others). The practicality of intentional exposure to ND as the basis of a breeding program toward controlling ND has not been demonstrated. Environmental factors, especially higher temperatures, may greatly alter the severity of ND among a given stock (Francis and Kish, 1955; Sinha et al., 1957; and others).

The statistically significant differences in resistance to ND among six families as well as two strains of White Leghorn chickens which support early observations of such variability have been reported by Cole and Hutt (1961). Mortality among 7,000 pullets

following Roakin strain wing web vaccination in successive years was 3.2 and 7.2 per cent in strain K as compared to 0.7 and 0.8 per cent among strain C birds.

Finally, eradication of ND must be a constant goal. Restriction of movement of poultry, day-old chicks, and hatching eggs together with slaughter of infected birds and contacts, as have been practiced in Britain (1936 Fowl Pest Order), have been relied upon to achieve complete eradication (Reid, 1955). The occurrence of mild, largely subclinical forms of the malady, however, complicates the problem of its eventual total suppression.

Prevention by Sanitary Management

Basic specific precautions to exclude ND infection from the poultry operation and to prevent its spread include: For the hatchery—its strict isolation from broiler, dressing, or other poultry operations or plants; complete separation of buildings for brooding "started" chicks; separate labor for work outside of the hatchery; a policy of selling only day-old chicks; weekly inspection and production records on the supply flocks in order to permit exclusion of those showing a significant drop in egg production; exclusion of return of used chick boxes and feed sacks; proper disposal of hatchery wastes; and exclusion of visitors and nonessential personnel from the hatching and brooding areas. For the farm flock—exclusion of visitors, both bird and mammal; proper precautions in changing clothing and disinfecting footwear of the flock owner or caretaker after visiting possible sources of contamination; insisting on the practice of proper clothes-changing and disinfection precautions for blood-testing crews or other essential service personnel; buying replacement stock as day-old chicks from reliable hatcheries, preferably local, to minimize the chances of disease exposure during transit by means other than the personal vehicle of the buyer; rearing of the replacement flock on clean premises entirely apart from the adult flock, or of prior disposition of the

previous year's flock to maintain an all-pullet flock; preventing the return or introduction of used poultry crates, feed sacks, or other equipment, materials, or vehicles; proper manure disposal; proper disposition of dead birds by burning or deep burial; replacement of contaminated or unfit deep litter; and annual, or oftener, routine complete cleaning and disinfecting of the laying and brooder houses and range shelters. For the broiler plant—observation of the strict sanitary precautions already defined and the exclusion of birds from outside sources for slaughter or evisceration. For the produce plant—guarding against the purchase of poultry in the active stages of ND and thus the gross contamination of crates, vehicles, etc., which may carry the infection to birds in feeding stations, on farms, in hatcheries, and in broiler plants; frequent periodic cleaning and disinfection of facilities, equipment, and materials; and proper disposal of offal and wastes. For the feed dealer and processor—avoiding re-use of feed sacks unless properly cleaned and sterilized; practicing and encouraging proper measures to avoid spreading infection to and from farms. For the local veterinarian—disseminating knowledge on basic sanitation and advising the poultrymen on general and specific disease prevention problems; reaching an early diagnosis with prompt laboratory assistance and, if necessary, instituting a proper vaccination service and control program under the various circumstances encountered (Pomeroy and Brandly, 1953).

Experience with the extensive application of triethylene glycol aerosol as a means of controlling spread of ND in a large broiler plant led Ellis et al. (1952) to the conclusion that while the aerosol appeared to reduce the incidence of ND, as estimated by development of HI titers, it did not prevent the spread of benign ND infection or have a significant effect upon the weight of birds at slaughter. The hazards and means of sanitizing used burlap feed bags

contaminated with NDV and other agents have been clarified by Jungherr (1950).

Prevention by Vaccination

As with many viral diseases, experience with ND has stimulated efforts to minimize the shortcomings of both the killed or inactivated vaccines and the living, usually attenuated, vaccines (Beaudette, 1943, 1949, 1950, 1951; Beach, 1942, 1947; Traub, 1943–44; Brandly et al., 1946c; Hanson et al., 1951; Osteen et al., 1961; Jungherr and Markham, 1962; Lancaster, 1964; and others).

The necessity of more critical and satisfactory standards for commercial ND vaccines has prompted research and organization toward establishment of adequate criteria by various groups and agencies, especially in the U.S.A. (Technical Committee on Newcastle Disease of the North Central Region, Report of the Subcommittee on Vaccine Evaluation, 1951; Interregional Subcommittee on Vaccine Evaluation of the Advisory Committee on ND and Other Respiratory Diseases of Poultry —Johnson et al., 1954; Report Poultry Disease Subcommittee, 1959 and 1963). Major objectives have been provision of vaccine strains of maximal antigenicity and potency of suitably pathogenic challenge strains for assessment of immunity to various routes of exposure as well as of proper criteria for test birds and time of challenge for immunity after vaccination.

Tests applicable to identification and safety of vaccine strains of ND have been devised (Hanson and Brandly, 1955; Hanson, 1956; Lancaster, 1964). The need for rigid requirements of ND vaccine purity, especially with living virus vaccines, is emphasized by the demonstration of NDV in some lots of commercial pox and laryngotracheitis vaccines (Zargar and Pomeroy, 1950; Hofstad, 1949; and others) and of the possibility of vaccine contamination with lymphomatosis via the eggs of carrier hens used for ND vaccine production (Burmester et al., 1956).

Both types of Newcastle disease vaccines.

the inactivated virus and living virus, are now in general use. If properly prepared, handled, and administered, they may be expected to stimulate a substantial degree of immunity in a large proportion of healthy vaccinated fowl. However, even the more pathogenic living NDV vaccines fail to engender permanent or life-long protection in healthy, immunologically mature chickens against clinical or subclinical infection. At hatching, immunologic capacity is weak but strengthens substantially so as to equal that of the mature bird at about 6 weeks of age (Wolfe and Dilks, 1948). However, vaccination at an early age is frequently necessary where ND is enzootic (Ellis and Crook, 1952). Present knowledge regarding preparation, use, merits, and limitations of the two types may be summarized as follows:

Inactivated, or killed, Newcastle disease virus vaccines are prepared by growing suitably antigenic strains of virus in embryonating eggs, harvesting the dead or dying embryos and tissues, and inactivating the virus, usually by chemical agents, e.g., formaldehyde, crystal violet, beta-propriolactone. Growth of virus in tissue cultures for vaccine production is also being practiced. Adjuvants such as alumina gel are added to increase and prolong the immunizing effect. The vaccines must be tested for safety and potency and be given a "use expiration" date before release.

Each dose of the vaccine contains a relatively large quantity of killed virus, the normal reaction to which governs directly the degree and duration of the immunity which the bird can develop.

Inactivated Newcastle disease vaccine affords some protection by a blocking, or "interference," effect within several days to a week after injection. Specific immunity against Newcastle disease develops within a week after vaccination; it is well advanced after two weeks in healthy birds 10 days of age or older when vaccinated. All individuals in a flock may not develop a substantial immunity and the immunity may wane considerably 2 to 6 months after

vaccination. The degree to which protection is enhanced by revaccination depends upon the residual immunity, either active or passive, which is present at the time of revaccination. Critical work (Hofstad, 1953, 1954, 1955) has demonstrated that a minimal period of 9 weeks is required between initial vaccination and revaccination with killed vaccine if a maximal degree and duration of immunity to the "booster" dose is to be stimulated. Satisfactory reinforcement of immunity with living virus vaccine has been reported with intervals as short as 1 to 3 weeks (Geurden et al., 1950; Zuijdam, 1953; Lancaster, 1964).

The titer and persistence of immunity evoked by inactivated vaccines is usually less than that by the living vaccines, yet only the former may be relied upon to prevent undesirable effects of vaccination in laying flocks, in stock suffering from other diseases or devitalizing factors, and in baby chicks (Brandly, 1953; Van Roekel, 1955; Lancaster, 1964; Bankowski and Hill, 1954; Bankowski, 1961b; Gross, 1961; and others).

Living Newcastle disease virus vaccines. These are usually prepared by growing, in embryonating eggs, modified, or "weakened," strains of Newcastle disease virus (Komarov and Goldsmit, 1946; Brandly et al., 1946c; Van Roekel et al., 1948; Beaudette et al., 1949b; Clancy et al., 1949; Hitchner et al., 1950; Lancaster, 1964). Virus tissue cultures have also served as a source of ND vaccine (Bankowski and Boynton, 1948; Bankowski, 1950). Cultures of mammalian cells as a substitute for those of chicken origin are suggested in order to avoid contamination with chicken latent or orphan agents (Bankowski, 1957). Great care is required to keep the vaccine virus strain at a satisfactory stage of modification and to avoid contamination with other viruses and with bacteria. Usually the infected embryo material is dried to powder from the frozen state. Further refrigeration before it is used in reconstituted liquid or in dust form and proper care dur-

ing its use are required to keep the vaccine virus alive and capable of producing satisfactory results.

The living Newcastle disease vaccines now available from commercial sources are administered by different routes, including the "stick" or wing web puncture, intramuscular injection, "drop" intranasal or conjunctival sac installation, and by spraying or nebulizing as well as dusting for inhalation. Mechanical spraying of liquid vaccine and dispersion of micronized dry virus vaccine, as well as adding the virus to the drinking water, were designed to permit vaccination exposure and infection of entire lots or flocks, i.e., mass vaccination, thus saving the time and labor required for individual administration of the vaccine. The trend toward the mass method of vaccination, i.e., aerosol, dust or drinking water administration is indicated by the fact that about 91 per cent of the Newcastle disease either alone or combined with bronchitis vaccine produced in licensed establishments during the year ending June 30, 1964, was of this type (Agricultural Research Service, 1964). The saving of time, labor, and vaccine cost by mass vaccination is not without sacrifice in uniform and often stronger immunity resulting from vaccination of each bird of the flock (Lancaster, 1964).

Obvious disadvantages are lack of uniformity in dosage and particle size, particularly with very young and devitalized birds (underexposure and overexposure); great variation in environment (variable humidity and temperatures, foreign substances as well as viricidal factors in air and water); and likely exposure of persons and dissemination via air to other fowl and mammals (Bankowski and Hill, 1954; Markham et al., 1955, 1957; Van Waveren and Zuijdam, 1955; Johnson and Gross, 1952; Hitchner and Reising, 1953; Ceccarelli, 1954; Winterfield and Seadale, 1956; Larose and Van Roekel, 1959; Dardiri et al., 1962; Lancaster, 1964).

The NDV strains employed in living vaccines are of reduced or modified patho-

genicity. The least pathogenic (lentogenic) strains, e.g., B_1, La Sota, and F strains, are examples of those employed in birds of all ages for intranasal or intraocular instillation, admixture with the drinking water or dusting and spraying (Hanson and Brandly, 1955). The moderately pathogenic (mesogenic) strains, e.g., Roakin, MK 107 (L), Mukteswar, H (Hertfordshire), Haifa (Komarov), have been commonly used for wing web (intradermal) or intramuscular, or occasionally via feather follicle, vaccination of stock older than 4 weeks of nonlaying birds, and other disease-free, vigorous stock (Hanson and Brandly, 1955).

The quantity of virus introduced as living vaccine is so small that unless infection is established and multiplication ensues to a moderate degree, enough virus is not present to stimulate a satisfactory degree of immunity. The specific immunity engendered by living vaccine infection should appear within 5 to 7 days after vaccination and should be of substantial degree after the second week. The duration of immunity from living vaccine may vary greatly from flock to flock and among individuals. It may wane appreciably within 2 months, and proper revaccination is usually recommended within 2 months to a year (Doll et al., 1950c; Lancaster, 1964). However, revaccination of laying hens with mesogenic Roakin virus, within 1 to 2 weeks after initial vaccination with a killed vaccine, has been recommended (Zuijdam, 1953), and with the mesogenic Hertfordshire strain after 2 to 3 weeks (Geurden et al., 1950). One cannot, however, overlook the evidence that residual antibody, passively acquired (Brandly et al., 1946d) or resulting from vaccine or from natural infection, may impair the response to vaccination and revaccination even though less by respiratory than hypodermic or skin puncture introduction (Levine and Fabricant, 1950; Doll et al., 1950b, 1951; Markham et al., 1954; Winterfield and Seadale, 1957a; Bankowski et al., 1958; Keeble et al., 1963; Lancaster et al., 1960). Neverthe-

less, protective antibody concentration following vaccination or infection diminishes or is first lost by the epithelial lining of the respiratory tract and, hence, permits a "take" to inhalation revaccination earlier and more readily than by the deeper tissues which are in contact with higher antibody concentrations of the serum and tissue fluids. The dimensions of revaccination infection, reaction, and immunity "booster" effect are, therefore, directly dependent on the degree of antibody titer and tissue refractivity of the individual bird with proportional limitation of the degree and extent of the reinfection. Immunity of the respiratory epithelium to challenge infection does not become absolute in spite of excess dosages and repeated vaccination (Bankowski and Hill, 1954).

Adequate and reliable information on the maximal and average duration of a serviceable immunity to ND resulting from a single or repeated vaccination is limited (Lancaster, 1964). Age and individual immunologic capacity, as well as environmental and other factors affecting the host animal, all mitigate against uniformity of its immunity response to vaccination, especially under the great variations prevailing in the field. Inapparent infection from repeated exposure can be ascertained with reasonable but not unequivocal accuracy by testing for antibody titer before, and at intervals after, challenge. That failure to induce a lasting immunity is not characteristic of the less pathogenic strains of virus was illustrated with the use of a mesogenic Indian (Mukteswar) vaccine (Barnstein et al., 1949). These workers concluded in consequence of ND "breaks" following vaccination that the immunity engendered by it could not be depended upon for longer than a year. It is, however, necessary to differentiate between breaks due to antigenic inadequacy of the vaccine and those associated with improper handling and use of the vaccine (Jungherr and Markham, 1962; and others).

After initial live virus vaccination, the flock must be considered infected and capable of spreading the virus by excreta or eggs for three weeks or longer (Zuijdam, 1953); after re-exposure some birds may excrete virus for periods of three weeks (Markham et al., 1955). The possibilities that the vaccine virus may regain full activity and destructiveness are not great but cannot be entirely overlooked. ND vaccine virus used among six- to eight-week-old turkeys, without adverse effect, did spread and caused marked involvement as well as moderate mortality among two- to three-week-old poults on the same farm (Brandly et al., 1949).

Simultaneous vaccination against Newcastle disease and bronchitis or Newcastle disease and fowl pox has been further exploited toward saving labor and handling of birds. However, pox vaccination, either with chicken or pigeon source virus, requires manipulating the individual birds. Although a mixture of pigeon pox and ND viruses has been applied by the feather follicle method (Richter, 1956), an individual or mass method of ND vaccination may be applied immediately afterward to the birds comprising the group or flock.

The saving in time and expense of simultaneous vaccination invites the risk of interference with development of maximal immunity against one of the diseases (Hanson et al., 1956) or of exalting one of the agents (Hanson, 1957; and others). Also, there are various reports of the activation or aggravation of latent infections or parasitic effects and other devitalizing influences (Markham et al., 1957; Placidi, 1956; Russell, 1956).

It may not be expected that one kind or type of vaccine applied by a certain route or method will be adequate and satisfactory for all ages of birds and for various needs and circumstances. Factual, unbiased information free of commercial expediency together with judicious professional guidance are essential in the interests of the entire poultry industry.

Obviously the indiscriminate, careless,

nd improper use of vaccines will result in difficulty, confusion, and loss. Only when vaccination is practiced as an adjunct to a long-range sanitation and regulatory program, with eventual eradication of ND as the goal, can the control program progress effectively (Reid, 1955).

Ornithosis

In his thesis written in 1895, "De la psit-tacose ou infection spéciale déterminée par des perruches," Antonin Morange intro-duced the term "psittacosis" for a clinically defined disease of man arising from associ-ation with parrots, and, because of its ap-propriateness to what was then known of the infection, this term found wide usage. Much later, as it was learned that a great variety of birds, including poultry, can be affected, the more descriptive, more general term "ornithosis" was introduced (Meyer, 1942). Psittacosis is the term used for a generalized infection man contracts from birds and for the infections caused by the same agent in psittacine birds. Ornithosis, regarded as an equivalent term in the sixth revision of the *International List of Dis-eases and Causes of Death* and as a syno-nym in the eighth edition of *Control of Communicable Diseases of Man* (Official Report Am. Pub. Health Assn., 1955), is re-served for the infection in extrapsittacine birds. The known history of the infection

clarifies how the term psittacosis estab-lished itself. The imprint of the pandemic of the early 1930's, before the advent of the antimicrobial drugs, has not faded. But preoccupation with the psittacine aspects too long limited the pursuit of the infective agent, not only in wild and domesticated birds, but also in mammals, where its parasitism is being increasingly recognized.

Acute ornithosis is at times a severe dis-ease of pigeons, ducks, and turkeys. This true zoo-anthroponosis has been the source of single or extensive group infections throughout all occupational groups that come into contact with infected fowl. The host range is wide and cosmopolitan, and the steadily increasing number and kinds of avian hosts have altered the concepts on the infection chains. The importance of sources of human psittacosis other than cage pets became more apparent than ever during the 1950's. At the same time, growth of the pet bird trade after World War II increased the incidence of human

[675]

psittacosis from that source. As an occupational disease among pigeon breeders, poultry farmers, and poultry processing plant employees, it has created new problems. Fortunately the mortality rate has been lowered by use of the wide-spectrum antimicrobial drugs.

HISTORY

The little-known history of ornithosis in poultry has been recorded only since 1930, and the few existing fragments described, mainly by workers interested not in poultry but in the organism or the infection in man, must be pieced together. The result cannot be considered a true picture of the progress of the disease in either poultry or man.

By the time of the 1929 and 1930 epidemics of psittacosis due to contact with cage birds, methods of studying microorganisms had been improved, and as experimental hosts were sought and means of transmission and sources of infection were studied, some investigators (Bedson and Western, 1930; Dahmen and Hamet, 1930; Krumwiede et al., 1930; Levinthal, 1930; Meyer, 1935) used chickens in their experimental work on the psittacosis agent. In one experiment, Bedson and Western (1930) attempted infection of pigeons but failed.

That pigeons are infectable was first learned through a natural infection in Johannesburg in March, 1939, when a pigeon fancier sent 2 birds to the Onderstepoort Laboratories, Department of Agriculture, Union of South Africa, because he was losing a few birds from his flock of 200 to 300 (Coles, 1940). Naturally acquired infections were soon reported in racing and carrier pigeons in California, and there was good circumstantial evidence of 2 human infections acquired from a sick feral pigeon in New York City (Meyer, 1941; Meyer et al., 1942a). The bulk of subsequent reports on human psittacosis arising from contact with pigeons has been concerned with racing and fancy pigeons rather than poultry pigeons, but there is serologic evidence that squab raisers do contract it and that it is an infection of poultry pigeons in the United States. The first known infection was contracted through contact with racing pigeons in California (Meyer et al., 1942a). The isolate from the lung of the patient was indistinguishable from that from the organs of pigeons to which the victim was exposed for only a short time.

Inevitably a natural infection in poultry was identified, in 1939, after serodiagnosis of psittacosis was made in a case of atypical pneumonia in New Jersey (Meyer and Eddie, 1942). The patient had tended a flock of 700 White Leghorn chickens and had dressed birds from the flock. The serum of 3 other members of the family also reacted in the complement fixation test. The agent was isolated from 1 of 3 chickens tested at the Hooper Foundation—the first isolation from a naturally infected fowl. This may have been an instance of epizootic ornithosis, but the death of 500 birds from "range paralysis" and of over 100 additional birds, an unusually high mortality for ornithosis in poultry, especially chickens, makes it seem probable that some other infection was also active in the flock at the time.

Serologic evidence of naturally acquired ornithosis in ducks and turkeys was provided by a survey of these fowl in Michigan in 1942 (Eddie and Francis, 1942). Within 3 years human infections due to contact with ducks were found in California (Meyer and Eddie, 1952) and in New York (Wolins, 1948; Korns, 1955). The Long Island outbreak is interesting in several respects. It is the first poultry outbreak in which an extensive epidemiologic and serologic investigation was made. These revealed a higher incidence of clinical and subclinical infections in duck handlers, hence the first proof of the occupational importance of the disease in poultry workers. It showed that the situation with respect to poultry is similar in some ways to that of cage birds—that infection of man may result from only brief contact and that many subclinical infections take place. Isolates from wild birds (feral pigeons and sea

gulls) were also found in the course of the study. The agent was isolated from sick and well ducks, and the incidence of positive seroreactors was high (40.2 per cent). The disease in the ducks was not of primary concern here, and reports do not describe this in any detail. There were sick ducks and there were concurrent *Salmonella typhimurium*, *Pasturella multocida*, *Pfeifferella anatipestifer*, and other infections.

Extensive research initiated in 1952 resulted in isolation of *Bedsoniae* from patients, ducks, geese, and sea gulls, and learning that young ducks were a main source of infection in Bohemia, Moravia, and Silesia. The highest incidence in man was in the age group of 40 to 60 years. The infection was not always present, but fatal cases and reinfections were observed (Strauss, 1957). Uncontrolled transfer of poultry between Bohemia and Slovakia or of ducks from Hungary to East Slovakia resulted in epizootics on duck farms. There were serious economic losses (an estimated mortality of 10,000 duck embryos and 30,000 hatched ducklings), clinical psittacosis of 10 employees and serologic evidence of infection in 24 of 213 workers on other farms. Annual ornithosis epizootics have become a serious health problem (Strauss *et al.*, 1960). Ornithosis in ducks followed by human causes has been reported from Austria (Fürst *et al.*, 1957), Poland (Parnas *et al.*, 1960) and Roumania (Sarateanu *et al.*, 1960).

In 1958 German medical and later veterinary publications began to call attention to the increasing number of ornithosis outbreaks in poultry processing plants and in breeding and fattening farms in the German Democratic Republic. Between 1958 and 1960, 783 human infections were attributed to contact with ducks, chickens, geese, pigeons, or poultry in general (Ortel, 1960, 1961, 1963). The clinical disease described in several excellent articles (Voight *et al.*, 1962; Siegmund, 1960; Reinwein and Walther, 1961; Kukowka, 1961c; Otto, 1962; Gneuss and Koitzsch, 1961) can be conclusively diagnosed as ornithosis only

by isolation or serologic tests. In the outbreak in Halle, sputum and throat washings yielded a bedsonia in 10 patients (Ortel, 1960). One third of 71 sick or dead ducks and ducklings from a breeding and fattening farm in northeast Germany harbored bedsonia (Illner, 1962b). In serologic screening of 70 flocks, 1,428 ducks were examined in the direct complement fixation test: 233 from 35 flocks were considered positive, 5 flocks suspicious, and 30 uninfected (Lehnert and Hille, 1960).

The first report that ornithosis can infect the turkey was fairly recent (Irons *et al.*, 1951, 1955), and in subsequent outbreaks many isolates from turkeys and from human beings have been of unusual virulence for the indicator host, the mouse. In several outbreaks the mortality rate in the flocks has been much higher than that formerly noticed in poultry (Osgood *et al.*, 1956; Francis, 1960). On the other hand, in other flocks without unusual illness but with gross fesions of ornithosis, as high as 13.8 per cent have been condemned by inspectors at the time of slaughter and have caused human outbreaks (Rich *et al.*, 1962).

An important observation was made in 1954 in California (Meyer and Eddie, 1956b; Meyer, 1959b; Page, 1959c, 1960): *bedsoniae of low pathogenicity for mice and guinea pigs produced gross visceral lesions, but rarely illness or deaths in turkeys.* Isolates of similar low pathogenicity have been encountered in tissues of other flocks in California (Page, 1960), in Michigan (Meyer, 1959b), in Minnesota (Pomeroy *et al.*, 1957; Graber and Pomeroy, 1958; Graber, 1959; Gale, 1960) and recently in Oregon on a ranch where a highly virulent bedsonia had caused severe ornithosis since 1956 (Meyer and Eddie, 1962b). The first California observation was of particular interest to the epidemiologist: 88 employees of a poultry plant were exposed during processing of 2 different batches of turkeys at two different times; 37 to 83 per cent of the turkeys were seropositive. *None became ill and only 3 showed serologic evidence of experience with bedsonia, even though during one processing 900 pounds*

of visibly diseased viscera were condemned.

Originally it was reasoned that the low pathogenicity of the isolate from the epizootic was responsible for the absence of human infection, but the large reservoir of ornithosis in domestic turkeys in Wisconsin and Minnesota, proved by serologic tests to exceed 40 per cent of the tested flocks, caused clinical and subclinical human ornithosis of sporadic nature in 1956 to 1960 (Graber and Pomeroy, 1958; Graber, 1959). From 16 to 29 per cent of the over 200 poultry workers examined reacted in the complement fixation test in dilutions of 1:8 and above. According to serologic screening surveys, bedsonia isolates of low pathogenicity for mice are widely spread in the turkey population of the United States. Recently ornithosis in one turkey has been reported from Great Britain (Grattan, 1963). They are quite similar to the isolates from pigeons, ducks, and even some psittacine birds. How and why they become highly toxic and pathogenic for mammals including man cannot be answered because the history of ornithosis as a disease of poultry is largely unknown.

Major changes in poultry-raising practices in this country could change the importance of infectious diseases of poultry in general. Individual owners of small flocks have probably accepted minor losses, some in all probability due to mild epizootics of ornithosis, but when poultry birds are raised in large groups, under some circumstances affording much better opportunities for intraflock spread, the economics of the infection also changes. The new outbreaks in the costly turkey, with a mortality rate that can no longer be ignored, a higher concentration of the cost of the infection to a single flock owner, and the occurrence of clinical infections in heavily exposed processing plant workers warn that the position of this infection may be undergoing a change. Recently the turkey in the United States and the duck in eastern Europe have come into as much prominence as a source of infection in man as cage pets had in former years.

Infections have been found in domestic pheasants (Ward and Birge, 1952; Meyer and Eddie, 1956b) and geese (Strauss, 1956; Fürst et al., 1957), but not yet in the guinea fowl. Among wild birds used for food, the fulmar (Haagen and Mauer, 1938) and the muttonbird (Mykytowycz et al., 1955) bear mention. There are no known instances of transmission of the virus through ingestion of poultry.

There have been single cases and outbreaks in human beings (5,390 cases, 89 deaths) due to poultry and other food birds (Table 23.1). There are several reports in which ornithosis is considered primarily as a poultry disease, in pigeons (Hughes, 1947) and in turkeys (Pate et al., 1954; Davis, 1955; Davis and Delaplane, 1955; Davis et al., 1957a, b; Pomeroy et al., 1957), but its history as a disease of poultry is largely unknown.

Occasionally an astute physician encounters a case of pneumonia in which the clinical picture deviates enough from the pneumococcal pneumonias to arouse his suspicions so that he must look for the cause elsewhere. The patient's history leads to poultry. In most cases the patient recovers and no further inquiry is made. Under exceptional circumstances the matter has been pursued further, and something is learned about the infection in the responsible flock, but mainly in relation to the human infection, not as a subject in itself. Almost never is the epidemiologic investigation carried beyond identification of the source of a human infection. Some groups particularly interested in ornithosis have made small surveys in a limited area usually in only one season when there have been human infections, and they have found the bedsonia or serologic evidence in poultry flocks. Published reports again and again describe evidence of the infection in poultry and in people who come into contact with poultry at any point on its way to market, but this information usually comes after the flock has already been marketed and all useful material for study has been destroyed. It is obviously then already too late for a careful study of the course of the

disease in the flock. Since the people now concerned in preparation of poultry for the market constitute an occupational group, the infection is becoming the subject of wider interest again, and again it is the spread to man that is the stimulus.

Its position as a poultry disease has simply never been defined, probably at least partly because the mortality rate in the flocks, as far as is known, has usually been relatively low. Since writers on this subject have been mainly physicians, epidemiologists and public health workers, and only recently veterinarians, the interests of these groups are reflected, and its course in the responsible poultry is almost never dealt with at all beyond mention of sick birds.

In the 1959 edition of this book, based on statistics for the period 1931 to 1956 maintained by the George Williams Hooper Foundation and published reports, the incidence of human psittacosis in 19 countries attributed to contact with pigeons, turkeys, ducks, chickens, and seashore birds had been tabulated. Bringing these data up to 1963, the following conclusions are suggested: (a) With the exception of the United States, sporadic cases attributed to exposure to pigeons are rarely reported or described. (b) The records rarely make a sharp distinction between clinical or merely serologically recognized cases. Therefore, the figures include all the reported cases. (c) Statistics for 9 additional countries have been added. (d) The marked increase in occupational infection in the duck raising and processing industries of Czechoslovakia, East Germany, and Hungary and in the turkey industry of North America due to epizootics of ornithosis in the poultry flock has increased the total number of human psittacosis cases attributable to poultry to 5,390 with 89 deaths (Table 23.1). The absence of statistics cannot be accepted as proof that human psittacosis does not exist in countries not included in the tabulation. What is more important, however, is the likely inadequacy of the tabulation for other reasons: In view of the wide host range of the many species

of bedsoniae of proven infectivity for mammals in the vicinity of man, it is reasonable to suspect that infections must occur more frequently, but they are not recognized except under special circumstances.

Search for the cause of atypical pneumonia in the U.S.A. and Europe indicated that in from 5 to 16 per cent the serologic evidence was in keeping with a diagnosis of psittacosis (Smadel, 1943; Eaton, 1945; Westwood, 1953; Lepine and Sautter, 1951; Jansson, 1960, and others). It is not known precisely how many cases of the pneumonitis originated from feral pigeons. According to large serological surveys to measure the incidence and distribution of psittacosis within (a) social, urban, and rural groups and (b) certain occupational groups, more people had been infected with bedsoniae than is indicated in Table 23.1. The reaction rate of one group of poultry plant workers in Connecticut exposed for several years was 24 per cent (Rindge et al., 1959); it reached 68 to 75 per cent in poultry processors in Texas and Oregon (Osgood et al., 1956). Valuable data collected in Czechoslovakia by Serý and his associates (1961) and Strauss and Serý (1964) are even more informative since only complement fixation titers higher than 1:32 on one serum specimen were considered indicative of past or present psittacosis. The average percentage of reactors in healthy persons living in rural areas was 15 per cent, but in 213 employees on poultry farms it rose to 22.5 per cent, and to 74 per cent in those who had worked from 3 months to 5 years in the contaminated environment. It may be mere coincidence but 52 per cent of 63 keepers of pigeons in Czechoslovakia corresponds with the 35 per cent of 169 pigeon breeders in Germany (Mohr, 1954; Siegmund, 1960; Wohlrab, 1955). Similar findings of high (39-50 per cent) incidences in occupational groups have been reported from Germany and Roumania (Sarateanu et al., 1961). Regional as yet unexplained differences, e.g., only 5 per cent reactors in 1,527 poultry plant workers in Poland reacted in dilutions of 1:8 and above, have been pub-

of visibly diseased viscera were condemned.

Originally it was reasoned that the low pathogenicity of the isolate from the epizootic was responsible for the absence of human infection, but the large reservoir of ornithosis in domestic turkeys in Wisconsin and Minnesota, proved by serofogic tests to exceed 40 per cent of the tested flocks, caused clinical and subclinical human ornithosis of sporadic nature in 1956 to 1960 (Graber and Pomeroy, 1958; Graber, 1959). From 16 to 29 per cent of the over 200 poultry workers examined reacted in the complement fixation test in dilutions of 1:8 and above. According to serologic screening surveys, bedsonia isolates of low pathogenicity for mice are widely spread in the turkey population of the United States. Recently ornithosis in one turkey has been reported from Great Britain (Grattan, 1963). They are quite similar to the isolates from pigeons, ducks, and even some psittacine birds. How and why they become highly toxic and pathogenic for mammals including man cannot be answered because the history of ornithosis as a disease of poultry is largely unknown.

[680]

plying bedsonia in the cytoplasm of a mammalian host cell.

These microscopic studies were made possible through the early discovery by Krumwiede that the agent can be transmitted and readily perpetuated in white mice.

Working with a strain of psittacosis agent well adapted to the mouse, killing them regularly in 48 hours, they studied the parasite in the spleen. About 10 hours after infection there were only large forms; at the time of the animal's death the forms were all coccal elementary bodies. There was a definite sequence of changes. When the infection had proceeded half way to death of the mouse, the infected cells showed clusters of particles of all sizes—large, intermediate, and small (elementary bodies). Some of the large forms appeared to be dividing. These observations convinced Bedson and Bland (1934) and Bland and Canti (1935) that the psittacosis agent passes through certain developmental forms and multiplies by binary fission. Burnet and Rountree (1935) and Lazarus and Meyer (1939) studying the cycle in the cells of developing chicken eggs and Yanamura and Meyer (1941) using chicken embryo cells in tissue cultures as host cells observed similar forms and sequences.

The discovery that the mouse is susceptible experimentally to the filterable infective agent of lymphogranuloma venereum (Hellerström and Wassen, 1930) led Miyagawa and his colleagues (Miyagawa et al, 1935) to demonstrate that the agent could be stained and that in size and staining reactions it closely resembles the psittacosis agent. The full extent of the resemblance was proven by Findlay and his colleagues (1938) and Rake and Jones (1942) when they showed that the lymphogranuloma venereum agent goes through a growth cycle similar in all respects to that described by Bedson and Bland (1932). Later other related agents were studied—ornithosis (Meyer and Eddie, 1942), mouse pneumonitis (Karr, 1943), feline pneumonitis (Hamre et al., 1947), and enzootic abortion of ewes (Stamp, 1951), and their cycles were similar. These studies established the common character of what became known as the psittacosis-ornithosis-lymphogranuloma, or psittacosis-ornithosis-mammalian pneumonitis (P.O.M.P.) agents (Terzin, 1958).

Of the studies that followed this period, those of Weiss (1955) deserve mention: Bland and Canti had placed the developmental cycle intracellularly, but Weiss, like Loosli and Ritter (1948), presented evidence of extracellular growth in the alveolus of mouse lungs infected with the murine pneumonitis agent.

Various aspects of the growth cycle were the subject of study, and numerous observations suggested that the psittacosis agent behaves like a true virus. It has a latent phase in its developmental cycle and changes from an infectious to a noninfectious form (Girardi et al., 1952). A restudy of the kinetic of a psittacosis infection in mice by Bedson and Gostling (1954) confirmed the observations by Heinmets and Golub (1948): the elementary bodies rapidly attach to the host cell surface and then penetrate it. Evidently during the ensuing resting phase, analogous to the lag phase during bacterial growth, the fully infectious units acquire the energy potential to multiply rapidly. When the host cell wall is finally burst, new infective units are released into the extracellular environment.

With the advent of the electron microscope and the ultramicrotome, Swain (1955), Gaylord (1954), Officer and Brown (1960), and Tajima et al. (1957) re-examined the forms developing during the growth cycles. Finally Litwin (1959, 1962) and Litwin and his associates (1961) recognized, documented, and described a simple and coherent sequence of events in the growth cycle of this group (Fig. 23.1).

Growth and Morphology

The course of the bedsonia parasitism of cells of the chorio-allantoic ectoderm or Chang's human liver cells infected with these agents is as follows:

Infection of a susceptible cell is initiated

lished (Parnas *et al.*, 1960 and 1961). In Hungary, the course of investigations of 3 outbreaks of psittacosis in poultry processing plants disclosed the following serological attack rates: outbreak I, 96 of 446 employees (21.5 per cent); II, 79 of 453 employees (17.4 per cent) and III, 30 of 852 employees (3.6 per cent). A screening test carried out on 334 employees of one plant (I) in the fourth week of the outbreak showed that 183 or 55 per cent proved negative while 151 reacted in dilutions of 1:4 to greater than 1:128; in fact, 42 or 12 per cent had CF titers greater than 1:52 (Solt *et al.*, 1962/63). Of 260 workers of poultry breeding and processing plants near Moscow, 56 or 21 per cent reacted in the CF test while 80 or 30 per cent gave positive skin tests (Il'inskii and Dareva, 1963). Another survey on 451 workers in the Sverdlovsk region in the U.S.S.R. gives similar figures with regard to the reactors; while 76 or 17 per cent were considered reactors in the CF test, 136 or 29 per cent gave allergic skin tests (Kortev and Fedorova, 1963).

In summary, the surveys briefly considered confirm the view repeatedly advanced that the reported cases of human psittacosis represent only a small percentage of the actual number of clinically mild, even inapparent, infections seen in occupations which bring man into contact with pigeons, ducks, geese, turkeys, or poultry in general in the order mentioned. Permeation of bedsonia infections on breeding farms and in processing plants may lead to subclinical attack rates of as high as 45 per cent of the employees. These facts must be taken into consideration while accepting and using the statistics presented in Table 23.1. Last of all, it is well to remember that psittacine birds continue to be responsible for sporadic and, occasionally, occupational group and family infections.

ETIOLOGY AND PARASITOLOGY

Ornithosis and psittacosis are caused by intracellular, biologically distinct parasites. These share the following characteristics:

1. They stain readily with basophilic dyes.
2. They are antigenically related according to complement fixation, immunity, and toxin neutralization tests.
3. They grow well in the yolk sac of embryonated eggs.
4. They produce, with few exceptions, pneumonitis in the laboratory mouse when introduced by the intranasal route.
5. They are susceptible to the action of certain antimicrobial drugs, particularly tetracycline.

The original studies of Bedson and Western (1930), Levinthal (1930), Krumwiede *et al.* (1930), and Sacquépée and Ferrabouc (1930) showed that their isolates from infected parrots had the following principal characters of a virus according to the views prevailing at that time:

1. Inability to multiply on the nonliving media used for bacteria and filterability through the coarser grade of Berkefeld and Chamberland filters. Filtrates of splenic and hepatic emulsions that are sterile on media used for bacteria reproduced the disease in healthy birds (parakeets and parrots).
2. Several of the first accounts made reference to very small coccal bodies resembling microorganisms which when stained with Giemsa could be seen in smears of virulent material obtained from naturally occurring human or avian cases or from experimentally infected animals by means of the ordinary microscope using white light. These bodies resembled rickettsia in their microscopic appearance. The virulence of the test material was correlated with their presence, and they were held back only by the less coarse bacterial filters. Early in psittacosis research these bodies were referred to as Levinthal-Coles-Lillie (L.C.L.) bodies.

It is to the lasting credit of Bedson (1932), Bedson and Bland (1932), and Bland and Canti (1935) that they demonstrated, through painstaking microscopic studies, that the L.C.L. bodies were pleomorphic, a constant feature of the *multi-*

plying bedsonia in the cytoplasm of a mammalian host cell.

These microscopic studies were made possible through the early discovery by Krumwiede that the agent can be transmitted and readily perpetuated in white mice.

Working with a strain of psittacosis agent well adapted to the mouse, killing them regularly in 48 hours, they studied the parasite in the spleen. About 10 hours after infection there were only large forms; at the time of the animal's death the forms were all coccal elementary bodies. There was a definite sequence of changes. When the infection had proceeded half way to death of the mouse, the infected cells showed clusters of particles of all sizes—large, intermediate, and small (elementary bodies). Some of the large forms appeared to be dividing. These observations convinced Bedson and Bland (1934) and Bland and Canti (1935) that the psittacosis agent passes through certain developmental forms and multiplies by binary fission. Burnet and Rountree (1935) and Lazarus and Meyer (1939) studying the cycle in the cells of developing chicken eggs and Yanamura and Meyer (1941) using chicken embryo cells in tissue cultures as host cells observed similar forms and sequences.

The discovery that the mouse is susceptible experimentally to the filterable infective agent of lymphogranuloma venereum (Hellerström and Wassen, 1930) led Miyagawa and his colleagues (Miyagawa et al., 1935) to demonstrate that the agent could be stained and that in size and staining reactions it closely resembles the psittacosis agent. The full extent of the resemblance was proven by Findlay and his colleagues (1938) and Rake and Jones (1942) when they showed that the lymphogranuloma venereum agent goes through a growth cycle similar in all respects to that described by Bedson and Bland (1932). Later other related agents were studied—ornithosis (Meyer and Eddie, 1942), mouse pneumonitis (Karr, 1943), feline pneumonitis (Hamre et al., 1947), and enzootic abortion of ewes (Stamp, 1951), and their cycles were

similar. These studies established the common character of what became known as the psittacosis-ornithosis-lymphogranuloma, or psittacosis-ornithosis-mammalian pneumonitis (P.O.M.P.) agents (Terzin, 1958).

Of the studies that followed this period, those of Weiss (1955) deserve mention: Bland and Canti had placed the developmental cycle intracellularly, but Weiss, like Loosli and Ritter (1948), presented evidence of extracellular growth in the alveolus of mouse lungs infected with the murine pneumonitis agent.

Various aspects of the growth cycle were the subject of study, and numerous observations suggested that the psittacosis agent behaves like a true virus. It has a latent phase in its developmental cycle and changes from an infectious to a noninfectious form (Girardi et al., 1952). A restudy of the kinetic of a psittacosis infection in mice by Bedson and Gostling (1954) confirmed the observations by Heinmets and Golub (1948): the elementary bodies rapidly attach to the host cell surface and then penetrate it. Evidently during the ensuing resting phase, analogous to the lag phase during bacterial growth, the fully infectious units acquire the energy potential to multiply rapidly. When the host cell wall is finally burst, new infective units are released into the extracellular environment.

Last of all, it is well to remember that psittacine birds continue to be responsible for sporadic and, occasionally, occupational group and family infections.

ETIOLOGY AND PARASITOLOGY

Ornithosis and psittacosis are caused by intracellular, biologically distinct parasites. These share the following characteristics:

1. They stain readily with basophilic dyes.
2. They are antigenically related according to complement fixation, immunity, and toxin neutralization tests.
3. They grow well in the yolk sac of embryonated eggs.
4. They produce, with few exceptions, pneumonitis in the laboratory mouse when introduced by the intranasal route.
5. They are susceptible to the action of certain antimicrobial drugs, particularly tetracycline.

The original studies of Bedson and Western (1930), Levinthal (1930), Krumwiede *et al.* (1930), and Sacquépée and Ferrabouc (1930) showed that their isolates from infected parrots had the following principal characters of a virus according to the views prevailing at that time:

1. Inability to multiply on the nonliving media used for bacteria and filterability through the coarser grade of Berkefeld and Chamberland filters. Filtrates of splenic and hepatic emulsions that are sterile on media used for bacteria reproduced the disease in healthy birds (parakeets and parrots).
2. Several of the first accounts made reference to very small coccal bodies resembling microorganisms which when stained with Giemsa could be seen in smears of virulent material obtained from naturally occurring human or avian cases or from experimentally infected animals by means of the ordinary microscope using white light. These bodies resembled rickettsia in their microscopic appearance. The virulence of the test material was correlated with their presence, and they were held back only by the less coarse bacterial filters. Early in psittacosis research these bodies were referred to as Levinthal-Coles-Lillie (L.C.L.) bodies.

It is to the lasting credit of Bedson (1932), Bedson and Bland (1932), and Bland and Canti (1935) that they demonstrated, through painstaking microscopic studies, that the L.C.L. bodies were pleomorphic, a constant feature of the multi-

passing from one cell to another. The fluid or semifluid content of the vesicle (originally called matrix by Bland and Canti, 1935) is probably formed by enzymatic digestion of the surrounding cytoplasm by the multiplying psittacosis agent; it is rich in RNA (Pollard et al., 1960). In the trachoma and lymphogranuloma growth cycle the matrixes are unique in their content of a glycogenlike, iodophilic polysaccharide (Rice, 1936; Orfila, 1962).

The appearance of bedsonia in smears prepared from infected tissues or cultures is important. When stained by the Macchiavello method (basic fuchsin decolorized with citric acid followed by methylene blue) the dense particles and the highly infective elementary bodies show affinity for basic dyes—basic fuchsin, and stain red; the coarse reticulated forms are blue. These differences are not striking when the Castaneda procedure or the Giemsa stain is used. Neither the coarse nor the dense particles retain gentian violet, after decoloration with 95 per cent ethanol, as well as the rickettsia do. In an electron microscopic study of the structure of 15 isolates, the diameter of the individual organisms ranged from 280 to 980 mμ; the elementary bodies derived from parakeets were spherical while those of turkey, egret, pigeon, and mammalian origin were angular, suggesting a polygonal architecture (Page et al., 1961).

Biochemistry of Growth

A variety of experimental findings, reviewed by Moulder (1954), Weiss (1955), Wenner (1958), and again more recently in an admirable manner by Moulder (1962b) point to the conclusion that many members of this group are obligate intracellular parasites rich in both DNA and RNA have enzyme systems that can synthesize micromolecules of protein and nucleic acid specific for each agent. Likewise they produce metabolites of low molecular weight such as folic acid, lysine, and muranic acid, that are not synthesized by the host cells. Purified suspensions of bedsonia particles prepared from infected chick-embryo yolk

sac or allantoic fluid digested with pancreatin or cobra venom (Allen and Bovarnick, 1962) (their freedom from host cell contamination determined by serological tests and electron micrographs) have served for determination of the chemical composition. There is evidence that the two morphologic types of particles have different compositions and correspondingly different activities; the reported results are not always comparable. The psittacosis agents are chemically complex organisms. Of all the common amino acids, only arginine and histidine are missing from the parasite protein estimated at 35 per cent of the dry weight for the meningopneumonitis agent. Lysine is present, probably in the cell walls, in appreciable amounts (Jenkin, 1960).

Many members of the group contain a lipid; 6BC psittacosis strain yields lecithin (Gogolak and Ross, 1955).

About 3.5 per cent of the dry weight of the meningopneumonitis particle is DNA; the RNA varies from 2 to 7 per cent (Gogolak and Ross, 1955). The dry weight of the same organism has about 2 per cent carbohydrate (½ is hexosamine) (Jenkin, 1960).

Significant are the findings that the meningopneumonitis and murine pneumonitis particles contain the amino sugar—muranic acid—found only in bacteria, rickettsiae, and the blue-green algae (Allison and Perkins, 1960).

Nutritional requirements of the bedsoniae have been greatly clarified by intriguing studies (Morgan and Bader, 1956 and 1957) using a sensitive tissue culture system consisting of the L strain of mouse fibroblasts. Amino acid or B vitamin not required for the growth of L cells was essential for psittacosis multiplication. Four amino acids (arginine, glutamine, histidine, lysine) and two vitamins (folic acid and riboflavin) necessary for the multiplication of L cells were not required by the 6BC psittacosis agent. The first two amino acids are not found in the psittacosis agents (Jenkin, 1960). Lysine, a component of the cell wall, is formed by the meningopneumonitis agent by decar-
FIG. 23.1 — Growth cycle of bedsonia agents.

by an elementary body, a particle about 0.2 to 0.3μ in diameter and consisting of a limiting wall or membrane containing an electron-dense central body surrounded by less dense peripheral material. In susceptible cell cultures the elementary body becomes adsorbed to a host cell within 2 hours (Weiss, 1955; Officer and Brown, 1960). The invading body or particle undergoes an internal reorganization as it adjusts to the intracellular environment. The particle then appears as a highly granular coarse meshed reticular form surrounded by a vesicle. These larger particles (0.7 to 1.0μ in diameter) can be seen with the light microscope and have been described as initial bodies. This description is not appropriate because such units persist throughout the growth cycle, not merely at the beginning.

Between the tenth and twentieth hours after infection intense metabolic activity, but little division, is observed; the infectivity of the culture at this stage remains low and fairly constant.

After 20 hours the particles begin to increase in number, according to most evidence, as the result of binary fission of the large forms. The agent leaves the lag phase

and enters the logarithmic phase of multiplication; this is accompanied by an increase in infectivity of the culture. At a time characteristic of each host-agent system, some large forms differentiate into small dense-centered highly infective particles, and these small particles do not divide. Others of the larger reticulated particles continue to divide.

Between 25 and 30 hours division of the large forms also ceases, but differentiation of large into small forms continues for a short period. The terminal population in the host cell consists of a mixture of large and small particles. The critical analysis by Bedson (1959) and in particular the studies of Litwin and his associates (1961) on eight host-agent systems lend no support to the view that the elementary bodies develop from a viral matrix or that multiple endosporulation is an important phase of multiplication of the bedsoniae. The nature of the dense-centered bodies is unknown; they consist in large part of material other than DNA or RNA (Jenkin, 1960) and may be an aggregation or condensation of the protoplasma of the elementary body that cannot divide but can resist extracellular stresses encountered in

for 23 days. Chemical substances such as lysol, chloramine, sodium hydroxide, hydrochloric acid, and others at temperatures of 18 to 20° C. inactivated the agent within 30 minutes. Short-wave ultraviolet light inactivated the bedsonia on thin cotton material within 30 minutes from a distance of 1 m. from the source of radiation; long-wave radiation did not inactivate the agent even after an exposure of 2 hours (Bolotovskii, 1959).

Effect of Antimicrobial Drugs

Multiplication of most representative members of the group is inhibited by drugs effective against bacteria: the sulfonamides, penicillin, the tetracyclines, erythromycin, and chloramphenicol (Eaton, 1950; Hurst et al., 1953; Gale, 1959).

Bedsonia and penicillin interact in the same way as bacteria and penicillin. All members of the group are susceptible, the mammalian agents more so than the avian ones. Large, irregularly shaped and vacuolated bodies are observed when feline pneumonitis or lymphogranuloma agents are grown in the yolk sacs of chick embryos treated with penicillin (Weiss, 1955; Hurst et al., 1953; Tajima et al., 1957; Walz, 1963). These bodies, analogous to bacterial spheroblasts, remain viable and resume multiplication at a normal rate as soon as penicillin is removed by injection of penicillinase into the embryo (Moulder et al., 1956). In a manner similar to bacteria, bedsoniae become resistant to penicillin (Moulder et al., 1955; Gordon et al., 1957). The resistance develops stepwise and leads to the appearance of penicillin- and cross-neutralization-resistant mutants of the feline pneumonitis agent (Moulder et al., 1958). The peculiar properties of these mutants suggest a nondissociable bond and fundamental changes between the cell wall of the bedsonia and the drug. This led to the observation that the cell wall of the meningopneumonitis or murine pneumonitis bedsoniae is like that of bacteria and that the bedsoniae contain muramic acid (Jenkin, 1960; Allison and Perkins, 1960). This acid is synthesized by enzymes in the bedsonia and incorporated into the cell wall. Penicillin probably inhibits this incorporation and thus prevents multiplication.

Tetracyclines are currently the drugs of choice in the treatment of psittacosis (Katz, 1956; Wenner, 1958). Aureomycin did not affect the extracellular meningopneumonitis agent when propagated in the chick embryo (Allen et al., 1953); the action is directed against the intracellular growth cycle by interfering with some unknown metabolic process essential for reproduction (Moulder, 1954). Achromycin was superior to aureomycin and terramycin in delaying death of chick embryos infected with feline pneumonitis (Katz, 1956). The effectiveness was not directly proportional to the amount given but was independent of the concentration of the psittacosis agent. Achromycin administered within 48 hours after infection completely protected the embryos. After 72 hours the survival rates fell with increasing time between infection and administration of the drug. The remarkable growth inhibition by aureomycin compared with that of penicillin is clearly shown in a chart in a paper by Gogolak and Weiss (1950). Aureomycin produces smaller plaques or aggregations of particles than penicillin. Because chlortetracycline resistance developed in egg passage and in mice, Gordon and his colleagues (1957) warned that drug resistance might be produced in programs designed to eradicate psittacosis from poultry or parakeet stocks. To date drug-resistant isolates have not been obtained from avian species inadequately treated with tetracyclines for 15 to 30 days.

PATHOGENESIS

The psittacosis bedsoniae exhibit no special affinity for cells of the chicken embryo and multiply in the most readily available cells. Infected allantoic fluid, yolk sac, or mouse lung is useful for separating the elementary bodies from tissue components by procedures that include the use of proteolytic enzymes, surface active agents, absorption of cell components to

boxylation of diaminopimelic acid—a reaction not occurring in mammalian tissue (Moulder, 1962a and 1964). The lack of glutamine requirements is not understood. Folic acid is synthesized by the psittacosis group (Colón, 1960 and 1962). Cytochrome C reductase as an enzyme takes the place of nitroflavin in the meningopneumonitis agent (Allen et al., 1960). Infection causes no changes in the energy metabolism of the host cell, but alters the rate of nucleic acid synthesis. Several studies by independent workers have shown that diverse members of the group synthesize their own nucleic acid from precursors of unknown complexity within the host cells. Psittacosis agents, like bacteria and other cells, contain more than one kind of RNA, strongly indicating that the bedsoniae have synthetic systems. Quite recently careful studies by Ormsbee and Weiss (1963) with the trachoma agent have shown that purified suspensions of bedsoniae possess an independent carbohydrate metabolism in an extracellular environment; it appears that oxidation was not affected by molecular oxygen. The available evidence suggests that the psittacosis particles are active metabolic units, but there is a striking metabolic deficiency in the apparent lack of any sort of energy metabolism. Moulder (1962b) offers the explanation that the psittacosis group depends on the host cell to supply high-energy metabolites such as adenosine triphosphate and other nucleotide triphosphates that most likely penetrate the agents. Probably this deficiency explains the obligate intracellular metabolism: an adequate concentration and variety of high-energy compounds is not found outside living, actively metabolizing cells.

Inactivation

The members of this group are among the less stable infective agents under ordinary laboratory conditions. Older claims that complete destruction requires heating at 70° C. for 10 minutes must be re-examined. One of the turkey ornithosis isolates in 20 per cent mammalian tissue sus-

pension has been destroyed in less than 5 minutes at 56° C. and in less than 48 hours at 37° C. Resistance to lower temperatures is well known. When a portion of the same suspension was stored at −20° C. or at dry ice chest temperature for 400 days, the viability was gradually lost, until 99.95 per cent had been destroyed (Page, 1959b). Diseased turkeys frozen in processing plants retained the ornithosis agent in a viable state after a little over a year of storage at −20° C. or below.

A solution of 7.5 per cent dextrose in skimmed milk preserves the infectivity to a high degree whether stored after freeze drying or in a frozen state at −15° C.; lyophilized tissue suspensions yield higher infectivity than frozen suspensions (Schmittdiel, 1961). Either skim milk or glutamate medium at −70° C. preserved the meningopneumonitis agent (Allen et al., 1952).

The growth cycle is destroyed by freezing. This explains the drop of infectivity so frequently encountered when suspensions are not titrated in the fresh state (Litwin, 1959; Officer and Brown, 1960).

When preserved in 50 per cent glycerol in buffered saline (pH 7.6) and held at 0° ± 4° C., heavy suspensions of infective tissue may retain their activity for 10 to 20 days. The psittacosis agents in sputum, human lung tissue, and bird specimens rapidly lose potency in glycerol; this preservative should not be used.

Formalin (0.1 per cent) or phenol (0.5 per cent) inactivates even suspensions free from clumps in 24 to 36 hours; ether or ethanol at room temperature is destructive within 30 minutes. The pH range of stability is narrow (7 to 8), and the rate of inactivation of the feline pneumonitis bedsonia by ultraviolet irradiation is comparable to that of Escherichia coli (Moulder and Weiss, 1951).

Suspensions of ornithosis and psittacosis isolates grown in mouse brain and embryos preserved their activity in tap or well water for 17 days, in melted snow for 15 days, in natural light for 18 days, in snow in darkness for 29 days, and in pasteurized milk

Multiplication of the bedsonia is not essential for evocation of the lethal effect; it is sedimented with the infective particles when spun at 18,000 rpm for an hour, or when put through coarse Seitz filters. The lethal properties are unstable: the potency declines at 22° to 37° C. within a few hours and may be quickly lost at 44° C.; it is destroyed by 0.1 per cent formalin although the antigenicity is retained. If homologous antiserum-homogenate mixtures are administered together, the lethality is neutralized to the extent that from 80 to 90 per cent of the mice survive at least 48 hours. In the following days a variable percentage succumb to infection. Not all isolates (e.g., from severe human pneumonitis, from turkeys and egrets) may be fatal to all mice within 24 hours. The immunologic specificity of the lethality-neutralization reaction is identical or very similar to that of the infectivity-neutralization reaction (Manire and Meyer, 1950c). Recent studies have demonstrated that the toxic antigen is located in the cell wall, as is the neutralizing antigen (Ross and Jenkin, 1962). Incomplete physiologic and histopathologic studies on mice subjected to the lethal effect of bedsonia revealed profound changes in the blood elements—severe leukopenia, toxic granulation and shift to the left, thrombocytopenia and irregular marked anemia accompanied by delay in blood clotting, hemoconcentration and disturbance in the glucose metabolism. Microscopic examination of the venae cavae of mice infected by the intravenous route revealed damage to the vascular epithelia (Schoenholz, 1962). These observations suggest that the toxin of the bedsonia in some manner reflects the damage done to the host during the act of invasion of the particles. Toxin neutralization and infectivity neutralization titrate the same antigen or polymolecular substances on cell wall that is intimately involved in invasion of host cells. On the other hand, it is known that several antigens of unknown toxicity are produced during multiplication of the bedsonia (Hilleman et al., 1951; Gogolak and Ross, 1955;

Benedict and O'Brien, 1958), and that apparently the synthesis or release of a lethal toxin of a penicillin-resistant mutant of feline pneumonitis is inhibited by penicillin. Although the neutralization technique of the toxin or factors in distinguishing avian from mammalian isolates is of value, it does not seem likely that the lethal effect that follows the intravenous inoculation of mice with homogenates consisting of very large numbers of highly infective bedsonia particles explains the pathogenesis of natural infections of man and animals by members of the psittacosis-lymphogranuloma group.

Antigenic Structure

It was shown early that the sera from persons convalescent from psittacosis (Bedson, 1935) and that from diseased or recovered psittacine birds (Meyer and Eddie, 1939a) fixed complement in the presence of the psittacosis agent in the splenic tissues of mice or tissue culture. Another finding was significant: the psittacosis antigen contained two antigens, one that was heat-labile was destroyed by temperatures above 60° C.; the other withstood boiling or even autoclaving at 135° C. Immune serum contained antibodies to both antigens, as could be demonstrated by complement fixation tests with the unabsorbed serum and with those that had been absorbed separately with the whole agent or with its heat-stable component. As other psittacosis and the lymphogranuloma agents were discovered, it was found that they all have, in the complement fixation test, the same heat-stable antigen now designated the group antigen. By treating human serum from lymphogranuloma venereum by absorption with heated homologous or heterologous (psittacosis) antigen, it was found that the lymphogranuloma venereum agent contains a heat-labile fraction that is specific for this bedsonia (Bedson et al., 1949; Barwell, 1952). Antiserum in rabbits, guinea pigs, and pigeons with the enzootic abortion of ewes agent (Monsur and Barwell, 1951) and similar studies with the psittacosis and feline pneumonitis agents (Ross and Gogo-

specific antiserum or to celite and cycles of high and low speed centrifugation (Zahler and Moulder, 1953), or simply by differential centrifugation (Gogolak and Ross, 1955). Purified preparations are also obtained by dialysis against distilled water (Crocker, 1954). By use of an ingenious counting method it has been learned how elementary particles infect chicken embryos by the yolk sac route.

Counting the number of particles in suspensions of infective agents with the light microscope (Lazarus and Meyer, 1939; Gogolak, 1953; Manire and Smith, 1959; Smith and Manire, 1959) or the electron microscope (Crocker, 1954; Litwin, 1959, 1962; Jenkin, 1960; Litwin et al., 1961) and inoculating the counted suspension into the yolk sac of embryonated eggs, their invasiveness and their LD_{50} have been determined. Thus it was demonstrated that the 6BC parakeet and Borg strains of psittacosis infected in the total particle/LD_{50} ratio of almost 1; the ratio for the trachoma was close to 1×10^6 (Litwin et al., 1961; Litwin, 1962). Agents with a ratio near unity can be considered highly infectious for a variety of hosts; they invade and grow in many different kinds of cells. Bedsonia isolates or members of the group with high ratios have restricted host range and multiply in few tissues or cells. It is guessed that the structures or enzymes involved in the invasion of the host cells by the dense particles may be located in the cell wall (Jenkin et al., 1961; Ross and Jenkin, 1962).

Latency

One characteristic of natural infections with members of this group is latency without obvious harm to the host. This was first demonstrated in parakeets and mice (Meyer and Eddie, 1933; Bedson, 1938; Early and Morgan, 1946a), then in chick embryos (Davis, 1949; Greenland, 1961) and in man (Meyer and Eddie, 1951b). Latency may result from nutritional deficiencies in host cells and recrudescences of frank disease may follow when these deficiencies are corrected (Morgan and Bader,

1957; Bader and Morgan, 1958, 1961). At first glance it might seem that the cells of living intact animals are unlikely to reach a state of starvation. But the absolute and relative concentrations of metabolites within cells are subject to a variety of complex regulatory mechanisms. Even in adequately nourished mammalian or avian hosts the conditions in certain cells or groups of cells essential for bedsonia growth may fall below the minimum; the lag phase in the growth cycle normally taking about 10 hours might be prolonged indefinitely. This still has to be proved. Another method of producing experimental latency was observed by Litwin (1959) when he altered the normal growth cycle by transferring the feline pneumonitis bedsonia at the early growth stages onto chorioallantoic membranes. The cycle was greatly delayed and fully infectious particles never appeared. In this manner the agent could be transformed indefinitely in the latent phase because the rapid transfer indefinitely prolonged the early stages of normal growth. A third factor may condition latency. In Benedict's study (1958b) the psittacosis bedsonia growth cycle was greatly suppressed in monocytes derived from immune guinea pigs; they grew well in normal cells. This observation suggests that immune reactions within the mammalian or avian cells may be partly responsible for latency.

Lethal Properties

Analogous to the observation on the rickettsial toxin studies, Rake and Jones (1944), Manire and Meyer (1950 a, b & c), and Meyer and Eddie (1953) observed that the psittacosis-lymphogranuloma agents form a toxin closely associated with the infectious particles that is rapidly lethal for mice on intravenous injection. Homogenates of yolk sacs infected with a highly virulent turkey ornithosis isolate in dilution of 1:1,000 killed 50 per cent of the mice within the first 16 hours after intravenous injection. The LD_{50} of the lethal factor was more than 1×10^6 times the infection LD_{50} (Manire and Smith, 1959).

sensitized with a soluble group antigen sedimented at 100,000 G for 80 minutes from meningopneumonitis-infected allantoic fluid was agglutinated by 70 per cent of serum from patients who had had psittacosis 1 to 5 years before the test. This sensitizing antigen, probably a protein, is apparently not associated with either complement fixation activity or with the murine hemagglutinin (Benedict and O'Brien, 1958).

HOST RANGE
Natural Infections

In 1930 when the psittacosis agent was isolated and first studied, it was thought that its natural hosts were to be found only in birds of the parrot family. Of course it was known then that other species of birds were susceptible and could even be the source of human infection. Since then naturally occurring infections have been found in steadily increasing numbers of extrapsittacine birds, as the tabulations in previous editions of this book fully indicate. By the end of 1963, members of at least 127 species belonging to 10 orders had been found infected. The species extensively studied, aside from the parrots, for example the pigeons, ducks, geese, chickens, and turkeys, all showed chronic latent infections and complement fixing antibodies in the peripheral blood serum. The host range of ornithosis in wild birds is much wider than had been suspected. In the course of investigations in the Caucasus and Transcaucasia, searching for viral infections, the sera of 263 birds were studied in the direct and indirect complement fixation test. At the same time the viscera of 3,712 birds pooled in 862 batches were examined for viral agents by intracerebral and intraperitoneal inoculation of mice and repeatedly passaged agents belonging to the *Bedsoniae* were never isolated. However 28 of 196 sera reacted in the complement fixation tests in dilutions from 1:4 to 1:64. The serum of 1 of 6 bustards (*Otis tetrax* Linn. 1758) was positive in a dilution of 1:61; 2 of 24 common kestrels (*Falco timunculus*) reacted 1:32 and 1:64;

7 of 133 nestling and adult rooks (*Corvus frigelaus*) reacted in 1:16, 1:32, and 1:64 (Basova *et al.*, 1960). Other Russian investigators found the sera of 5 species of water fowl collected at the Caspian Sea (Terskikh *et al.*, 1961, 1962) and 1 of 12 cormorants (*Phalacrocorax carbosinensis*) to give positive reactions in the complement fixation test (Boldyrev, 1961).

Sparrows (*Passer domesticus*) caught on the college farm near Adelaide, Australia, yielded bedsoniae from the spleens; others trapped in the city proved uninfected (Dane and Beech, 1955). These observations suggesting that sparrows acquire ornithosis from a contaminated environment are supported by findings of organism pools of nestling birds roosting in the vicinity of diseased duck farms to be infected (Illner, 1961).

While discoveries were extending the host range of the avian agents, it became evident that mammals other than man are hosts of bedsonia species (Wenner, 1958). The knowledge by comparison with that of the avian species is limited, but the host range seems much more restricted, and what is more important, the infection more commonly results in frank, often destructive, disease involving the respiratory tract and the central nervous system and causing abortion (Meyer, 1959b).

The human host specific lymphogranuloma venereum and trachoma are members of the psittacosis group, as originally proved by Findlay and his associates (1938). The trachoma and inclusion conjunctivitis agents undergo a growth cycle as do the psittacosis bedsoniae when they multiply in the embryonated egg (Gordon, 1963; Jawetz and Thygeson, 1964).

The suggestion has been put forward that certain bedsoniae with high person-to-person communicability without apparent connection with birds have become adapted to man and are becoming so adapted that they no longer acquire an avian host. Most observers of human psittacosis had been familiar with man-to-man spread from patients in hospitals to nurses, but this has rarely gone beyond one pas-

lak, 1957a) provided evidence that the heat-labile antigen is the species-specific antigen that is always serologically weaker than the group antigen. Considerable progress has been made in identifying these antigens with chemical fractions of the bedsoniae. Treatment of the agents with phenol, dilute hydrochloric acid, or papain had the same effect as boiling; it made them group specific. Prolonged extraction with ether placed the group antigen in solution in which it could be destroyed with potassium periodate in very low concentration or by lecithinase (Barwell, 1952). In subsequent careful investigations, Ross and Gogolak (1957a) grew the psittacosis and feline pneumonitis agents in the allantoic cavity of 8-day eggs, purified them by fractional centrifugation, disrupted the particles by sonic vibration and lyophilized the particulate material. Two complement fixing antigens were extracted from these preparations, one ether-soluble, the other alkali-soluble. The latter had both the specific and the group antigen. When treated with potassium periodate or lecithinase, the specific antigen that could be destroyed with papain (but not trypsin) was obtainable. It is believed that the specific serologic activity of the bedsoniae resides in a lecithin-nucleoprotein complex. The alkali-soluble antigen fraction yields lysolecithin when treated with lecithinase and choline is demonstrable in the phospholipid fraction. Solubility of the lecithin in the alkali-soluble, ether-insoluble extract suggests that it is firmly bound to a nucleoprotein identified as such by chromatographic and spectrophotometric methods. A water-soluble group complement fixation antigen has been extracted with sodium lauryl sulfate from purified bedsoniae (Benedict and O'Brien, 1956).

A serologic procedure to detect the specific antigen in psittacosis or ornithosis isolates would be invaluable to identify its host origin. Present methods have not informed whether the extrapsittacine isolates differ sufficiently from psittacine isolates to constitute a separate species. Such a method would be used to answer urgent epidemiologic questions, for example whether ornithosis in turkeys or ducks is introduced into breeding and fattening flocks by water fowl such as sea gulls. There remains also the question concerning the variable organotropism of bovine bedsoniae—for example, "Is the bovine abortion agent merely an adaptation of the bovine enteritis agent?" This cannot be answered without an analysis of the specific antigens in the different isolates so far reported. The precise method of Ross and Gogolak is too arduous for routine use. Promising results have been reported by Jenkin (1960) and Ross and Jenkin (1962) who used cell wall preparations as antigens, treating purified bedsoniae with deoxycholate and with trypsin. Specific antigens in the cell wall were demonstrated in both direct and indirect complement fixation tests.

Slide agglutination tests with purified bedsoniae are quite useful (Lazarus and Meyer, 1939; Labzoffsky, 1947; Mason, 1959; Chang et al., 1962). Treatment of infected yolk sac suspensions with fluorocarbon and concentration by centrifugation has proved highly useful in agglutination tests in darkfield preparations (Bernkopf et al., 1960), particularly when used in fluorescent antibody techniques (Nichols and McComb, 1962).

Allantoic fluid from duck embryos infected with psittacosis, murine or feline pneumonitis, or meningopneumonitis bedsoniae agglutinates mouse erythrocytes. The serologic reaction with this so-called murine hemagglutinin is group, rather than strain, specific. The hemagglutinin consists of two chemical fractions, a phospholipid and a nucleoprotein. The former contains lecithin, which is not serologically specific but can agglutinate mouse erythrocytes. Specific hemagglutination inhibition takes place in the serum of roosters immunized with purified elementary bodies, indicating that hemagglutinins are associated with the bedsonia particle (Hilleman et al., 1951; Gogolak, 1954; Gogolak and Ross, 1955; Inaba et al., 1957).

Tannic-acid-treated sheep erythrocytes

sage. In the San Francisco and Louisiana outbreaks of severe pneumonitis the sequence of case to case transmission was considered new and striking, notwithstanding that similar transmission chains had been described in 1930 (Hamel, 1932). The course of transmission was contrary to the concept of adaptation: these strains were transmitted only from fatal cases and only late in the disease. This suggested that a strain of unusual invasiveness had met a new host for the first time. The questions of which bedsonia has adapted itself to parasitism in the respiratory tract of the human host and whether such adaptation is possible remain open. One must continue to look to birds as the source of human psittacosis with interhuman transmission (Hansen and Sørensen, 1955).

Experimental or Indicator Hosts

Table 23.2 shows the pathogenicity of bedsoniae for experimental hosts.

At least 12 years before it became known that the white laboratory mouse is a natural host of mouse pneumonitis, this rodent was found to be invaluable as an indicator host for isolation of bedsoniae. The white mouse, readily available and relatively safe with respect to infection of man, has displaced birds for experimental work, except in rare instances when Java ricebirds offer advantages. Mice highly susceptible to bacterial but not necessarily to neurotropic virus infections are preferred. Intranasal administration of an avian psittacosis agent has disadvantages in that it may become contaminated with pleuropneumonia organisms and that the mice may be latently infected with murine pneumonitis (Gönnert, 1942; Nigg and Eaton, 1944; de Burgh et al., 1945). The duration of the illness and the rapidity with which death follows inoculation depend on the amount, virulence, and toxin-producing ability of the isolate. Intracranial injection is usually fatal within 4 to 6 days when 0.03 ml. of 50 to 1,000 LD$_{50}$ is injected. Titrations of isolates from birds, given intravenously or intraperitoneally to

mice, have yielded useful information about their virulence.

When highly virulent isolates from turkeys are injected, death ensues in 2 to 6 days, with the less virulent in 8 to 15 days; some mice recover and most become carriers. In animals infected orally or subcutaneously the course is always protracted. They may excrete it in feces and urine for up to 10 days after injection; however, mice infected with a pigeon isolate did not transmit it to uninfected cagemates (Weyer and Lippelt, 1956). Latent infection has persisted for 10 to 12 months. A psittacosis agent was isolated from mice inadequately treated with antimicrobial drugs as long as 9 months after inoculation (Hurst et al., 1953).

Ornithosis, psittacosis, human pneumonitis, meningopneumonitis, opossum B, and hamster pneumonitis agents and tissue suspensions from naturally infected hosts, administered intranasally to mice, produce widespread consolidation of the lungs (Hornus, 1940; Gogolak, 1953; Kovac, 1961). The psittacosis infection of the murine lungs begins as an unspecific irritation of the alveolar epithelium during multiplication of the agent. Then there follows sudden onset of specific proliferation within the alveolar wall, exudation into the alveolar cavity, and unsuccessful repair leading to fibrosis of the walls. Intranasal infection is invariably accompanied by perivascular infiltrations, granuloma formation, and necrosis in brain, heart, liver, spleen, kidneys, and suprarenals as a sequel to bedsonemia, infecting tissue descendants of ecto-, ento-, and mesoderm germ layers (Kovac, 1961). Discrete foci of pneumonia are manifested as limiting infective dilutions of the agents are approached; the areas are gray, almost translucent, and are 1 to 3 mm. in diameter (Loosli et al., 1948; Marinescu et al., 1960).

After they have been adapted to survival in the mouse, other bedsoniae induce fatal pneumonitis. Intracranial injection causes irritability, ataxia, convulsions, and death

turkey isolates by the intratracheal route; the resulting infection was fatal to 25 per cent of the birds (Pate et al., 1954). Parakeet and pigeon isolates and turkey isolates of low virulence inoculated into turkey poults by the same route produced neither death nor even illness, but specific antibodies appeared and the isolates persisted in the organs for 3 months or longer (Davis et al., 1958).

Virulence

This term is used in a relative sense to define the ability of different strains, injected with a syringe, to produce death from psittacosis or ornithosis in laboratory mice or avian species measured in their LD_{50}. The test measures the artificial virulence of a bedsonia for an animal species. It provides inadequate information about the pathogenicity for certain species since pathogenicity, aside from virulence, takes into consideration the invasiveness and communicability, those ill-defined characteristics that are involved before the agents are established in the tissues or blood stream. Differences in the observed infective capacity or virulence of individual strains or isolates of the bedsonia group on application to the tissues of certain hosts have been noted since the agents were first studied. Meager is the knowledge of pathogenicity or the disposition to virulence of the species and varieties within the bedsoniae. Isolates from human victims with severe psittacosis and from the psittacine bird that was the source of the infection have exhibited a high virulence for various indicator hosts on initial test infections on mice, ricebirds, or the chick embryo. Benign psittacosis observed here and abroad during the past 20 years among persons directly or indirectly exposed to pigeons, chickens, and ducks was, as a rule, caused by strains of low virulence for mice even after adaptation. In a study on the epizootiology of psittacosis in Australia, generally overlooked, Miles (1959b) refers to an important observation made in 1953, that a bedsonia isolated from the enlarged spleen of a sparrow (Passer domesticus) was

of such attenuated virulence for mice it could be isolated only in the yolk sac of the chick embryo. This must have been a unique observation, since Page and Bankowski (1959) in California and Illner (1961) obtained from nestling sparrows caught in East Berlin bedsoniae that infected mice with typical lesions in the second passage. Two significant observations have been made with the isolates from turkeys. Severe occupational human infections in Texas, New Jersey, and Oregon following temporary close association with grossly diseased turkeys were caused by bedsoniae of high virulence for all indicator hosts (Meyer and Eddie, 1954a). On the other hand, the processing of a flock of turkeys that had extensive gross visceral lesions caused no human infections. The bedsoniae isolated from these diseased turkeys when first isolated and even on passage remained of low virulence for mice (Meyer and Eddie, 1956b). Similar observations have since been made by others in Wisconsin and Minnesota, California and Oregon (Graber and Pomeroy, 1958; Gale, 1960; Page and Bankowski, 1959; Page, 1960; Meyer and Eddie, 1959, 4th ed., p. 526). Already in 1952 serologic surveys conclusively proved that ornithosis in turkeys though widely distributed in the United States had caused few serious explosive outbreaks of human illness. It was the epidemiologic study in Selma, California, that demonstrated that isolates of low virulence for mice are responsible for the serum reactions and the anatomical lesions on the viscera of the turkeys. Though of low artificial virulence in laboratory tests, the California and Wisconsin isolates have wide communicability, as attested by the high infection rate in the flocks. Identical conditions are fully recognized in ornithosis of pigeons. Subsequent investigations in California confirmed these facts, but brought others to light when the isolates from two flocks of diseased turkeys were studied carefully. Both isolates equally virulent for the chick embryo and mice differed greatly in their pathogenicity for pigeons and turkeys. One

within 3 to 6 days. The meninges are moist and deeply injected. Microscopically the meningo-encephalitis is characterized by an exudate of polymorphonuclear and mononuclear cells, rich in elementary bodies, extending along the blood vessels into the brain. This route is useful to increase the amount of bedsoniae in a clean, readily accessible form and to demonstrate quickly the specific particles, provided the material is free from contaminants and is relatively rich in elementary bodies. Irradiation with ultraviolet rays or cortisone alone or in combination failed to heighten susceptibility in pigeons, but whole body irradiation as well as histamine did render the birds more susceptible (Strauss and Vecerek, 1961). In fact, in a dosage of 0.05 mg. to 1.0 mg., histamine phosphate has activated some carriers to shed bedsonia (Arnstein, 1963).

Among the experimental hosts used to study the pathogenicity of a bedsonia, the guinea pig occupies a prominent position. It is used to isolate mammalian (bovine) bedsoniae, to determine the virulence of an isolate, and to provide high-titered antibodies for immunity studies.

In guinea pigs most isolates produce only a prolonged febrile illness, if that, when inoculated intraperitoneally. But the toxic Borg pneumonitis, egret, turkey, and mammalian (bovine enteritis and encephalomyelitis and pneumonitis of goats and sheep) bedsoniae are highly virulent. The animals succumb to large amounts of inoculum within 6 to 10 days after a febrile course of 3 or 4 days, with temperatures as high as 41.4° C., visible illness, weakness, and progressive emaciation. At necropsy, enlargement of the spleen is usual; a mucoid, viscous, stringy exudate covers the organs, and in a few animals pulmonary consolidation involves one or all lobes of the lung. Occasionally pigeon and duck isolates may cause fatal infection on intraperitoneal injection (Strauss, 1956).

Some isolates produce fatal meningo-encephalitis in rabbits infected by the intracerebral route; occasionally extensive pneumonic consolidation is produced by

intratracheal injection. Infection of the rabbit's eye has produced a violent pan-ophthalmitis (Evans and Moore, 1950).

Cotton rats are highly susceptible to the Borg isolate by the intraperitoneal, intra-nasal, or intracranial route. Wild and white laboratory rats and deer mice are not very susceptible. Syrian hamsters and squirrels (Citellus beecheyi) may be fatally infected with certain turkey isolates by the intranasal or intracranial route. Macacus rhesus may be infected by the intracerebral route; psittacosis and highly toxic turkey isolates produce typical pulmonary lesions (Rivers and Berry, 1931; McGavran et al., 1962). A parrot isolate inoculated intra-cerebrally led to meningo-encephalitis (Rivers et al., 1931).

The lesions produced in the rhesus monkey by small particle aerosol exposure have been discrete and never fatal (McGavran et al., 1962; Berendt et al., 1962).

Parakeets from aviaries free from psittacosis are susceptible to intramuscular, intranasal, or intracranial infection. Immature birds readily contract the infection by exposure to sick birds shedding bedsoniae in droppings. When death occurs during the acute stage, gross findings are a semipurulent coating over the air sac and the inner lining of the sternum, exudate in the pericardial sac, a large liver occasionally studded with areas of necrosis or infarction surrounded by hemorrhagic zones, a large spleen sometimes unevenly spotted and large soft kidneys; only rarely are lesions demonstrable in the lungs (Moritsch and Kovac, 1956).

Pathogenicity tests on pigeons by intracerebral inoculation may be useful. As a rule, isolates from pigeons, but not from other birds, produce meningitis and fatal paralysis (Pinkerton and Moragues, 1942; Strauss, 1956). Except for the meningo-pneumonitis and one murine pneumonitis isolate (de Burgh et al., 1945) no tested mammalian isolate has been pathogenic for ricebirds, parakeets, or pigeons by any route of inoculation, even with very large doses.

Turkey poults have been infected with

turkey isolates by the intratracheal route; the resulting infection was fatal to 25 per cent of the birds (Pate et al., 1954). Parakeet and pigeon isolates and turkey isolates of low virulence inoculated into turkey poults by the same route produced neither death nor even illness, but specific antibodies appeared and the isolates persisted in the organs for 3 months or longer (Davis et al., 1958).

Virulence

This term is used in a relative sense to define the ability of different strains, injected with a syringe, to produce death from psittacosis or ornithosis in laboratory mice or avian species measured in their LD_{50}. The test measures the artificial virulence of a bedsonia for an animal species. It provides inadequate information about the pathogenicity for certain species since pathogenicity, aside from virulence, takes into consideration the invasiveness and communicability, those ill-defined characteristics that are involved before the agents are established in the tissues or blood stream. Differences in the observed infective capacity or virulence of individual strains or isolates of the bedsonia group on application to the tissues of certain hosts have been noted since the agents were first studied. Meager is the knowledge of pathogenicity or the disposition to virulence of the species and varieties within the bedsoniae. Isolates from human victims with severe psittacosis and from the psittacine bird that was the source of the infection have exhibited a high virulence for various indicator hosts on initial test infections on mice, ricebirds, or the chick embryo. Benign psittacosis observed here and abroad during the past 20 years among persons directly or indirectly exposed to pigeons, chickens, and ducks was, as a rule, caused by strains of low virulence for mice even after adaptation. In a study on the epizootiology of psittacosis in Australia, generally overlooked, Miles (1959b) refers to an important observation made in 1953, that a bedsonia isolated from the enlarged spleen of a sparrow (Passer domesticus) was

of such attenuated virulence for mice it could be isolated only in the yolk sac of the chick embryo. This must have been a unique observation, since Page and Bankowski (1959) in California and Illner (1961) obtained from nestling sparrows caught in East Berlin bedsoniae that infected mice with typical lesions in the second passage. Two significant observations have been made with the isolates from turkeys. Severe occupational human infections in Texas, New Jersey, and Oregon following temporary close association with grossly diseased turkeys were caused by bedsoniae of high virulence for all indicator hosts (Meyer and Eddie, 1951a). On the other hand, the processing of a flock of turkeys that had extensive gross visceral lesions caused no human infections. The bedsoniae isolated from these diseased turkeys when first isolated and even on passage remained of low virulence for mice (Meyer and Eddie, 1956b). Similar observations have since been made by others in Wisconsin and Minnesota, California and Oregon (Graber and Pomeroy, 1958; Gale, 1960; Page and Bankowski, 1959; Page, 1960; Meyer and Eddie, 1959, 4th ed., p. 526). Already in 1952 serologic surveys conclusively proved that ornithosis in turkeys though widely distributed in the United States had caused few serious explosive outbreaks of human illness. It was the epidemiologic study in Selma, California, that demonstrated that isolates of low virulence for mice are responsible for the serum reactions and the anatomical lesions on the viscera of the turkeys. Though of low artificial virulence in laboratory tests, the California and Wisconsin isolates have wide communicability, as attested by the high infection rate in the flocks. Identical conditions are fully recognized in ornithosis of pigeons. Subsequent investigations in California confirmed these facts, but brought others to light when the isolates from two flocks of diseased turkeys were studied carefully. Both isolates equally virulent for the chick embryo and mice differed greatly in their pathogenicity for pigeons and turkeys. Our

(so-called C_2 Woodland) was at least 30 times more virulent for turkeys than the other isolate (C_4 Modesto); the latter isolate was 525 times more lethal for pigeons on intraperitoneal inoculation (Page, 1960). These important observations deserve confirmation before they are used to speculate on the ecology of the bedsoniae in turkey flocks. However, it is permissible to conclude that ornithosis of turkeys may be caused by bedsoniae of high or low virulence for mice. The latter variant is unquestionably responsible for the serologic reactions encountered in many flocks that show no abnormal mortality.

From experience with other infective agents it might be assumed that a bedsonia of low or attenuated virulence would survive best in its natural host. There are some indications that this assumption holds true for certain pigeon and duck isolates and to some extent of isolates from apparently healthy adult turkey carriers. Some from pigeons, even after repeated passage, retained their low virulence rarely killing more than 10 per cent of the intraperitoneally inoculated mice within 12 days after the inoculation. However, with some isolates from pigeons the mortality rate is 80 per cent in mice. Experiments using the natural host would require squabs or poults of uniform genetic background. Incidental observations indicate that in the "neutral host," the embryonated egg, some isolates are quite stable, others are labile and lose their virulence for the mammalian indicator host. The entire problem of virulence, and especially of changes in virulence under natural conditions, is of greatest importance and is basic to understanding the host-parasite relationship.

In this connection several observations on psittacosis in parrots deserve mention. During severe widespread epizootics in wild parrots of several species in Australia, the isolates by Burnet (1935) were apparently of heightened virulence only for parrots (Burnet, 1939). No unusual characteristics were discernible in their behavior after mouse inoculation and no human

cases were reported from the affected districts. There is no evidence on whether the epizootic bedsonia was a variant from the same host with enhanced virulence, invasiveness, and communicability, or whether it originated from another species of bird. During a survey of four parrot species made in South Australia (Miles, 1959b), 45 per cent of the Adelaide rosella (Platycercus elegans Adelaide) yielded a psittacosis agent from their viscera; the epizootic was not fatal and did not affect Kakatoe roseicapilla or Psephotus haematonatus commonly seen in close contact in the same tree. Nothing is known about the virulence for mice of the isolates from the rosellas, but the low communicability both for psittacies and such gregarious birds as starlings and pigeons suggests that bedsoniae of low virulence are more prevalent than those of high virulence. Already in 1934 it was pointed out that the psittacosis agent prevalent in recently captured budgerigars was of low virulence but became highly communicable and virulent when maintained in captivity under crowded conditions of aviaries.

The virulence test on the laboratory mouse has been used as a means to gauge the infectivity and pathogenicity of ornithosis strains in poultry. Titrations of isolates in the first or second passage given intraperitoneally to mice have yielded useful information. Repeated titrations reveal differences between log ID_{50} and LD_{50} and these may be used to calculate a pathogenicity index (Page, 1959c). As the lethality titer approaches equivalence with the infectivity titer the index approaches 0. A low index indicates high mouse virulence and a high index (3 to 4) indicates an infectivity 10,000 times greater than the lethality. In general isolates from human infections, parrots, many parakeets, and turkeys involved in single cases and in outbreaks have yielded a low index. Most isolates from pigeons, ducks, and a few from turkeys and parrots have yielded high indices. For example, the New Jersey turkey isolate with an index of 0.34 was responsible for 17 human infections; the

Selma isolate with an index of 1.92 caused no infections among 88 employees. Monreal (1960) modified the Page pathogenicity test and applied it to two isolates from human sputum and three isolates from spleen samplings of parakeet aviaries. He determined the log ID_{50} merely by gross and microscopic examination, not by subinoculations of the organs of the mice that were sacrificed on the 21 days after inoculation. In this respect his method differs from that of Page. It may yield slightly different indices since two of the parakeet isolates had lower pathogenicity indices than the human sputum isolates. One must agree with Monreal that his procedure does not appraise the human pathogenicity of isolates from parakeets. Numerous tests continue to show that turkey and isolates with a low index are as a rule involved in the epidemic episodes in processing plants, while with sporadic cases the index is above 2. For the sake of uniformity, dilutions of the isolate should be made with second or third lung passage material from mice infected intranasally after enrichment of the agent by intraperitoneal inoculation. The tests should not be made with isolates adapted to mice after initial yolk sac propagation.

TAXONOMIC POSITION OF THE GROUP

The taxonomy of this group has been critically reviewed by Weiss (1955). Bedson (1959), on the basis of his extensive experiences, also analyzed the evidence on which a taxonomic position could be decided. He came to the conclusion that these agents are neither large viruses nor small rickettsiae. They occupy a distinct position between the two. Incidentally, one characteristic that distinguishes the rickettsiae from the psittacosis agents is their occurrence in various arthropods under natural conditions. Experiments are now being made with feather mites, collected on chicken and turkey ranches having yielded isolates of variable virulence, to learn whether the insects are true hosts or merely passive vehicles of the agent in the environment of the poultry for many months (Eddie *et al.*, 1962). A few years ago Bedson (1959) concluded from his own studies and the observations of others that the psittacosis-lymphogranuloma venereum-trachoma group of infective agents have characters both of viruses and of rickettsiae, so providing a link between these microbial orders. Since then the superb studies of the Moulder school at Chicago and Camp Detrick clearly show that members of the group structurally, biochemically, and functionally are certainly not viruses, but bacteria adapted to intracellular parasitism. However, it must be reserved for the future to determine their true taxonomic position in the microbial orders.

ECOLOGY OF AVIAN INFECTIONS

The ecology of psittacosis in birds of show and pleasure, particularly in commercial breeding and raising establishments and in pet shops, has been elucidated, documented, and described (Meyer, 1942; Meyer and Eddie, 1958c). The infective agent is passed from parent birds to the offspring while they are closely associated; in parakeets while the young birds are still in the nest. Some become ill, a small percentage (up to 10 per cent) die, but the remainder recover slowly and in due course seem quite healthy. If stress of crowding, traveling, or unsuitable diet upsets the host-parasite balance, they may become ill with ruffled feathers and diarrhea. The bedsoniae are profusely shed in the environment and any cagemate not previously infected contracts psittacosis. Recovery is rarely complete and the chronic carrier stage in about 10 per cent maintains the infection in the breeding flock. In poorly managed aviaries, psittacosis has until recently been enzootic in the majority of domiciliated caged psittacine species. There is increasing evidence that the infection does not perpetuate itself in the wild psittacine birds through nest infection.

Modern air transportation enables the investigator to procure parrots directly from the wild. With the aid of serologic tests he can prove that many shipments

are entirely free; others may contain very few psittacosis carriers and shedders. During captivity over several months the infective agent may spread from the carrier and cause general illnesses, even loss of the entire shipment. Limited observations made on wild budgerigars (*Melopsittacus undulatus*) throughout Australia have shown that they were not infected. These findings on merely 28 birds differ from those recorded on the same species held in captivity. It raises the possibility that parakeets in the wild state are largely free from psittacosis and the agent is perpetuated through nest infection in rare instances. On the other hand there is good evidence that fatal and nonfatal epizootics of psittacosis occur in Australia (Burnet, 1939; Miles, 1959b) and South America (Parodi and Silvetti, 1916). How to explain these observations is quite difficult. Under aviary and pet shop conditions an epizootic of psittacosis affects most if not all the species, although there may be differences in susceptibility between different species. Evidence for such cross infection is not easy to obtain in the wild. Rarity or absence of infection in certain psittacine species or gregarious birds suggests that it cannot occur commonly except when a highly virulent agent spreads from rosellas to gray parrots as in 1938 to 1939.

Under natural wild conditions cross infection or transmission from one species of bird to another may be expected to take place only provided an infecting strain of very unusual virulence and transmissibility is epizootic (Miles, 1959b). Whether this interpretation is correct requires more searching and sophisticated ecologic studies than have been reported. Between 1909 and 1910, South American and Australian importations of parrots were made by sea voyages lasting for weeks, often after a prolonged holding period after they had been caught. Invariably such shipments consisted of a variable percentage (up to 55 per cent) of diseased and infected birds with ample evidence of cross infection (Meyer and Eddie, 1939b; Meyer, 1962). The epizootics were man-made and in no

way reflected the ecologic conditions as they occur in the wild.

At first it appeared that the fulmar ornithosis on the Faeroe Islands had been introduced. The human disease had not been seen on the islands before 1930, and bedsoniae could not be detected in Shetland Island fulmars from which the Faeroe colony originated (Miles and Shrivastav, 1951). The severity of disease and high mortality among the women victims suggested that a psittacine, instead of nonpsittacine, bedsonia was involved. Rasmussen (1938) suggested that infection of the Faeroe fulmars came from dead parrots thrown overboard from vessels bringing the birds to Great Britain and western Europe in 1929 to 1930. This speculation must be accepted with reservations since many water birds are naturally infected with bedsoniae of virulence comparable to that incompletely studied by Haagen and Mauer (1938); the serologic examination on the Shetland Islands was done on only 12 fulmars by the direct complement fixation test. This test may not have sufficed to detect an existing infection. The stable association of birds with bedsoniae extends over such a wide geographic area and involves so many species that it is hard to imagine that it has existed only the length of time it has been recognized. Maintenance of the bedsoniae is assured by the flocking and nesting of birds. Fulmars, petrels, mutton birds, domestic and feral pigeons congregate and nest together. They become hosts and maintain ornithosis indefinitely. Bird species of solitary habits are rarely if ever found infected with bedsoniae.

Enzootic ornithosis in pigeons has been conclusively proven by many studies in many places; it is latent and inapparent, producing no visible symptoms and no pathologic lesions beyond an enlarged spleen or pericardial lesions. There is conclusive evidence that the bedsoniae are transmitted in the nest. Young birds of high susceptibility may succumb, others recover and become immune, and some become carriers that shed the ornithosis agent

in the droppings; during raising of the young it is present in the crop content. Environmental factors may favor either host or parasite. If for some reason a high proportion of the nestlings escape infection, they may contract it later and succumb. Disturbances in the environment such as exceptional weather, low temperature, crowding in unsanitary quarters, and improper feeding induce relapses of the chronic infection. Wherever the ornithosis agent is dispersed in large quantities and the pigeons are held in crowded quarters, the spread from diseased to susceptible is rapid. The apparent stability of the relationship between the pigeon host and the bedsonia suggests that it is not of recent origin. The ornithosis agent with few exceptions is of relatively low virulence.

When ornithosis was discovered in chickens, ducks, geese, turkeys, and pheasants on game farms, the question arose as to how incubator-hatched poultry became the host to the ornithosis agents. Nest infections of the sort proved for psittacine birds and pigeons could not be proved, and egg transmission in turkeys could not be found (D. E. Davis et al., 1957a; Page and Bankowski, 1959). The ornithosis agent was transmitted through the eggs of ducks and the black-headed gull (Illner, 1962a, Lehnert, 1962). The infective agent may in some way persist on the farms, either in adult birds or in the soil or bedding of the environment, or be introduced from wild birds. Present knowledge is meager because poultry pathologists and epidemiologists have not studied the life history of large poultry flocks from incubator-hatched eggs through egg-laying maturity. As a source of the infection of poultry with the ornithosis bedsoniae, Oriel (1964) suspects a homogenous-heterogenous infection chain which he expresses as follows:

Wild bird species ← Poultry → Poultry →

(sea gulls, petrels,   (ducks, geese,
feral pigeons,   chickens,
herons, sparrows,   pigeons, and
migratory birds, etc.)   turkeys)

↓   ↓

Man   Man → (Man)
Pigeons

These fall into four groups—poultry pigeons, carrier and racing pigeons, fancy pigeons, and feral pigeons. Their wide distribution has made them readily accessible subjects for study. Pigeons, probably originally the rock dove in Europe, have been partially domesticated and carried to all parts of the world. They have adapted to living in close association with man, and they are readily bred in lofts to produce a variety of plumage or to provide squabs for the table. Their homing instincts are used for practical purposes as carrier or racing pigeons. Terhaag (1956) described how transportation of racing pigeons in baskets by train from Germany to southern France for the racing season and the sudden release of 10,000 to 20,000 birds created infective dust and spread the infection. In West Germany breeders of over 100,000 racing pigeons have created an epidemiologically important reservoir. The demand for squabs as luxurious table birds has led to high production on certain farms, sometimes housing as many as 5,000 breeding birds. The flocking and nesting of wild pigeons through all months of the year bears directly on the persistence of ornithosis (D. J. Davis, 1955; Shaughnessy, 1955; Fritzsche et al., 1956).

An excellent description of ornithosis in a self-contained pigeon flock at the Field Station of the Agricultural Research Council in Great Britain was given by Hughes in 1947.

The distribution of the infection within different age groups is significant. It mainly affects birds under 16 weeks of age. Of the 16-week-old squabs, or squeakers, as many as 20 per cent either may die or, when sacrificed, may show lesions of ornithosis. When processed for the market they may show extensive plastic exudates on the air sacs and over the heart and liver (Hughes, 1947). So-called wet squabs suffering from diarrhea may be affected with either ornithosis or salmonellosis. The incidence of these two infections was 60 and 62 per cent respectively in 552 birds

The known and reported incidence and geographic distribution among domesticated and wild pigeons, according to serologic surveys and bedsonia isolations, was first published in the 1959 edition of this book. At that time 18 countries on every continent had listed a varying percentage of reactors and isolations of the agent causing columban ornithosis. Now the number of countries where this infection has been recognized has risen to 25. Additional surveys have not been made in the United States. A summary is included in Table 23 3.

Ornithosis is a cosmopolitan, enzootic, principally inapparent infection in domesticated and feral pigeons. According to serologic surveys the proportion of reactors may range from 10 to 80 per cent, depending on the age of the birds and the complement fixation technique used. The percentages of reactors in adult birds may be higher when the indirect test is used. Isolation of bedsoniae from reactor birds has been successful in about 40 per cent of the attempts. Bedsoniae have been isolated from pigeons with no complement fixing antibodies (Meyer, 1941; Terzin et al., 1957); at the time of death, the only evidence was a slightly enlarged spleen. The endemicity among feral pigeons is roughly the same in Chicago, Baltimore, and New York as it is in Paris, Geneva, Hamburg, and Liverpool.

Certain commercial squab farms under excellent sanitary management have had much lower carrier rates and correspondingly fewer mortalities among squabs than the poorly run lofts of occasional breeders or fanciers.

In Holland, with a million people, ornithosis is widespread. In the course of examination of about 20,000 domesticated pigeons, Jansen (1955), director of the Pigeon Health Service at the Institute for Infectious Diseases at the state university at Utrecht, in 1954 found evidence of the infection in 16.4 per cent of 2,637 pigeons brought to the clinic and examined there on account of visible illness. Respiratory symptoms and conjunctivitis were pre-

eminently associated with ornithosis in racing pigeons; white fancy pigeons seem more likely to show intestinal disturbances. A sharp seasonal rise in September and October coincided with the beginning of the racing and exhibition season when large numbers of young birds came together for the first time. In isolated small flocks with a few carriers the incidence of acute disease was usually lower. A selection of 504 racing pigeons was made from 102 flocks during the winter months when they were not travelling and acute infection could be excluded. The sera of these birds were examined in the direct complement fixation test in the presence of bedsonia antigen. Accepting a titer of 1:32 and higher as indicative of infection, 77 (75 per cent) of the flocks were infected. If titers below 1:16 were considered, an additional 8 (7.8 per cent) were listed as suspicious; only 17 (16.67 per cent) of the flocks were free from ornithosis (Monreal, 1958).

In the United States infections have relapsed and become acute in pigeons fed thiamine-deficient diets (Pinkerton and Swank, 1940) or housed unhygienically (Meyer and Eddie, 1942). An outbreak of ornithosis (Smadel et al., 1943a) and an epizootic in a pigeon platoon (Smadel et al., 1945) disclosed a new virus, immunologically different from the psittacosis bedsonia, that produced intranuclear herpeslike inclusions and local necrosis of parenchymatous tissues. The malady at first affected adult birds, but later was limited to birds 1½ to 5 months old.

In other studies of lofts where pigeons have died of ornithosis, concurrent salmonellosis has been found. It is then impossible to determine which infective agent caused death.

Ducks

Ornithosis has been enzootic and for the most part clinically inapparent in ducks in the United States (Meyer and Eddie, 1953; Korns, 1955).

A bedsonia of low virulence for mice and causing a carrier stage in pigeons on intra-

cerebral inoculation was recovered from ducks of all ages, the youngest only 4 days old. Sick or dead ducks from flocks suspected to be infected were tested and about 30 per cent yielded bedsoniae. In one flock ducklings (54 per cent) had gross anatomical lesions, and the mortality rate was higher among ducklings than adult birds. Newly hatched ducklings probably contract the infection when brought to unsanitary premises where infected adults are kept. Since only very few duck farms have been conspicuously involved with human infections, the incidence is not known. Coexistence of ornithosis with duck virus hepatitis, salmonellosis and pasteurellosis may complicate an epizootiologic picture (Meyer and Eddie, 1952; Korns, 1955).

Early serologic studies (Eddie and Francis, 1942) in Michigan were indirectly confirmed when investigators in Chicago discovered that 5- to 8-day-old ducklings received from a neighboring state were infected with a bedsonia. The ornithosis infection apparently conferred a marked resistance to a challenge dose of *Plasmodium lophurae* malaria parasites. The resistance was associated with increase of reticuloendothelial elements in the enlarged liver and spleen due to the ornithosis infection (Jacobs, 1957).

Interest in ornithosis of ducks has shifted to Europe. Since the reports are not available in English, some details are given. In 1948 Terskikh (1957b) in the U.S.S.R. studied 5 outbreaks of human psittacosis in poultry processing plants where Peking ducks that looked normal were defeathered and eviscerated.

Bedsoniae were isolated from the liver and spleen of 3 of 8 ducks from a breeding farm in Austria; the isolates on intraperitoneal inoculation of the duck tissues caused death of the mice on days 4 to 6. Microscopically the agent could not be distinguished from a parakeet bedsonia. Cleaning of the duck pens had caused clinical pneumonitis in 6 attendants serologically diagnosed as psittacosis (Fürst *et al.*, 1957).

A steadily increasing incidence of atypi-

cal pneumonia among employees of poultry farms in Czechoslovakia since 1949 led to a systematic, comprehensive, and exceedingly well-conducted investigation of ornithosis in ducks. Isolation of a bedsonia from sputum of an infected poultry feeder in 1953 (Trojan and Strauss, 1955) led to investigation of 104 cases of pneumonias solely among workers in a processing plant engaged in plucking ducks and geese. Over 80 per cent of the patients were pluckers; others fed and killed poultry. In 1955, epidemic and epizootic ornithosis broke out in Bohemia and in Moravia; in a district in central Bohemia, 600 of 2,000 ducklings died. Two bedsoniae were isolated (Strauss, 1956). Further isolations were made in connection with outbreaks among dairy and poultry farmers who came in contact with newly hatched infected ducklings. In 3 of 35 apparently healthy mature ducks, which in the summer of 1955 had shown clinical signs of acute ornithosis, the bedsonia was isolated during the summer of 1956 (Strauss, 1957).

In the course of these studies a bedsonia was isolated from black-headed gulls (*Larus ridibundus* L.); large numbers of such gulls died during the summer on fish ponds in eastern Bohemia where ducks were bred. They may have been the source of the ornithosis in the ducks (Strauss, 1956; Strauss *et al.*, 1957). Pursuing the spread of ornithosis by importation of infected ducks from Bohemia to eastern Slovakia, Hungary, and East Germany, the Czech investigators recognized that the annually recurring epizootics of duck ornithosis caused both large economic losses among the ducks and a considerable number of human infections, some fatal. At least 10,000 duck embryos were lost and nearly half of the 30,000 hatched ducklings died. Purchase and distribution of hatching eggs and breeding stock without veterinary control is blamed for this. Hospitalization, ambulatory treatment, and tedious prolonged convalescence seriously incapacitated the working force on the farms. Detailed study of one farm where the ducks were raised on 7 uncovered natural fish

ponds revealed that 1,350 of 7,000 ducklings (2 to 4 weeks old) had died in 2 months; during June at least 500 had perished. Clinical examination disclosed symptoms of ornithosis in 1950; from a sample of 43 ducks, 15 yielded a bedsonia. The relationship of the results of the indirect complement fixation reaction to the isolation attempts (Table 23.5) confirms that in acutely infected immature birds the antibody titers may be low and that the bedsonia may be isolated from ducks with no demonstrable antibodies in the peripheral blood.

Importation of 18,000 ducklings under unfavorable hygienic conditions and long distance transportation to poorly developed facilities resulted in 100 per cent mortality on one farm and 60 to 70 per cent on others (Strauss and Reistetter, 1960). In 6 poultry hatcheries 165,000 ducks were incubated; only 63,000 ducklings were hatched, and death or elimination due to poor growth reduced this number to 30,000 ducklings finally raised. Of 10 employees in close contact with the birds 8 contracted psittacosis.

Workers in the State Institute of Veterinary Science in the course of epidemiologic studies on ornithosis in eastern Slovakia from 1958 to 1960 observed that the infection appeared in seasonal outbreaks usually connected with importation of larger shipments of poultry for breeding. Epizootics in chickens were combined with outbreaks of pox, cholera, and coccidiosis (about 3 per cent). Disease in the ducklings was always accompanied by severe salmonellosis which caused losses up to 90 per cent. Breeding had to be discontinued. On farms under proper hygienic conditions, ample feed, and good care, losses were minimal.

In the investigations by Polony and his associates (1960), 314 avian specimens from 78 localities were examined; bedsoniae were isolated from 14 hens and chickens, 6 ducks, and 1 partridge. The highest incidence of infection, always along with salmonella (typhimurium, anatis, and enteritidis), occurred in ducks from May through July.

In 1958 and 1959 in similar outbreaks with heavy losses in the ducklings, but no illness in the adult ducks, 4 persons in Roumania handling the birds contracted ornithosis. The bedsonia isolated was pathogenic for mice and chick embryos but not for guinea pigs nor for pigeons by the intracerebral or intraperitoneal route (Popovici and May, 1960).

In 1955, members of families in the U.S.S.R. who had bought ducklings 2 days old contracted psittacosis (Krivinka, 1959).

The ornithosis agent has been demonstrated in 5 ducks in Roumania (Sarateanu et al., 1960).

Fritzsche and his colleagues (1956), describing the illness of a 41-year-old woman who worked as a plucker in a poultry processing plant in Germany, stated that adult ducks from Holland, having suffered as ducklings from "duck plague," were apparently responsible for the apparent and many inapparent (50 per cent) infections in the butchering and even office personnel.

The rapidly rising rate of psittacosis since 1957 in workers connected with duck fattening or poultry processing in the East German Republic initiated thorough epidemiologic studies. Surveys with the direct complement fixation test on 1,428 serum samples collected from ducks on 70 different farms disclosed 223 positive (>1:10), 100 suspicious (± 1:10), and 1,095 negative reactors. Thirty-five farms were considered infected, five others were placed in the suspicious class; 42 per cent of the infected farms were breeding farms; 57 per cent

were fattening establishments (Lehnert and Hille, 1960). Indirect complement fixation tests on serum samples of ducks delivered to a poultry processing plant W. in District D in Leipzig in East Germany showed that of 20 farms housing from 100 to 1,170 ducks, 10 farms were infected with ornithosis. Breeding and fattening establishments furnished from 5 to 50 latent infection reactors irrespective of the size of the flock or the general sanitation. No relationship between infection and management of the farms could be established, but introduction of ornithosis through infected eggs is suspected (Voigt et al., 1962).

Some observers working in East Germany (Bukowka et al., 1960; Siegmund, 1960) emphasized that ornithosis in ducks there has run a clinically inapparent course, that losses on the farms have been within expected limits (3 to 15 per cent) and that ducks as a source of infection have been recognized only after single or group human infection. In this respect the experiences in East Germany differ from those reported from Czechoslovakia, Roumania, Hungary, and elsewhere. Ortel (1960), in connection with his serologic and epidemiologic studies on an ornithosis epidemic among the employees of a poultry processing plant, reported that he could not isolate bedsonia from organs of ducks from regions originally considered infected because of the results of earlier indirect complement fixation tests conducted by the Veterinary Health Services. The ducks were processed in a poultry slaughterhouse in Halle. Bedsoniae were isolated on feathers and in excrements collected in the processing plant (Ortel, 1960). They were also found in the sputum and throat washings collected during the first few days of illness from 10 of 35 patients. It was difficult to maintain bedsonia of duck origin in mice after the first passage: none of the isolates produced fatal infections, but they did cause peritoneal lesions and microscopic particles in the cells of the peritoneal exudate (Ortel, personal communication). Evidently the bedsoniae studied were of low pathogenicity. In a report

Ortel (1961) summarizes the ornithosis situation in the DDR (German Democratic Republic). He lists the number of human infections due to contact with poultry, principally ducks, as follows: 1958, 23; 1959, 110; 1960, 683; 1961, 385; 1962, 160 with monthly peaks in August, September, and October.

In a systematic study of dead and sick ducks from a duck breeding and fattening installation (Illner, 1962b) bedsoniae were isolated as follows: in the second mouse passage from the enlarged spleen of an old duck hen that also had inflammation of the air sacs and oviduct; from 6 of 21 ducks 5 to 8 weeks old in either first (4), second (1), or third (1) mouse passage (salmonellosis and aspergillosis were also present); and from 5 of 15 visibly diseased ducklings (shortly after hatching to 14 days of age) in the first to third passage. The remaining 10 ducklings proved free from bedsonia yielded *Salmonella typhimurium* and *S. bredeney.* Young and old laughing gulls (*Larus ridibundus*) were also proven infected with bedsonia: 2 old birds in third mouse passage; pools of organs from several gull chicks (killed 4 to 6 days after hatching) in the first or second mouse passage, producing peritoneal exudate, splenic tumor, and liver necrosis.

Bedsoniae isolated from ducks and gulls were moderately pathogenic for mice, and despite suspicious gross lesions in older birds, the agent was more readily demonstrable in the organs of ducklings than of adult birds. The wild mallards and table ducks present on the farm did not yield bedsoniae. However, the pool of 10 eggs *from two separate nests* contained bedsoniae. Egg albumin, allantoic fluid or yolk sac material, embryos or liver of embryos removed under strict aseptic conditions from one gull egg without and one with embryo, and 2 pools prepared from uninculated duck eggs tested on mice produced serofibrinous peritonitis, enlarged spleen, and necrosis of the liver in mice of the second passage; microscopic findings were typical of those in an infection with a bedsonia of low virulence (Illner, 1962b).

In another study (Lehnert, 1962) 48 eggs from ornithosis-infected duck farms were examined. In one experiment the pool of embryos removed from 3 eggs incubated for 20 days caused bedsonia lesions in mice of the third and fourth passage. One of 9 ducklings killed at the time of hatch was proved infected. The isolates thus obtained when inoculated into the yolk sac of 6-day-old embryonated chicken eggs killed the embryos on the sixth to eighth days; large numbers of ornithosis particles were demonstrable in smears.

To ascertain whether in water fowl the bedsonia localizes in the ovaries and passes through the egg and thus maintains the infection requires more field and laboratory study. Some earlier experimental attempts to demonstrate transovarian passage in pigeons (D. J. Davis, 1935; Fritzsche et al., 1956) and turkeys (Davis et al., 1957a; Page and Bankowski, 1959) were unsuccessful.

In Czechoslovakia almost all 155 patients in the 1955 outbreak (Serý et al., 1957) kept ducks from the same hatchery. Strauss (1956) suspected that the incubator had been contaminated by eggs infected through transovarian passage.

Investigators of a poultry farm in Czechoslovakia where ornithosis and salmonellosis had prevailed for some time (Serý and Strauss, 1957; Strauss et al., 1957) discovered a concurrent destructive epizootic among young black-headed gulls in their nesting grounds in the vicinity of the duck farm. The organs of 31 of the 44 dead gulls harbored Salmonella typhimurium. Two of 15 young gulls yielded bedsonia in mouse inoculation tests. The observers called attention to the danger of salmonellosis and ornithosis being conveyed by gulls from their breeding places to poultry farms. They did not suggest the possibility that gulls feeding on dead ducks and frequenting the duck pens may have introduced the infection into the young gull population.

With confirmation of the high incidence of ornithosis and salmonellosis in gulls by East German workers, the ecologic relationship between ducks and other water fowl deserves further study. Ducks may be found on fish ponds simultaneously frequented by flocks of gulls. During the breeding season gulls in a wild bird reserve adjacent to two duck-breeding farms were found to be heavily infected with Salmonella typhimurium: 40 per cent of the examined birds and 5 per cent of their eggs; only 7 per cent of the ducks or other wild birds were proved infected. Salmonella was readily isolated from the ponds in the park, the duck ponds, the intestines of a carp, and three specimens of the common field mouse (Apodemus sylvaticus). These observations raise many questions about the role of wild birds in salmonellosis and possibly ornithosis in poultry breeding establishments (Koppel and Polony, 1958). The viability and persistence of bedsoniae shed in the droppings by wild and domiciliated water fowl into the pond water or elsewhere in the environment of the ducks are not known, nor are the principal causes of deaths among ducklings. The available limited data suggest that only a small percentage of deaths can be attributed with certainty to ornithosis; salmonellosis, hepatitis, pasteurellosis, and viral infections complicate the epizootiology.

Only a few bedsoniae isolated from ducks (in U.S.A., over 40; in Czechoslovakia, 33) have been studied to learn their microscopic appearance, antigenicity, and pathogenicity (Strauss, 1956; Strauss and Reistetter, 1960; Meyer and Eddie, 1956a). Compared with other members of the group, the isolates are of low virulence for white mice and embryonated eggs, but on adaptation may be fatal to embryos on days 3 and 5; the pathogenicity index (Page, 1959c) is between 3.5 and 4.8. They rarely produce fatal meningoencephalitis in pigeons or guinea pigs. Cross protection tests have not revealed differences between duck and pigeon isolates, but in toxin neutralization tests antiserum prepared with a duck isolate from California neutralized a duck isolate from Michigan but did not neutralize a pigeon strain toxin. As antigens, 5 isolates tested all gave group re-

actions. Antigens specific for duck isolates have not been demonstrated, and consequently their relationship to the isolates from gulls and their eggs cannot be evaluated.

Turkeys

Investigations that followed the outbreak of psittacosis in a poultry processing plant in 1948 inductively incriminated turkeys as the most likely source of the infection. The workers did not recall the processing of any unhealthy birds; in fact they said that the turkeys had been in an usually good condition (Irons et al., 1955). Three years later two additional human outbreaks, attention was focussed on a flock of turkeys with an illness undiagnosed for some time. Autopsy of two turkey hens showed cloudy thickened air sacs, brownish fluid in the peritoneal cavity and fibrinous pericarditis. Bedsonia was isolated from the pooled tissue suspensions from each bird (Bonev et al., 1952). This isolate was a highly toxic, elementary body agent with a broad host-infection spectrum. In toxin- and infection-neutralization tests it was distinct from isolates from psittacine birds and pigeons and from mammals; it is in some respects like the egret and Louisiana (Borg) pneumonitis bedsonia (Meyer and Eddie, 1953). Similarly toxic isolates have been found in flocks in New Jersey (Beaudette et al., 1956), Oregon, and Vancouver.

In the intervening 16 years, either isolations or serologic tests have revealed ornithosis in Arizona, California, Massachusetts, Michigan (Mack, 1955), Minnesota (Pomeroy et al., 1957), New Jersey a bedsonia of low virulence (Ilner, 1962b). (Beaudette et al., 1956), Ohio, Oregon (Osgood et al., 1956), Vancouver, British Columbia (Bowmer, 1958), in Alberta (Carlson et al., 1961), and New Mexico (Francis, 1960). Processing plant epidemics continued in Texas in 1951, 1952, and 1954 (Irons et al., 1955) and again in 1961 and 1963 (Rich, 1962; Rich et al., 1962; Peavy and Dickerson, 1963). Details on the

last two episodes in Texas, involving 11 employees, are not available.

During October, 1954, some turkeys in a flock of 2,100 in New Jersey had mild respiratory symptoms and diarrhea. After an illness lasting 5 to 6 days some birds died, and the total mortality reached 50 to 60. In November, inoculation of embryonated eggs with material from 4 dead birds yielded a highly virulent toxic isolate (Beaudette et al., 1956). Isolates from this flock were found at the Hooper Foundation to be indistinguishable from those from Texas and Oregon flocks. Poultry farmers and processing plant employees became infected through contact with this flock.

Attention was first called to the possibility of ornithosis in an Oregon flock in February, 1956, when the State Board of Health was notified by Veterans Hospital in Portland that a patient with symptoms suggestive of ornithosis had been exposed to turkeys (Osgood et al., 1956). This led to the discovery of 3 infected flocks on Sauvies Island near Portland, and in 2 (SK and J) of these flocks epizootics ran a particularly destructive course (mortality rate of 25 to 30 per cent). Because the infection in the flock was diagnosed during the epizootic, it was possible for the investigators to observe its course. Dead birds from the flock had been examined when illness was first observed in December. The clinical characteristics suggested erysipelas, but no evidence of this was found, and further diagnostic efforts were not productive (Dickinson et al., 1957). Birds continued to die and during the unusually wet winter the disease progressed. By the time the diagnosis was made the whole flock was heavily infected, many sick and dead birds could be seen, the premises were extensively soiled with droppings, and care of the flock had become a great burden. Treatment with tetracycline compounds in the feed improved the clinical situation but did not completely clear the organs of all birds of the bedsonia. Attempting to cope with such an outbreak in the absence

of the necessary detailed knowledge and policy is strenuous and disappointing to all concerned. In December, 1956, the infection reappeared in the breeding flock on one of the farms. Although it was treated, persistence of the agent in the tissues of the tested sample made it necessary to destroy the flock and compensate the owner, according to regulations enacted in the intervening months.

In December, 1957, the inspector in an Oregon plant condemned about a quarter of the hearts and livers of turkeys from another flock previously unsuspected of infection. A moderately virulent bedsonia was readily isolated from organs examined by a poultry laboratory. Periodic illnesses among the flocks were treated with medicated feed (terramycin, 200 gm/ton). In March, 1958, the poultry inspector removed the hearts and livers from 2 of 3 turkeys sent from the J ranch for processing. The lesions yielded a virulent bedsonia. Sera of a sample of turkeys reacted in dilution of 1:256. Chemotherapy for varying periods and doses of from 200 to 500 gm/ton were given until May when the entire breeding flock (1,189 hens and 63 toms) was processed. From 25 to 40 per cent of the hens and only 4 to 5 per cent of the toms showed lesions; 15 per cent of the toms had heart lesions. The agricultural authorities ordered destruction of the 113 turkeys remaining on the farm.

During 1959 the infection was again found on the J ranch. A virulent bedsonia was isolated from the viscera of culled and dead birds. In March, 2 sea gulls shot on the premises proved infected. A sample of the flock on a neighboring ranch (SK), previously suffering from ornithosis, showed 22 per cent reactors. Six of 146 tissue specimens collected during processing of turkeys from the J ranch were infected with a virulent bedsonia. By December, 26 per cent of 62 blood serum samples from turkeys of the same flock set aside for breeding proved positive. Visibly sick birds observed from January to April, 1960, reacted in the ICF test, and bedsonia was found in grossly

diseased tissues. Late in December, 1961, turkeys were inspected and sick birds were not seen on the farm, but when processed suspicious lesions were observed. In February, 1962, a bedsonia of low virulence was found in 3 lots of birds from J ranch; dead or sick turkeys had not been seen in the course of several inspections. In the ICF test of blood samples (32) taken in April, 1962, during processing of the flock 14 reactors were revealed (>1:32); in further blood samples collected in June the reactor rate was similar in 21 turkeys. The bedsonia from 4 of 7 tissues with lesions failed to infect mice by the intraperitoneal route and was fatal only by the intracerebral route in the dilution of 10^{-1} and 10^{-2}. The pathogenicity index determined with the second mouse passage was 4, indicative of low virulence.

The J turkey ranch was under observation for 6 years, and ornithosis of varying clinical severity reappeared annually in older poults and the breeding stock. The infection in epizootic form was invariably reflected in the direct and indirect complement fixation tests which showed that as high as half of the flock had been infected. Until 1961 a highly virulent bedsonia was in the gross lesions discovered when the birds passed over the processing lines. Supervision of the ranch was very difficult. When a shift from virulence to less virulence took place is not known. Poults though clinically well had visceral lesions in December, 1961, and a sample of serum collected while they were being processed showed a 40 per cent infection rate. Not until June, 1962, were organ specimens suitable for animal inoculation obtained. Apparently a bedsonia of low virulence evolved in poults growing up in 1961, and since the breeding stock was selected from the flock, the same agent was present when the adults were processed in 1962. For 6 years ornithosis tenaciously persisted on the J ranch. One would like to know the factors that maintained this niche, and in particular those responsible for the shift in virulence. The discovery

that pools of ground feather mites (*Glyco-phagidae*) removed from litter collected on the ranch after it had been depopulated of turkeys in 1959 carried a virulent bedsonia suggests that ectoparasites may in some way be involved in maintenance of the infection on turkey farms.

In 1958 a turkey ranch in New Mexico experienced a mortality of 300 birds in a flock of 2,200. The sick turkeys had diarrhea and cyanosis and pericardial and air sac lesions typical of those in ornithosis. A bedsonia was isolated by inoculation of allantoic cavity of embryonated eggs with suspensions of pericardial exudate. It was fatal to chick embryos on days 3 to 8. Tetracycline therapy (200 gm/ton of feed) reduced the mortality to 1 to 2 birds a day after the fifth day of treatment. Later the disease was completely arrested. No one contracted the illness from this flock (Francis, 1960).

In May, 1957, a poultry-processing plant outbreak in Canada led to isolation of a bedsonia from the only bird remaining on the farm in British Columbia from which the flock originated. The owner reported that the flock had been sick in February (Bowmer, 1958). Serologic tests (up to 25 per cent positive) conducted on five turkey flocks and isolation of a bedsonia *from sterile purulent pericardial exudate fatal to* mice on intracerebral (but not intraperitoneal) inoculation and from newly hatched turkey poults proved the existence of ornithosis in Alberta (Carlson *et al.,* 1961).

Ecology of turkey ornithosis had not been studied very thoroughly. With few exceptions the investigator rarely had the opportunity to collect data on the events that preceded the arrival of an infected flock of turkeys at a processing plant. Serologic and microbiologic examination made at the time the birds were processed or subsequently on the ranch where they had been raised proved that ornithosis due to bedsonia of high or low virulence was epizootic. When and how the infection was initiated and how long it had prevailed among the poults late in the year or among

the adult breeding flocks in spring and summer could not be learned. It is worth noting that 10- and 14-week-old poults were found infected in June (Davis and Delaplane, 1955). Since the droppings of acutely diseased birds yield the parasite in abundance, the feathers and the immediate environment heavily contaminated would certainly facilitate interbird exchange. Within a few weeks after the illness is first noticed, between 20 and 50 per cent of a turkey flock may reveal serologic evidence of infection. The natural mode of transmission has not been definitely determined. *Turkeys exposed to infective aerosols became acutely diseased, and 15 per cent died;* ingestion of a bedsonia produced inapparent infection followed by abundant shedding of bedsoniae. It was reasoned that ingestion is the most likely mode when the epizootic develops slowly; airborne spread by desiccated infected excreta is more likely when the disease spreads rapidly (Page, 1959a). In an experiment by Davis and Delaplane (1955) healthy poults were exposed to the air current collected from a pen in which artificially infected turkeys were held. None developed the disease, and the bedsonia could not be recovered from the tissues after an observation period of 5 weeks. In view of the observations made on pigeons, in all probability the turkey bedsonia may infect the host by the respiratory and the intestinal routes.

Spot serologic surveys in 1954 and 1955 in 11 states in which a complement fixation titer of 1:16 was considered indicative of present or past ornithosis showed that except in Iowa and Washington many flocks were infected. In 1957 a survey of 8 flocks ranging in turkey population from 350 to 1,761 birds indicated that 8 to 58 per cent (average 22 per cent) had antibodies to the psittacosis group antigen (Meyer and Eddie, 1957, unpublished data). Several thousand sera collected from turkey flocks in areas in Wisconsin and Minnesota where ornithosis had been proved yielded 18 per cent reactors with titers of 1:8 to above 1:128. Similar tests on flocks in different

parts of Minnesota yielded few low-titer reactors, but in 1957, 15 per cent had titers similar to those in 1954 (Pomeroy *et al.*, 1957).

Some similarities of turkey to pigeon ornithosis are striking. Many well established turkey-breeding and raising farms harbored a variable percentage of poults and adult breeding birds with latent infection. Man-made crowding and perhaps in some instances poor husbandry greatly favored exchange of the parasite. However, there is one difference: the infection was not contracted in the nest, the eggs were incubated and the poults were artificially brooded, many on the same contaminated premises where there were infected adult birds. Even if incubation and brooding are commercially done in special installations, it is reasonable to assume that many eggs originated from infected ranches. Contamination of the exterior of the eggs with bedsonia-containing excreta is suspected. Transovarian passage of bedsoniae to duck or sea gull eggs has been demonstrated, but the evidence in turkeys is more equivocal.

Several investigators searched for bedsoniae in dead turkey embryos or poults from eggs laid by breeding turkeys experimentally infected with highly virulent turkey bedsoniae. A total of 2,344 eggs were collected, incubated, and candled daily from the seventh day until hatching. The allantoic fluid from all dead turkey embryos was inoculated into 6- and 9-day-old chick embryos. Bedsonia could not be recovered. A portion of the hatched poults was placed on an isolated farm. There were no deaths due to ornithosis during a 12-week observation period (Davis and Delaplane, 1955). In another series of 2,954 eggs laid by breeding turkeys experimentally infected with the virulent JO ornithosis strain, although 500 of the eggs were laid during times at which the agent could be recovered from the blood of representative birds, bedsonia could not be found in the eggs. When fresh turkey eggs were inoculated with turkey bedsonia, the inoculated agent was not recoverable after

the ninth day after inoculation. The turkey bedsonia failed to live longer than 3 days on turkey eggshells or longer than 4 days on cotton swabs under egg incubator conditions (Davis *et al.*, 1957a). Attempts to isolate a bedsonia from 262 embryos of turkey eggs collected during an acute ornithosis epornitic were not successful; antibodies in titers as high as 1:64 and 1:512 were detected in the amniotic fluid or the serum of some turkeys (Page and Bankowski, 1959). During the extensive investigations of ornithosis in Oregon, 340 pipped turkey eggs and 110 dead turkey poults from flocks in which ornithosis was epizootic were, by repeated mouse passage tests, found free from bedsoniae. A sample of 200 eggs, hatched from eggs derived from infected hens and incubated on the infected premises, were tested before they were put on a range and proved sero-negative. In December an ornithosis epizootic with a fairly high progressive mortality rate broke out among a flock of 3,000 hens and toms that had been selected for breeding from the raised and previously tested poults. The sample to test the absence of infection in the poults may have been inadequate; since egg transmission could with confidence be excluded, other modes of infection into the flock were considered (Meyer and Eddie, 1957, unpublished). It was thought that on the open ranches turkeys might intermingle with a variety of avian and mammalian carriers and shedders of bedsoniae and might become infected. This received some support when sea gulls located on islands in Oregon, frequenting a farm where a turkey epizootic caused many deaths, were found to harbor bedsoniae indistinguishable from turkey isolates (Dickerson *et al.*, personal communication). Since gulls are avid scavengers it is impossible to say in which direction, if either, the infection passed. Both could contract it from a third source. In Texas several species of free flying birds of the *Ardeidae* family (mostly herons) were collected on a turkey ranch where ornithosis had been epizootic, but bedsoniae could not be found (Davis *et al.*, 1957b). Investi-

gation of an epizootic of ornithosis in Texas disclosed that the eye of Hurricane Carla had passed over the ranch in September and had deposited sea gulls singly or in small groups on the premises. Perhaps some of the turkeys became infected by water or sea birds and spreading of the infection took one and a half months to reach epidemic proportions (Rich, 1962).

Three of 15 pigeons, roosting on a turkey ranch for 1 year prior to an ornithosis outbreak in turkeys, furnished a bedsonia morphologically and by crude antigenic analysis and pathogenicity tests on mice and chick embryos indistinguishable from the one isolated from sick turkeys on the same premises. This suggested that the turkeys had acquired their infection from the pigeons. Adult pigeons heavily infected with a bedsonia of pigeon origin suspended in a wire cage from the ceiling of an enclosure holding 10 normal turkeys 17 weeks old apparently infected the turkeys. Within 6 weeks 9 of the 10 exposed turkeys developed indirect complement fixation titers ranging from 1:4 to 1:32. The infection was subclinical and transient, but there was serologic evidence that it was in turn transmitted to new groups of normal turkeys. No lesions were induced in the turkeys and no bedsoniae isolated (Page, 1960). The pigeon ornithosis agent used for these transmission studies was not described.

Sparrows are known to be hosts of bedsoniae. Without transmission experiments or specific antigen analyses, the isolation from sparrows of bedsoniae highly lethal for pigeons on intracerebral inoculation on a turkey ranch in central California does not yet clarify the ecology of epornitics.

Conclusive proof that ornithosis in turkeys on previously uncontaminated premises is an incidental event resulting from the intermingling with free-living avian or mammalian species carrying bedsoniae can only be proved by actual field experiments through carefully planned systematic environmental studies over many years on a number of turkey flocks established and maintained in different geographic areas. Whether such experiments are necessary will depend largely on whether the results of extensive serologic surveys widen and confirm the prevailing view that inapparent ornithosis in turkeys is more universal than generally recognized or admitted. Explanations of the origin of epizootics, recognized since 1948 on account of their relation to occupational human infections or because the poultry inspectors condemned diseased birds, have largely depended on verbal reports by the grower. Turkey raisers have commonly said that they have never seen this form of illness or abnormal death before and that it must have been introduced. But "how" neither he nor the investigator has been able to establish. According to available records, only 2 ranches, on which ornithosis was proved, have been under observation in subsequent raising and breeding seasons after the catastrophic epizootics. On one ranch 83.5 per cent of 289 sera were positive; the bedsonia was of low virulence; the following year 161 sera collected during processing of part of the flock gave no indirect complement fixation reactions. Other follow-up studies could not be made. By contrast, annual epizootics of varying severity plagued another breeder and grower for at least six years.

Feather mites belonging to the glycophagidae contaminated with bedsoniae have been found in the bedding on the premises many months after depopulation of living birds. It is suspected that these arthropods may assist in the maintenance of the disease agent through generations of turkeys (Eddie et al., 1962).

A variable percentage of poults may acquire the infection without showing symptoms. As they grow older and during the breeding season, for reasons entirely unknown, the ornithosis agent may undergo changes in virulence in certain flocks. More birds become infected and shed; some show symptoms and die. If highly virulent mutants appear, the epizootics become economically serious and a source of disease both to the raiser and his workers and to

the employees in processing plants exposed to grossly diseased turkeys. The ecology is quite similar to that of pigeon or duck ornithosis; it is rarely man-made. Wild turkeys serologically and microbiologically examined in Utah and Ohio were not infected.

Ornithosis in domestic turkeys has been recognized during the past 15 years; it has principally affected breeders' flocks. It became the subject of study when the parasite infected large human occupational groups. Through direct isolation of bedsoniae from the viscera of apparently normal turkeys, or indirectly through serologic surveys, the wide geographic distribution of ornithosis in turkeys in the U.S.A. has been established. Strangely, these facts are either overlooked, deliberately suppressed in order to protect the poultry industry, or despite overwhelming evidence the specificity or validity of serum tests is questioned. The number of farms raising turkeys dropped from 169,807 in 1954 to 86,712 in 1959; the number of turkeys produced increased from 67,693,000 to 84,493,000. In both Texas and Oregon the number of farms raising turkeys has dropped; Texas, 1954, 25,356; 1959, 11,295, and Oregon, 2,386 to 994. Examination of even a small percentage of these farms presents technical difficulties, but it must be re-emphasized that for example in Oregon, random chosen samples of 50 sera from nine farms yielded from every one at least 1 to 12 sera which reacted in dilutions of 1:16. Since the infection was low grade, the mortality not abnormal, and the marketability not affected, neither the poultry industry nor the official livestock control agencies could be interested in extending the surveys to secure a broader understanding of the ecology of ornithosis in turkeys.

Chickens

Millions of chickens are raised and marketed annually in the United States, but an epizootic or epidemic of psittacosis in chicken processing plants has not been reported. Sporadic cases have been attributed to contact with chickens (Karrer et al.,

1950a; Meyer, 1952; Irons et al., 1955; Scruggs, 1957), and there is extensive serologic evidence of ornithosis in chickens. In indirect complement fixation tests of 464 chicken sera from hatcheries in California, Iowa, Michigan, Texas, and Washington, 18.3 per cent were positive (Karrer et al., 1950c; Eddie and Meyer, unpublished data). In Connecticut, of 319 serum samples, 31 were positive to some degree (12, 1:2; 12, 1:4; 6, 1:8; 1, 1:16), the reactors were confined to 4 flocks and the birds were, except in 1 flock, over 6 months old (Rindge et al., 1959). Limited attempts to isolate a bedsonia from chickens in the United States have been successful in a few instances. Pools of emulsified spleen, liver, and kidneys of 4 of 35 chickens from a farm in New Jersey yielded a bedsonia of low virulence for mice but fatal to parakeets, ricebirds, and pigeons, on intramuscular and intracerebral inoculation (Meyer and Eddie, 1942). An isolate of low virulence was obtained from the organs of 2 emaciated chickens from a flock in California (Karrer et al., 1950a). One of 6 hearts with extensive bacteriologically sterile fibrinous exudates from chicken fryers in a processing plant in Oregon showed ornithosis particles and on mouse passage yielded a bedsonia that infected but was not fatal to 1-month-old chicks. It persisted in 3 of 4 chicks for 1 month, but healthy chicks placed in the same enclosure did not contract the infection. One serum specimen of 32 collected from fryers of this flock reacted in a dilution of 1:32. An inapparent epizootic was revealed in Oregon in the course of surveys: 5 of 7 specimens reacted (2, 1:2; 1, 1:4; 1, 1:16; 1, 1:32).

According to recent reports from Hungary, ornithosis diagnosed by isolation of bedsonia from hens and chickens has been an epizootic fatal disease causing considerable economic loss (Derzsy, 1958). Polony and his associates (1960) in their observations on ornithosis in eastern Slovakia in 1958 and 1959 recovered 14 isolates of low virulence from dead or sick chickens (1 to 2 years old) and chicks (2 months old); salmonella was also found in these birds.

Simultaneous outbreaks of pox and fatal cholera caused losses of from 5 to 15 per cent.

Bedsoniae were isolated from a group of free-living chelated mites from White Rock roosters in the Midwest that for many years had furnished birds invariably free from ornithosis (Eddie *et al.*, 1962). This was the first isolation of a bedsonia from an insect *(Menopon gallinae* L.). Interpretation of this finding is at present impossible. It is being ascertained whether this ectoparasite could introduce ornithosis into a flock and whether it could perpetuate or spread it.

Domesticated Pheasants

Inductive epidemiology of human infections has pointed to commercially raised pheasants. The owner of a large pheasant farm in Illinois contracted pneumonitis and his serum gave a positive complement fixation reaction (1:128). Several pheasant sera have been positive in the complement fixation inhibition test in significant titers (1:64) (Morrissey and Meyer, 1951). In 1956, through the courtesy of Dr. Richard E. Shope, spleens were obtained from 3 pheasants from a game bird farm. A bedsonia of low virulence was isolated from one. In pathogenicity tests on mice it has behaved liked a pigeon isolate. Fifty-four pheasants of a different lot from the same farm were sero-negative in both the direct and indirect tests.

CLINICAL FINDINGS AND PATHOLOGY

Pigeons

Coles (1940) was the first to describe ornithosis of pigeons. The birds were visibly sick, listless, and showed no interest in food; vent feathers were soiled with liquid feces. At necropsy the lungs were edematous, the liver and spleen swollen. There were moderate aerocystitis in the abdominal air sac and moderate catarrh of the intestines. There were elementary bodies in the blood, lungs, and spleen, and a bedsonia was isolated in mice. *Haemoproteus columbae, Trichomonas hepatica,* and *Sal-*
FIG. 23.2 — Ornithosis in racing pigeons. Normal eye at top; moderate conjunctivitis, center; severe conjunctivitis, bottom. (Courtesy of Professor Jac. Jansen, Utrecht, Netherlands.)

monella typhimurium were also found in this flock.

The clinical picture is never typical. Infected squabs are usually undersized and feeble. Diarrhea is common, and vent feathers are matted with grayish-green concretions. Adults that have shown no premonitory symptoms may die suddenly. Others are weak, emaciated, lose their appetites and have diarrhea. The following has been considered typical of the course in acutely diseased racing pigeons (Jansen, 1955, 1959; van Vloten, 1954): unilateral or bilateral serous conjunctivitis, rattling respiratory noises, serous purulent rhinitis ("dirty nostrils"), incapacity in flight, bluish discoloration of the skin over the pectoral muscles, anorexia, and soft feces. Fritzsche and his associates (1956) described respiratory distress with creaking rattling sounds, temporary paresis of the limbs and neck, edema of the vent, and severe diarrhea. According to both Coles and Jansen, ornithosis should be suspected whenever a pigeon is affected with conjunctivitis (Fig. 23.2). The ornithosis agent can be readily isolated by intracranial inoculation of mice with exudate or swabbings from the eye (Monreal, 1958). Experimental studies indicate that acute or latent ornithosis may be produced in pigeons. Carrier and racing pigeons exhibit respiratory disturbances, serous nasal discharge, turbidity of the eyes, swelling of the lids, and conjunctiva combined with pronounced exudates leading to matting of the feathers around the head. Anorexia leads to weakness followed by roughened feathers and quiet sitting in the corner of the pen or cage.

Adult pigeons may recover within a few weeks. In squabs or squeakers the disease is more severe and the mortality may be high. Recovery is incomplete in many birds, growth is retarded or impaired and the pigeon breeders are obligated to eliminate the birds from the flock. Adult pigeons may remain shedders for months. Fancy and poultry pigeons held in lofts exhibit principally intestinal symptoms and reduced fertility (Meyer, 1942; Fritzsche *et al.*, 1956; Weyer and Lippelt, 1956). Transient paralysis has been observed in the U.S.A. and Europe (Jansen, 1959).

At necropsy two types of lesions are observed (Meyer *et al.*, 1942a; Hughes, 1947; D. J. Davis, 1955; Fritzsche *et al.*, 1956; Monreal, 1958). In young birds a dry fibrinous plastic exudate covers the air sacs and the acutely inflamed serous membranes of the pericardium, liver, and intestinal coils. The liver is swollen, hemorrhagic, occasionally mottled, and saffron colored; the moderately enlarged spleen is dark pink or purple and very soft. Parenchymatous changes in the kidneys are common. If there had been catarrhal enteritis, urates may have accumulated in the cloaca. In less acute infections the inflammatory exudate may be limited to the lining of the abdominal air sacs.

In adult birds with relapsing latent infection, the enlarged liver with intense congestion and rounded edges is striking. Necrotic foci the size of pinheads are scattered throughout the liver of some pigeons. The spleen may be quite enlarged; in a few cases subcapsular hemorrhage is followed by rupture of the capsule, bleeding into the abdominal cavity, and sudden death. Enlargement of the spleen does not seem to be so constant in pigeons as in psittacine birds (Fig. 23.3).

In sero-positive adult birds from which a bedsonia has been isolated, there may be no gross anatomical lesions, and the size of the spleen may be in the normal range (3 x 11 mm.). Occasionally, normal sero-negative pigeons from which a bedsonia has not been isolated may have large spleens (7 x 18 mm.) (Weyer and Lippelt, 1956). In infected racing pigeons enlargement of the spleen, discolored liver, swelling of the kidneys, and grayish discoloration and enlargement of the pancreas with pinhead necrotic lesions have been described (Fritzsche *et al.*, 1956). The pancreatic lesions are not due to the ornithosis agent; they consist in faultily stained cells containing elementary bodylike elements surrounding the Langerhans cells and in-

FIG. 23.3 — (A) Spleens of pigeons proved to be infected with ornithosis virus. Natural size. (B) Two spleens and one liver of mice infected with psittacosis virus. Liver is necrotic. Small spleen not infected. Natural size.
clusions caused by the intranuclear inclusion virus (Smadel et al., 1945). Both the ornithosis and intranuclear inclusion agents can cause epizootics in pigeons.

In a few pigeons with caseous pneumonic foci, Salmonella typhimurium (var. Storrs) has been isolated from the cheesy material. In such cases the pulmonary lesions are probably not part of the ornithosis. Organs and exudates from pigeons with pure ornithosis are sterile when planted on ordinary medium or medium enriched with brilliant green broth. Smears prepared from the fibrinopurulent exudate in the pericardium or over the liver are usually rich in particles, either free or in the cytoplasm of monocytes. Sections of exudates on serous surfaces, such as the pericardium, reveal intense inflammatory infiltration with large mononuclear cells and lymphocytes and few polymorphonuclear leukocytes. The reaction may penetrate into the superficial layers of the myocardium. Vascular congestion in the liver and kidneys is associated with cloudy swelling and varying degrees of necrosis. Hemorrhagic areas are present in the spleen.

Pigeons, like parakeets, ducks, and turkeys, with or without complement fixing antibodies, may harbor the bedsonia. Most pigeons from infected commercial pigeon lofts are immune to intramuscular injection with pigeon isolates, but they contract fatal meningoencephalitis when the injection is made intracranially. The remarkable resistance of this species to ornithosis bedsonia by feeding or by intramuscular injection is probably attributable to acquired immunity, in many instances conditioned by persistence of the bedsonia in

the tissues. According to Jansen (1955), there is no evidence that a pigeon that has recovered from ornithosis has contracted it a second time. Ornithosis in pigeons is very contagious, so it is likely to affect all racing pigeons kept by one owner, but, despite the high morbidity, the mortality may be very low. Recovery may be rapid, with a few birds being completely normal a month after the onset of symptoms, but the illness usually lasts 2 to even 4 months. The Pigeon Health Service in the Netherlands does not recommend the separation of infected birds because "it is much better and less disheartening when all the birds are sick together, instead of having a small number of patients among his pigeons at regular intervals."

Chemotherapy with streptomycin in two subcutaneous injections (0.5 ml. saline containing 25 mg. of streptomycin and 25 mg. of dihydrostreptomycin sulfate) three days apart has induced rapid clinical improvement (Jansen, 1955; van Vloten, 1959). Dekking (1961) pointed out that the ornithosis agent is not susceptible to streptomycin and recommended the use of tetracycline as originally tried by Meyer and Eddie (1955). Prolonged oral treatment, consisting of offering the pigeon a mash containing 0.5 mg. of chlortetracycline per gm. of feed for 1 month, has eradicated the bedsonia from pigeon tissue. Contrary to the warnings of Fritzsche and his associates (1956), who observed shock following oral therapy with chloramphenicol (700 mg/ bird) for 1 week, side effects or death were not seen after oral treatment with tetracycline.

Chickens

Little is known about the infection in this bird. It has almost always been subacute or inapparent. Nothing is known about the clinical disease, and at necropsy, aside from enlarged liver and spleen, the air sacs appear normal. In very rare instances, and then only in fatal infections in young birds, fibrinous pericarditis has been present. Attempts to produce these lesions experimentally by infecting chicks intratracheally with chicken or pigeon isolates have failed. The birds remained clinically well but shed the bedsonia for several days, and in 3 months the indirect complement fixation titers rose. By that time the agent could not be found in the viscera. A German textbook on diseases of poultry (Fritzsche and Gerreits, 1959) mentions (on p. 112) only the clinical and pathologic observations in the U.S.A.

Ducks

Ornithosis observed in ducks in the United States has been clinically inapparent (Meyer and Eddie, 1952; Korns, 1955). Clinically normal ducklings and adult ducks have had no gross anatomical lesions, despite the presence of bedsoniae in the spleen, liver, and kidneys and intestinal tract of about a third of the birds examined. Concurrent and secondary infections are quite common, but little is known about their causal role in epizootics on duck farms. Diagnostically useful clinical symptoms suggesting ornithosis in ducks have been singularly absent.

An entirely different picture appears in the excellent Czechoslovakian investigations, in particular those by Serý, Strauss, and their associates. While studying 3 small foci in a district in central Bohemia, where 600 of 2,000 ducklings died, Kukásek and Strauss (1956) noted stunted growth, weakness, unbalanced gait, watery diarrhea, and cachexia. During an epizootic in east Bohemia, of 3,670 ducks several weeks old derived from the same incubator on an infected farm and kept by small farmers, about a fourth in the acute stage showed bilateral purulent conjunctivitis and keratoconjunctivitis, which may lead to blindness (Fig. 23.4A). Serous or purulent yellowish discharges were present even at the auricular and nasal orifices; around the eyes the secretion formed a narrow strip. In the more advanced stages the feathers around the eyes were glued together and covered by crusts of dried secretions. In several instances the bedsonia was isolated from diseased ducks (Serý et al., 1957). The photographs furnished by Dr. V. Serý impressively illustrate the ocular lesions in epizootic ornithosis. The swollen lids nearly always close the eye (Fig. 23.4B).

A prominent symptom in all acute infections is greenish or gray-greenish droppings that contain bedsoniae but not salmonella. The agent is massively excreted onto the feathers, and this endangers the health of the pickers.

As the disease progresses, emaciation and atrophy of the muscles become marked.

When the clinical phase has completely disappeared, serologic and isolation tests in 8-month-old birds proved them to be carriers and shedders (Trojan and Strauss, 1955). However, only ducklings up to the age of 4 months were sources of human infections. When the epizootic had subsided, although ducklings showed no gross evidence of the infection, latent ornithosis was readily demonstrable. When these latently infected birds were then held under unhygienic conditions, the disease became manifest and in some instances infectious for man.

During the epizootics in Slovakia, though conjunctivitis was recognized in only 3 to 25 per cent of ducks, the sera of from 10 to 80 per cent reacted in the indirect complement fixation test in a dilution of 1:4 or higher. More visibly diseased ducks were observed in flocks held in an unsanitary environment.

Postmortem findings in infected ducks are similar to those in pigeons. In ducklings a few weeks old, acute or subacute inflammation with exudation on the serous membranes of the pericardium and air

FIG. 23.4A — Sera-purulent discharge and crusts from eyes, auricular and nasal orifices of ducks suffering from ornithosis

FIG. 23.4B — Bilateral conjunctivitis and keratoconjunctivitis. Swollen lids closing eyes in ducks with ornithosis. (Courtesy of Dr. Vladimir Sery, Prague, Czechoslovakia.)

sacs accompanies congestion of the liver and spleen. Hepatic necrosis may affect only small foci, or it may extend to large, marginal, yellowish areas; the latter are usually characteristic of concomitant salmonellosis. The serofibrinous pericarditis is well illustrated by a photograph kindly furnished by Dr. V. Serý (Fig. 23.5).

Latent infection of older birds is indicated by hepatomegaly and pronounced splenomegaly (spleen may measure 3.8 x 1.2 to 2.2 cm). Aside from inflammatory areas in the lungs, older ducks present saffron-colored livers, splenic tumors, and variable pericardial and air sac inflammatory reactions (Krivinka, 1959). Microscopic examination of organs of 8 ducks from the farm that supplied the poultry responsible for six occupational infections in Austria revealed unusual findings: the architecture of the liver was greatly transformed by necrotic, fully degenerated parenchymatous elements; new formations in the bile duct interspersed by inflammatory infiltrations convey the impression that these changes developed because of an acute liver atrophy. In the Giemsa-stained section the Kupffer cells contained small and large bine particles that could be identified as bedsonia because the larger granules consisted of phagocytized nuclear detritus of erythrocytes as a sequel to intravascular hemolysis. Throughout the voluminous tumor-shaped splenic tissues nodular infiltrates of necrotic cells were distinct; the myocardium showed fatty disorganization of the fibers (Furst et al., 1957).

On a duck breeding and fattening farm in Germany where within 21 days 500 ducklings had died, the management reported that paralysis and spasm preceded death by a few days. Systematic postmortem examinations of dead or moribund ducklings and adult ducks over a period of 18

FIG. 23.5 — Serofibrinous pericarditis in duck yielding bedsonia. (Courtesy of Dr. Vladimir Sery, Prague, Czechoslovakia.)

months revealed pericarditis, pneumonia, enlarged spleens and livers, inflammation of the abdominal air sacs and oviducts (17 of 19 birds examined), and oophoritis. Bedsoniae were seen in stained smears prepared from the pericardial exudate of ducklings under 2 weeks old and of young ducks 5 to 8 weeks old that had similar grossly observable lesions. Since salmonellosis and aspergillosis were encountered and bedsonia was isolated by mouse passage only in 12 of 71 examined ducks, it is reasonable to suspect that other infectious agents may have caused the gross lesions. But 5 ducklings 3 to 4 days old, from which a bedsonia of low virulence was isolated and that were bacteriologically free from salmonella, had saffron-yellow livers and patches of pneumonia (Illner, 1962b). In ducks less than 6 days old, intravenous injection of suspensions prepared from infected spleens has caused a typical disease and gross changes with great regularity. All livers and spleens were enlarged due to

numerical increase of the reticuloendothelial cells; fibrinous exudates were present in the pericardial sac and in the air sacs. Bedsonia particles were found in all air sac membranes stained with the Macchiavello stain (Jacobs, 1957).

Geese

Czechoslovakian investigators (Trojan and Strauss, 1955; Strauss et al., 1960) incidental to their studies in east Bohemia and Slovakia isolated a bedsonia from geese. The clinical and autopsy findings have been similar to those in ducks (Sery, 1962) (Fig. 23.6). Additional isolations are on record from Roumania (Sarateanu et al., 1960) and the U.S.S.R. (Terskikh et al., 1961).

Turkeys

Two flocks in Oregon furnish information on the clinical course of epizootic turkey ornithosis (Osgood et al., 1956). The date of onset of the first illnesses is not

FIG. 23.6 — Microscopic lesions of hepatomegaly. Lesion yielding bedsonia observed in goose suffering from subacute ornithosis. (Courtesy of Dr. Vladimir Sery, Prague, Czechoslovakia.)
known, but in December some minor losses (about 2 deaths a week) were attributed to fowl cholera or erysipelas; laboratory tests did not confirm this suspicion. Of 1,796 turkeys processed, 79 were condemned because they showed "air sac disease." The losses in the remaining birds increased in January, and by March the daily mortality reached 50 to 60 birds. Total losses were 2,000 (30 per cent) of one flock and 350 (20 per cent) of another flock.

There were dead turkeys in the pens and yards, and the balance of the flock in general was droopy, anorexic, and feverish. Many were weak and reluctant to move even when disturbed. On being driven some staggered and fell, manifested acute respiratory distress, and died within a few minutes. Some were extremely emaciated, their wattles dry and cyanotic, and their eyes dull and sunken. Many had eye lesions ranging from slight inflammation of the conjunctiva to complete necrotic obliteration of the orbit. The grounds of the pens were heavily blotched with soft or liquid yellowish droppings, some of which were blood tinged. Soiling and matting of the vent feathers were common, and the cloacas of many birds were everted. Some birds had lost many feathers from the

breast and back, exposing large areas of flesh. The keels of many birds were ulcerated and abscessed, and the wing tips were heavily contused and abraded by the efforts of the birds to rise to their feet. Evidence of cannibalism was noted on the carcasses of dead birds and quite frequently on the moribund and sicker ones.

Egg production was far below normal in both flocks. Both hens and toms were infected, but in one flock the infection was slower to manifest itself in the toms, was not as severe, and the mortality was lower. Such differences were not as conspicuous in the other flock.

Necropsy of several sacrificed birds that had been ill and several birds that died presented the following lesions: Inflammation of the serosal surfaces with fibrinous exudation was consistently observed. Air sacs were inflamed and thickened and in one or two instances contained masses of cheesy exudate. The mesenteric and serosal surfaces of the intestine also were injected and inflamed in many birds. The abdominal cavity of a few birds contained fluid and fibrin deposits. The livers were slightly enlarged and off color, and in many birds the surface was covered with whitish, fibrinous films. These films ranged

FIG. 23.7—Ornithosis in turkey. Note fibrinous pericarditis and enlargement of the liver.

from small to extensive patches covering the surfaces. Few spleens were enlarged. The pericardium of almost all birds showed evidence of inflammation, with fibrinous exudation, and epicardial adhesions were beginning to form (Fig. 23.7). The pericardial cavity of some contained transudate and fibrinous flakes. Myocarditis was evident in large, soft, flabby hearts, and in some cases the coronary vessels were injected. Diffuse pneumonia was seen, but pulmonary edema was more often noticed. Many birds were markedly cachectic and poorly feathered and had decubital breast ulcers. Yellowish-green soiling of the vent feathers was a consistent finding.

At processing, about 5 weeks after the acute epizootics were arrested by the use of tetracycline compounds, the residual lesions in a large part of both flocks were critically appraised. The lesions were classed in three groups: (A) No lesions, or only slight, well healed residua—slightly thickened pericardium or small (less than 1 cm. in diameter) fibrinous to fibrotic patches on the epicardium or liver. (B) More extensive, but not active, lesions—fibrinous to fibrotic patches on the liver, chronic pericarditis with or without epicardial adhesions. (C) Severe lesions in an active stage or in an early stage of resolution—chronic pericarditis with fibrinous exudation on the pericardium, liver, air sacs and peritoneum, or extensive chronic lesions with massive adhesions and marked cachexia.

Of 1,200 hens of one flock processed, 59 were condemned. All birds with Group C lesions and other birds with diseases unrelated to ornithosis were condemned. The Agricultural Marketing Service inspecting veterinarian condemned at least 80 per cent of the livers and 90 per cent of the hearts. Lesions in 1,081 (85 per cent) were grouped as follows: 925 (85 per cent) Group A; 120 (12.5 per cent) Group B; 26 (2.5 per cent) Group C. The lesions in another infected flock of 1,808 were similar: 86.6 per cent Group A; 11.1 per cent Group B; 2.2 per cent Group C. From flock 1 there were 695 that had as high a rate of lesions, although less severe. This supported the owner's report that the mortality was less in the toms and the clinical course less severe.

The findings in flock 2 were essentially the same. More than 90 per cent of the birds showed some residual lesions on the heart and liver. Most had no more than small fibrino-fibrotic patches on the epicardium and slight adhesions to the pericardium. This was true in both flocks. In ordinary inspection many of these lesions would have been overlooked, but these were particularly well observed because of the foregoing infection.

The pathologic changes in the gonads in both toms and hens were strikingly different in the two flocks. In flock 1 reproductive functions were interfered with during the epizootic but improved after treatment. Neither egg production nor fertility was improved in flock 2 in spite of marked

clinical improvement after similar treatment. In flock 1 more than 90 per cent of the hens showed evidence of prolific ovulation. This was apparent even when there were advanced lesions in other organs. There was very little pathologic change in the ovaries or testes. In flock 2 more than 60 per cent of the hens had nonfunctioning or diseased ovaries. Most were simply atrophic or blighted, but others were necrotic, hemorrhagic, caseated, or inspissated masses. In a few instances, fully shelled eggs were incarcerated or adhered within the oviduct. These apparently were obstructed by rapidly forming fibrinous adhesions that later fibrosed. Gonadal lesions were also found in toms in flock 2. Atrophied testes were common; many were greenish. Well inspissated old hemorrhagic masses enveloped several testes. Adhesions to surrounding structures were also common. Flock 2 was much further advanced in egg production when the epizootic reached its peak than was flock 3. Also, flock 2 received high levels of sulfonamides over a longer period. Either or both of these may have been factors.

Several enormously enlarged spleens were observed in flock 1, but most of the spleens were of normal size in both flocks.

Published descriptions by other observers on naturally and experimentally infected flocks differ in a few details. They all stress that infected turkeys may look normal at antemortem inspection and still have typical lesions at autopsy (Carlson et al., 1961; Francis, 1960).

Early observations, clinical and pathologic, in Texas were made on turkeys of mature breeding stock in the latter part of the laying season. However birds 10 to 14 weeks old were also involved in the outbreak. Birds of all ages were susceptible but the mortality was much higher in younger birds. Among the symptoms noted were yellowish-green diarrheal droppings, droopiness, coughing, rattling, or other signs of respiratory involvement. The most prominent lesions of turkey ornithosis may be confused with those of other diseases characterized by fibrinopurulent inflammation of the serous surfaces of the thoracic and abdominal viscera. Frequently the only organs visibly affected are the spleen, liver, and kidneys (Boney et al., 1952; Pate et al., 1954). In an outbreak in New Jersey (Beaudette et al., 1956), aside from mild respiratory symptoms, the most striking symptom was diarrhea in which the droppings were sulfur yellow and of an unusually disagreeable odor. Turkeys that died did so after an illness of 5 to 6 days; rigor mortis was complete within a half hour after death. Autopsy revealed necrosis of the liver and spleen, congestion of the lungs, and hemorrhages in the skeletal muscles. The air sacs showed evidence of infection in absence of sinusitis.

Experimental ornithosis has been studied to find pathognomonic lesions to differentiate turkey ornithosis from other poultry diseases (Davis and Delaplane, 1958a). Turkeys have been readily infected with a Texas isolate by the intracranial, intratracheal, intraperitoneal, or intra-air sac route. Poults and adults were infected by the intratracheal route with allantoic fluid collected from chick embryos dead as a result of a highly virulent turkey isolate. The incubation time ranged from 4 to 7 days depending on the age of the turkeys. Mortality was influenced by the same factor: within 7 days it was 100 per cent in poults 1 week old; it was 25 per cent in birds 6 weeks old. In the age group of 3 to 6 months the average mortality was 22 per cent.

Pericarditis was the most constant autopsy finding. The spleen was rarely enlarged, but the liver was streaked with gray or green bands. Biliary stasis was indicated by greatly enlarged gallbladder, and the intestines contained bright green feces throughout the entire length. Aside from the fibrinous inflammation of the pericardium, the incidence of exudates over the liver (perihepatitis) was more marked in the older birds and was apparently influenced by the duration of the illness. The incidence of congestion and edema of the

lung was high in poults, but was usually absent in older birds (Boney et al., 1952; Pate et al., 1951; D. E. Davis, 1955).

A different experimental approach was chosen by Page (1959a) to study the pathway of infection and pathogenesis of an ornithosis isolate from a turkey involved in an epizootic and human occupational infection. Broad-breasted Bronze turkey poults 10 to 23 weeks old proved free from ornithosis were exposed to infective aerosols. They became acutely ill, and about 15 per cent died. Infected birds were sacrificed at various stages of the disease in order to learn the extent of multiplication of the bedsonia and the pathway of infection. Within 24 hours and until death high concentrations of the inhaled bedsonia were found within the lung. Bedsonia were found in the blood within 18 hours and were thereby distributed to tissues throughout the viscera. The epi- and pericardial surfaces and peritoneal serosa became infected by extension from the air sacs. Continued multiplication in these sites intensified the inflammatory response in the form of heavy deposits of fibrinous exudates.

Recovery from the acute experimental infection was followed by complete disappearance of the agent by the seventieth day, demonstrable by mouse inoculation of small fragments of liver, spleen, and kidney. However in a few instances bedsonia were found in the pericardial sac and kidneys.

In this connection, systematic field observations were made to determine the extent of latent infections in well turkeys. Some spleens removed at the processing lines were tested singly by inoculation of mice; of 98 selected from 215 normal or moderately enlarged spleens from 3 different flocks, 7 yielded isolates. Only 4 of these 7 birds had been sero-reactors.

Questions remain about the pathogenesis. Ornithosis has at times been a highly contagious disease, but limited experimentation by blowing the exhaust air from an enclosure holding infected sick turkeys into an adjacent pen with healthy turkeys failed to infect the birds (Davis and Delaplane, 1958b). Artificial spray aerosols readily infected; simple feeding with a pipette into the crop of the bedsonia in the dose of 310,000 mouse LD_{50} produced no clinical effects or serologic response. By inserting gelatine capsules containing 40,000 mouse LD_{50} of the virulent New Jersey isolate into the esophagus, a low-grade infection was established in a few turkeys within 2 weeks. The ingested agent multiplied, invaded the blood stream, was excreted by some birds, and caused severe disease in healthy turkeys exposed in the same pen. By the end of 2 months all the fed and contact birds had rising indirect complement fixation titers, gross lesions, and bedsonemia.

If ornithosis were initiated in a few turkeys by inhalation or ingestion of infective material of extrinsic origin, it could permeate rapidly through a flock, particularly if the birds were crowded and infected excreta were to be either ingested or inhaled (Page, 1959a); the spread may in some way be promoted by cannibalism.

Transmission experiments with isolates of low virulence administered by various routes successfully reproduced clinical and anatomical ornithosis, with a case mortality rate of up to 42 per cent in 1-day-old, 2 per cent in 10-day-old, and no death in 14-day-old turkey poults. Thirty (in groups of 10) healthy control turkeys 6 weeks old, held in the pen with the 65 diseased experimental birds did not get sick, but recovery of the bedsonia and appearance of antibodies proved that isolates of low virulence are as contagious as virulent ones (Gale, 1960). Even isolates from pigeons transmitted to turkeys by exposure to diseased turkeys, apparently by the aerogenic route, were contagious in contact tests (Page, 1960). The isolates of low virulence induced no clinical signs of disease except for fever and marked leukocytosis in turkeys over 2 weeks old, even though internal lesions were extensive.

The localization of the inflammatory

lesions differed in no way from those observed in turkeys infected with highly virulent bedsoniae. Autosterilization has been apparently less active: the parasite of low virulence seems to be better adapted to persist in the organs since it has been found there for over 120 days. The highly virulent parasite disappears around the seventieth day (Gale, 1960). The cellular proliferation, fibrosis, necrosis, and capillary hyperplasia were nearly identical with those noted on specimens collected in an active epizootic among turkeys in a flock parasitized by highly virulent agents (Gale et al., 1960).

The well documented extensive observations by Beasley and his colleagues (1959) and their comparative study of pleuropneumonialike organisms and ornithosis in pure and mixed infections (Beasley et al., 1961) deserve careful study by every poultry pathologist. Changes in the parenchymatous organs in the older birds were essentially proliferative, but they were necrotizing and proliferative in the younger turkeys. The most common cell type in the exudates was the mononuclear macrophage, invariably parasitized by psittacosis-ornithosis particles. In the spleen the reticuloendothelial cells, in the liver the Kupffer's cell, and in the seminiferous tubules the germinal epithelia are the host cells.

Of particular interest are the pulmonary lesions in experimentally infected turkeys because they are rarely a feature of avian ornithosis or psittacosis. Older turkeys dead from spontaneous ornithosis rarely have had pneumonic lesions, but young birds less than 2½ months old infected by the intratracheal route invariably had epithelioid pneumonitis, apparently originating at the primary bronchus extending to involve the portion of the lung ventilated by the bronchus. Just as in man (Lillie, 1933; Güthert, 1938), the monkey (Rivers and Berry, 1931), and the mouse (Kovac, 1961), the infiltration of normally inconspicuous stroma obliterates the respiratory tubules with varying amounts of fibrin, mononuclears, and septal cell proliferation and represents the reaction to the bedsonia in the lung of turkeys. The granulomatous nodules in the lumina of the tertiary bronchi in part explain why turkeys in the third to fourth week after infection are hypersensitive and exhibit cutaneous allergy to the ornithosis antigen. Infections caused by all members of the group induce allergy because they cause granuloma formation.

In contrast to the extensive focal inflammatory infiltrations in the myocardium seen in many fatal human infections (Scheidegger, 1961) it was affected in few turkeys despite extensive epicarditis with capillary hypertrophy. However, the wasted pectoral muscles of turkeys that have succumbed to experimental ornithosis may reveal myositis with extensive fragmentation of the fibers.

In the light of these gross and microscopic lesions, it seems important to search carefully for the cause of the "lower" form of turkey sinusitis, commonly referred to as air sac syndrome. Cultures alone should not be relied on. The similarity of the lesions of pleuropneumonia and pasteurellosis to those of ornithosis emphasizes the necessity for mouse or embryonated egg inoculations with tissues and exudates of diseased turkeys.

Seagulls (Larus ridibundus)

Little is known about the clinical picture or the lesions in gulls. The shot birds dissected by Meyer and Eddie (1952) showed no abnormalities other than the injuries due to penetration by the lead pellets. Strauss et al. (1957) illustrate and describe examinations of the lung of gulls from which they had isolated a bedsonia; they found a focal area of necrosis close to a small bronchus moderately infiltrated by monocytes. Reticulocyte reaction was noted in the spleen. Scattered necrosis and mononuclear granulomas admixed with polymorphonuclear leucocytes were in the liver, but since lesions were similar in a gull infected solely with salmonella they cannot be considered pathognomonic of ornithosis. According to Illner (1962b),

captured adult gulls (two of them) with no gross lesions yielded bedsoniae; *Pasteurella multocida* was cultured from tissues and exudates from those with symptoms of respiratory distress and fibrinous exudates on the pericardium and costal air sacs. Gull chicks may have enlarged spleens, and bedsonia with and without *Salmonella typhimurium* may be isolated from such spleens.

LABORATORY TESTS

Since ornithosis cannot be diagnosed clinically nor by gross anatomical inspection, the pathologist must use laboratory procedures (Meyer and Eddie, 1961) (Fig. 23.8).

Any material containing bedsonia must be regarded as highly infectious and dangerous to handle unless proper precautions are taken. Birds scatter infectious material in moist feces and nasal discharges attached to feathers and particles of down. Dead birds or birds killed with chloroform should be immersed completely in 5 per cent lysol solution; the bird should then be wrapped in lysol-soaked cheesecloth, frozen with dry ice, and preferably sent to a specially equipped laboratory. If the pathologist wishes to conduct his own examinations he should carry out the necropsies in a special room where there is no chance of infective material becoming dried. A special gown, rubber gloves,

and a suitable face mask with goggles should be worn by anyone in the examining room. Inoculated mice should be kept in glass jars with perforated metal lids. Diagnostic experiments on birds should not be undertaken by the inexperienced.

Smears prepared during necropsy from pericardium, serous surface of the liver, hepatic lesions, or spleen are fixed for 5 minutes with methyl alcohol and then stained with a reliable brand of Giemsa's stain for 5 to 20 hours (1 drop of stain to 5 mL of absolutely neutral distilled water). The stained impression on the slide may be differentiated rapidly in absolute alcohol, rinsed in water, dried, and examined (Fig. 23.9).

For rapid examination, the staining methods of Castaneda or of Macchiavello for rickettsia are very useful. Particularly the Macchiavello gives excellent preparations when used as follows: A 0.25 per cent solution of basic fuchsin in distilled water is prepared, and the pH adjusted to 7.1 with sodium carbonate. The tissue smear is dried gently with heat, and the fuchsin solution (dilute carbolfuchsin) is filtered over it through a coarse filter paper in a funnel. The fuchsin is left on the slide for 5 minutes and is washed off very rapidly by dipping the slide in a solution of 0.5 per cent citric acid held in a Coplin jar.

FIG. 23.9 — Intracellular colonies of ornithosis virus in pericardial exudate of a pigeon. Approximately ×1,200.
FIG. 23.10 — Section through chronic fibrinous plaque on pericardial surface of turkey recovering from ornithosis caused by bedsonia of low virulence. Slow, diluted and repeated Giemsa stain differentiated with acidified 70–80% alcohol. (Courtesy of Dr. R. A. Bankowski, Davis, California.)

The acid solution is washed off very rapidly with tap water. The smear is then stained for about 10 seconds with 1 per cent aqueous solution of methylene blue or 3 per cent aqueous malachite green (Mitscherlich, 1955). Excellent contrast stains can be prepared after a little practice; most intracellular and extracellular elementary bodies stain red, and cellular elements stain blue or green (Fig. 23.10).

Impression preparations of exudates stained with Giemsa solution are particularly instructive. Some investigators recommend the following staining (Stamp et al., 1950): Smears after fixing by heating are stained with dilute Ziehl-Neelsen carbolfuchsin (1:10) for 10 minutes and then differentiated very rapidly with dilute acetic acid lightly counterstained with dilute methylene blue. This modification is claimed to demonstrate the particles more distinctly than the Macchiavello method, and when smears stained by this method are examined by dark-field illumination, the bedsonia particles show as bright, pale green, round bodies.

Direct and indirect fluorescent antibody techniques have been used to see bedsoniae in peritoneal exudates of mice and impression preparations from air sacs of birds, but they were not successful in examining the enlarged spleens of chronically infected animals (Fig. 25.11). Impression preparations stained with an aqueous solution of acridine orange (1:50,000) and placed in a moist chamber show the particles in bright
FIG. 23.11 — Elementary forms of psittacosis virus set free from a crushed cell. Peritoneal exudate of a mouse. Approximately ×1,400.

green against a background of dull luminescence (Neustroev et al., 1958, 1959). Results of examination of tissues from naturally infected birds have not been superior to those with the standard methods described.

In a comparative examination of spleen and liver from 44 ducks by the fluorescent antibody technique of Coons and the indirect complement fixation test, the former was more sensitive by about 30 per cent (Zelenkova and Strauss, 1963).

Similar procedures developed by Buckley and his colleagues (1955) for recognizing the intracellular psittacosis particles have been tried to rapidly diagnose ornithosis in turkeys. Explant monolayers of yolk sac cells were seeded with streptomycin-treated specimens of tracheal slime or cloacal content collected on swabs from turkeys suspected to be diseased. By applying the fluorescent antibody to such cultures, developmental stages of the bedsoniae could be recognized and identified early. A diagnosis of ornithosis could thus be rendered long before the mice or embryonated eggs yielded the agent (Donaldson et al., 1958). It is not known whether this method would be sufficiently sensitive and specific to be useful as a field test (Carski, 1961).

Material from birds with gross lesions in which elementary bodies can be seen with the microscope are excellently suited for isolation of the agent by inoculation of mice. Bacteria-free emulsions prepared from blood clots or fibrinous exudates are given to the mice by the intranasal, intracranial, or intraperitoneal route. Attempts to propagate the agent directly from infected birds in the yolk sac of the embryonated egg are not always successful; the parasite must first be enriched or enhanced in virulence by intraperitoneal mouse passage.

If the bedsonia cannot be seen through the microscope, for example in latent infections, separate pieces or pools of fragments of spleen, liver, and kidney of the suspected host are ground up with carborundum or sand to a paste and diluted with broth to a 20 per cent suspension. Cultures in blood broth deoxycholate medium and on blood plates must first be made in order to detect bacterial infections (PPLO, salmonellosis, streptococcosis, aspergillosis, and others). Then 0.5 ml. of the tissue suspension is injected intraperitoneally into each of at least 4 mice. Since isolates from pigeons, ducks, and other birds are only weakly pathogenic for mice when inoculated intraperitoneally, it is often necessary to establish infection by additional intranasal and intracranial inoculation of 0.03 ml. of the sterile suspension in the same animal at the same

time. Repeated intraperitoneal inoculation of the emulsion at 24-hour intervals may prove useful. It is preferable to treat contaminated suspensions with bacteriostatic agents; then pass them through collodion membranes with an average pore size of 450–600mμ (Meyer and Eddie, 1964).

Isolations of bedsonia from the peripheral blood and from fecal specimens are the most reliable and useful diagnostic tests.

Either defibrinated or freshly collected blood in heparin-rinsed syringes may be inoculated intraperitoneally in mice. The clot from a blood specimen carefully collected for serum yields the agent in many cases.

To isolate bedsoniae from excreta, droppings from individual birds or cloacal content from dead birds are suspended in broth or in 10 per cent horse serum in buffered water in the proportion of 1:3. Centrifuge at 500 times gravity for 10 minutes and treat with streptomycin sulfate in a concentration of 2 mg. per ml. of supernatant for several hours. The mixture is inoculated in volumes of 0.3 ml. intraperitoneally into groups of 3 to 5 mice, preferably 3 to 4 weeks old. The inoculated mice are then kept under observation; the spleens are removed from any that die and are emulsified and inoculated intranasally, intracranially, or intraperitoneally into a fresh pair of mice. Use of both the intracranial and intraperitoneal routes is particularly valuable. Those that survive are held under observation for 5 weeks; then they are sacrificed and their spleens used for further passage. Highly virulent material from turkeys causes death of the mice in 4 to 10 days; few mice recover. Material from pigeons, chickens, ducks, and some turkeys inoculated intraperitoneally proves fatal only to a few mice and long after inoculation. Repeated blind passages may be required to produce fatal infection or peritoneal exudates suitable for microscopic examination.

Large amounts of macerated suspected bird tissue emulsions may be inoculated intraperitoneally into mice repeatedly on consecutive days, and this enriches even specimens that cannot be freed of contaminants by antimicrobial drugs and may yield bedsoniae when use of the embryonated egg may fail.

The experimental disease in the mouse is not very characteristic; symptoms and signs consist of ruffled fur, apathy, closed eyes with discharge, and occasionally diarrhea. The incubation period and the severity of the disease depend on the amount of bedsonia in the test material, its infectiousness, its pathogenicity, the route of administration, and the strain of mice. If death occurs within 5 to 10 days the abdominal cavity is lined with exudate that covers the surface of the liver and is rich in elementary bodies. The liver may have undergone necrosis, and the spleen is enlarged. If death occurs between 15 and 30 days, the distended abdominal cavity contains a turbid effusion; the liver and spleen may be enlarged; elementary bodies are usually scant. Isolates of low virulence injected intranasally cause by the tenth day large foci of desquamative alveolitis accompanied by proliferation of interstitial elements (Kovac, 1961). Aggregates of lymphocytes around blood vessels, indicative of interstitial pneumonia, may lead to complete hepatization by the thirtieth day (Babudieri and Moscovici, 1955).

Bacteriologically sterile emulsions of the spleen and liver, in which the elementary bodies are rarely demonstrable, injected intracranially, produce choriomeningitis clinically recognizable by the paralysis they induce. Smears prepared from the meninges and choroid plexus usually show an enormous number of particles. They grow well in the yolk sac epithelium or when injected intranasally produce pneumonitis, the lesions of which furnish specimens suitable for microscopic examination. Demonstration of elementary bodies is considered adequate to establish a presumptive diagnosis of ornithosis. In pregnant mice bedsoniae produce extensive inflammatory and desquamative changes in the fetuses (Scheidegger, 1955).

Laboratories for the study of poultry

diseases may prefer the so-called chicken embryo technique. The tissues, properly macerated in broth and centrifugated, and the supernatant, treated with antimicrobial drugs, are used for inoculation of embryonated (6- to 10-day-old) eggs. The inoculum is introduced into the yolk sac or the allantoic cavity. Embryos dying after 48 hours are cultured for bacteria and the yolk sac membranes are examined microscopically. In the hands of persons skilled in handling embryonated eggs this test has resulted in primary isolations (Dane, 1955; Fagan, 1958). However, only experienced microscopists can identify the elementary bodies in properly stained yolk sac preparations. If tissues contain bedsoniae in low concentration and low virulence, they may fail to kill the embryos; repeated passage is then required.

For routine examinations the white mouse is the best indicator animal for the bedsoniae.

IDENTIFICATION OF THE BEDSONIAE

Field specimens or mouse material to be tested is held in lusteroid tubes at −70° C. until it can be examined. An agent with tinctorial characteristics and a development cycle typical of the group seen in smears prepared from the infected mouse, bird, or chicken embryo yolk sac, may be further identified through special tests.

Complement Fixation Test

Mouse spleen or yolk sac material rich in elementary bodies is converted into a coctoantigen according to the procedures described by Meyer and Eddie (1939a and b) or by Davis (1948) and then is used as an antigen in the direct complement fixation test with high-titered ornithosis antiserum obtained from naturally infected pigeons or produced in guinea pigs by inoculation with live bedsoniae.

Pathogenicity Tests

Inoculation of mice, guinea pigs, hamsters, parakeets, ricebirds, and pigeons with suitable dilutions of bedsonia suspensions by different routes is useful for distinguishing isolates from avian and mammalian sources; these tests separate, to some extent, the psittacine from the columban and from the turkey isolates (Meyer and Eddie, 1952). Most isolates from pigeons, ducks, and chickens have been of relatively low virulence for mice and have to be adapted by passage. As a rule, chicken, dove, and psittacine isolates induce fatal meningoencephalitis following intracerebral inoculation of pigeons. Duck isolates bring about temporary paralysis lasting for a week (Meyer and Eddie, 1952; Strauss, 1956).

Differences in virulence of bedsoniae, from different bird species for mice, the embryonated egg, and birds (particularly turkeys) are striking. Since these differences may reflect fundamentals of the ecology of ornithosis and evaluation of their infectivity for man, such systematic studies by the poultry pathologist are imperative (Page, 1959e).

In connection with pathogenicity and other tests, an estimate of the number of bedsonia particles, or elementary bodies, is essential. The counting method described by Smith and Manire (1959) comparing the number of particles with the number of polystyrene latex particles, under darkfield, phase contrast, or better, fluorescent light, is useful and reliable.

Cross-Immunity Tests

Subcutaneous inoculation of mice, once or several times, with sublethal doses of live or with large doses of killed bedsoniae and subsequent challenge with homologous or heterologous isolates may disclose resistance or susceptibility to certain isolates. While cross-immunity is definite, differences, corresponding roughly to those reflected in pathogenicity tests, become apparent. A weakly virulent isolate may immunize only against homologous challenge. Highly virulent isolates from psittacine birds or pigeons have given variable resistances against every isolate tested. Mice that survived immunization with the standard living virulent parakeet strain 6BC were resistant to 1,000 MLD of several pigeon isolates (Smadel et al., 1945a). The

results of these tests are difficult to interpret with the epidemiologic evidence or pathogenicity tests.

The Illinois pneumonitis strain, highly virulent for mice, has protected against two pigeon isolates (Shaughnessy, 1955). Guinea pigs that have recovered from infection with the egret or Borg strains have been resistant to intraperitoneal challenge with turkey isolates that cause death in control animals in 4 or 5 days (Meyer and Eddie, 1962a).

Lethality-Neutralization Tests

The results of this test have grouped 27 isolates into at least 6 separate groups (Manire and Meyer, 1950c). This technique is valuable in studies on the antigenic relationships of members of this group, but it is generally of little value in determining the exact source of an unknown bedsonia.

Neutralization of Bedsonia Infectivity

Antiserum prepared by hyperimmunization of roosters with known strains is mixed in the test tube with serial dilutions of the isolate to be studied. The mixtures are inoculated intranasally into mice. The animals are killed and examined on the tenth day, and the extent of the lung consolidation is scored according to the method of Horsfall (1939). Using this test, isolates may be classed into several distinct groups quite similar to those established with the toxin neutralization test (Hilleman, 1945).

When homologous toxic bedsonia-serum mixtures in proper proportions are injected intravenously, usually 50 per cent of the mice survive. The protection is quite specific for certain isolates, and several serotypes have been identified consistently. A hyperimmune serum prepared with a parakeet isolate renders 1×10^9 elementary bodies of the homologous strain noninfective. Carefully prepared serum cross-reacts little, if at all, with other avian isolates (Meyer, 1954).

In vitro neutralization tests of trachoma or inclusion blennorrhea in HeLa cell cul-

tures (Reeve and Graham, 1962) may prove applicable to ornithosis bedsoniae.

Serologic Differentiation

In preliminary studies a refined fluorescent antibody technique combined with cross absorption of serum has proved useful for distinguishing the trachoma agents. It may likewise be specific for ornithosis isolates (Nichols and McComb, 1962). Species-specific antigens in the cell wall of the bedsonia can be demonstrated in both the direct and indirect complement fixation tests (Ross and Jenkin, 1962). It is anticipated that once the techniques have been developed it will be possible to establish either the antigenic homogeneity or heterogeneity among isolates from certain avian species suffering from ornithosis. Many problems in the epidemiology and ecology of these infections could be elucidated if the specific antigenic structure of a bedsonia could be determined simply and accurately.

All bedsoniae share a heat-stable group antigen that fixes the guinea pig complement with the corresponding antibodies in the serum of man, monkeys, guinea pigs, cattle, sheep, psittacine birds, many pigeons, and ducks. They also produce heat-labile, type-specific antigens (for example, lymphogranuloma venereum and trachoma) in complement fixation tests with antiserum from which the group antibodies have been absorbed (Rice, 1961). The direct CF test for psittacosis was developed by Bedson and his colleagues (1935, 1937). It has been intensively applied to avian serum at the Hooper Foundation (Meyer and Eddie, 1939a, 1942; Meyer et al., 1939) and modified by others.

Antigens

Crude antigens have been prepared from the spleens or the pneumonic lesions of infected mice. More recently the peritoneal exudate has been used as a source material (Brand and Lippelt, 1954). Tissue cultures grown in Li and Rivers fluid medium or on Zinsser-Wei-Fitzpatrick solid medium (Meyer and Eddie, 1939a) or yolk

sac preparations (Smadel *et al.*, 1943b) are preferred by routine laboratories. Instead of infected yolk sac material, allantoic fluid rich in elementary bodies freed from anticomplementary substance by ether extraction (Davis, 1949), differential centrifugation, and lyophilization (Whitney and Gnesh, 1954) are preferred by some (Christensen, 1957). At the Hooper Foundation the following readily prepared antigen is used.

Inoculate 7-day-old embryonated eggs directly into the yolk sac with a suspension of a standardized virulent psittacosis strain. The suspension of the adapted psittacosis strain to be used is standardized so that most of the embryos die between hour 56 and 72 after inoculation with 0.25 ml. of a dilution of 10^{-4}. This requires a strain that is so adapted that a dilution of 10^{-8} to 10^{-10} kills the embryos. Harvest the yolk sacs as soon as possible after death of the embryos and examine them for elementary bodies; if rich in these bodies, pool and weigh. Grind thoroughly in a mortar with sterile sand and add beef heart broth pH 7.0 to make a 20 per cent suspension (a Waring blender presents risks). Culture for bacterial sterility. Hold in the refrigerator ($0° \pm 4°$ C.) for 3 to 6 weeks, preferably the latter. Centrifuge the emulsion for 30 minutes at 2,500 rpm to remove coarse particles, and put the supernatant in a heavy, sterile Pyrex flask and steam it in an Arnold sterilizer at 100° C. for 30 minutes or immerse it in boiling water for 30 minutes. When cool, add liquefied phenol to a concentration of 0.5 per cent. Permit the antigen to ripen in the refrigerator for at least a week. If the emulsion is kept sterile the antigenicity will be retained for at least a year.

A soluble phosphatide antigen (Volkert and Christensen, 1958) is potent, stable, and easily produced. The method of preparation (Volkert and Christensen, 1955; Jørgensen *et al.*, 1963) is as follows: fresh, heavily infected yolk sacs harvested on the third day after inoculation are boiled for 30 minutes over a water bath, and after cooling, are repeatedly extracted with 10 volumes of cool diethyl ether. The clear yellow ether extract is removed; the ether is distilled off on a water bath at 37° C.; a volume of warm acetone equal to the volume of ether is added to the oily residue; and the mixture is shaken and held at 55° C. for 1 hour. The acetone is decanted, and the precipitate freed from acetone by partial vacuum at 37° C. overnight. Buffered saline is used to suspend the fatty precipitate. This phosphatide antigen is extensively used in the Scandinavian countries (Jørgensen *et al.*, 1963) and the U.S.S.R. (Chervonskii and Popova, 1959).

A water-soluble group complement fixing antigen, efficiently extracted with sodium lauryl sulfate from purified suspensions of the meningopneumonitis bedsonia, has been found more active than the phosphatide antigen or the water-soluble coctoantigen (Benedict and O'Brien, 1956). The molecular configuration of this type of antigen renders the reactive site of the soluble antigen more readily available. Union of antibody and complement is believed to be firmer than with other bedsonia preparations. This type of antigen has been used with varying success in the direct CF test with turkey serum.

Interpretation of any CF or ICF reactions must be guided by the following:

In flock surveys when only a single serum specimen is tested, a titer of 1:4 or higher in the serum of pigeons, turkeys, chickens, ducks, or psittacine birds indicates either latency or recovery from infection. Carriers and active shedders may have high titers. Early in the infection, particularly in young birds, antibodies may not be demonstrable despite the presence of bedsoniae in the tissues. In a flock of pigeons a variable percentage of birds may harbor bedsoniae in spleen and kidney, but CF antibodies cannot be detected in the direct test. On the other hand, it may be impossible to isolate bedsoniae from birds with high titers. Flocks of pigeons yielding serum reacting in titers of 1:4 to 1:256 can be assumed to harbor infected birds. Invariably subinoculations of organs,

singly or in pools, have yielded bedsoniae. The antibody reaction pattern to bedsonia in pigeons has been described in detail (Monreal, 1958).

It is impossible to draw sound diagnostic conclusions on the basis of a test of one serum sample. If the test is being used to evaluate the results of chemotherapy, it is advisable to leg-band the pigeons and test the antibody levels monthly. The titer either remains stationary or rises to a peak and then gradually declines. The efficacy of attempted immunization may be followed by similar systematic examinations.

Persistence of antibodies in high titer for months or years is strong evidence that the bird is latently infected, even though attempts to isolate the bedsonia may be unsuccessful in the larger birds. A rapid or gradual drop in antibodies may indicate complete recovery and disappearance of the bedsonia from the viscera. Repeated serum tests, however, may fail to furnish titers reflecting the actual state of infection in an individual bird. Neither can the infectiousness of a pigeon or psittacine bird be determined from a series of serum tests.

Isolation of the bedsonia from the blood, droppings, or necropsy material remains the only conclusive method of diagnosis in individual birds, but this expensive, time-consuming, and destructive method need not be applied to detect infection in flocks. For this purpose the complement fixation test is reliable and inexpensive (Kissling et al., 1956).

The commercially available lymphogranuloma venereum antigen Lygranum is not a dependable test antigen in the diagnosis of ornithosis. Pigeon or human serum that reacts with a psittacosis antigen may fail to react with Lygranum (Eddie and Francis, 1942; D. J. Davis, 1955; Michael, 1957), thus the existence of a flock infection could escape detection if Lygranum were used. In tests of human serum referred to the Communicable Disease Control Section of the U.S. Public Health Service, 9.7 per cent of those positive in the CF test with a psittacosis antigen were

negative with Lygranum, and 61 per cent of the positive titers were lower than the corresponding titers with psittacosis antigen (Bucca, 1958). Other data are quoted that either antigen in 2 unit amounts is suitable for routine tests (Volkert and Christensen, 1954).

Two further limitations of this test in studying enzootics or epizootics of avian ornithosis or psittacosis deserve mention: (1) Handling and bleeding of the birds endangers those who are not immune. It should be entrusted only to persons with serologic evidence of a past infection or to those who take all of the necessary precautions against infection, including the wearing of properly constructed masks. (2) It may be difficult to secure enough blood to run the test from the peripheral vessels (wing vein or jugular vein) of small birds (Kissling et al., 1956).

The direct complement fixation test is useful in the rapid detection of flock infections in pigeon lofts and parakeet aviaries. The reactor rate in pigeons suspected as sources of human infections has differed significantly from that in groups of feral pigeons that have caused no apparent illness. The latter group has had fewer positive reactors and lower titers than the former (Dekking, 1949; Jansen, 1955). It is advisable to test pigeon serum simultaneously with both the direct and the indirect tests. In old pigeons the indirect test has yielded a higher percentage of reactors than the direct test. Isolation of bedsonia from the organs of reactors in the indirect test has been quite difficult. Apparently as the antigenic stimulus diminishes, inhibiting antibody is produced before all antibody demonstrable in either test finally disappears (Miles, 1954).

Modifications of the test for fowl serum have been recommended: Detergent-extracted antigens (Benedict and O'Brien, 1956) and the usual antigens fortified with normal chicken serum in the presence of turkey serum that have not been heated, but have been stored at $-29°C$, have yielded promising results (Brumfield and Pomeroy, 1957). Agreement between the

results of the direct and indirect tests using detergent-extracted antigen has been found (Neal and Davis, 1958; Page and Bankowski, 1960).

An extract antigen prepared from a Gram-negative coccoid bacterium closely related to *Bacterium anitratum* has been used in place of the specific psittacosis antigen (Volkert and Matthiesen, 1956). Because in the hands of several workers preparation of the *B. anitratum* has not been uniformly successful, the modification of the direct test is not recommended. Prolonged extraction of a saline suspension of a Herellealike bacterium has also been recommended as a substitute (Shimizu and Bankowski, 1963a and b). CF titers with the ornithosis or psittacosis antigen using Brumfield's direct CF test and ICF test were well correlated. Though not as sensitive as the ICF test for avian serum, this modification with a safe and stable antigen, if its reliability is confirmed, could be readily employed as an aid in the presumptive diagnosis of ornithosis in turkey flocks.

Indirect, or Inhibition of, Complement Fixation Test

Certain avian antiserums, including those from the chicken, duck, turkey, pheasant, and older pigeons, infected with bedsoniae do not fix guinea pig complement in the presence of homologous antigen (Rice, 1918, 1961; Karrer et al., 1950; Boulanger and Rice, 1954). Certain avain antibody-antigen complexes fail to activate the first component (C^1) of guinea pig complement; by substituting species specific avian C^1_1, the guinea pig C^1_2, C^1_3, and C^1_4 are fixed, and turkey, duck, and chicken serum may be examined in a modified direct CF test (Benson et al., 1961). The method has not been widely used because the ICF test has proved efficient, sensitive, and specific in diagnosis and serologic surveys (Karrer et al., 1950; Morimoto et al., 1958; Rindge et al., 1959; Page and Bankowski, 1960; Basova and Levi, 1960; Strauss et al., 1958; Strauss et al., 1960). The reaction in the ICF test is revealed by

adding specific CF indicator antibody (serum from a naturally infected pigeon or man or from immunized animals) to the chicken serum-antigen mixtures; if all the antigens have been used to saturate the inhibiting substance in the poultry serum, then none is left to combine with complement fixing antibody and complement yielding hemolysis. The rather difficult but valuable procedure for use in turkey and duck flocks is fully described (Meyer and Eddie, 1964), and an explanation of the reaction patterns has been advanced (Miles, 1954). The interpretation of the results is the same as that of the direct test. In routine tests with poorly collected serum from turkeys, the titer of 1:16 has been arbitrarily set as an indication of infection and should serve as a warning that the disease may appear clinically or anatomically on the processing line.

Microcomplement Fixation Test

Equipment and specific procedures for microtechniques have been refined and modified. Applied to the CF test and to the hemagglutination inhibition tests with standard reagents, the saving is eight-fold (Sever, 1962).

Hemagglutination Inhibition and Conglutinating Complement Absorption Tests

The hemagglutination inhibition procedure is simple, highly sensitive, and has the advantage of detecting complement fixing or complement fixation inhibiting antibody in bird serum (Hilleman, 1955); thus, both kinds of antibody may be detected in a single test. The hemagglutinin is apparently a phospholipid nucleoprotein complex, with lecithin being the agglutinating fraction and the nucleoprotein being the group-specific antigenically active component (Gogolak and Ross, 1955). One disadvantage is that the antigens have deteriorated during storage. The results have been less reliable as indicators of infection than the results of the ICF test (Bucca, 1958). The activity of the hemagglutinins has been well preserved when

the antigen is stored at $-20°$ C. or $-40°$ C. Some have found the hemagglutination inhibition test as useful a diagnostic test as the CF test (Matumoto et al., 1960). A passive hemagglutination reaction with tannic-acid-treated sheep red cells on which the meningopneumonitis protein antigen was adsorbed proved difficult to interpret, since correlation between the CF and hemagglutination reactions could not be discerned (Benedict and O'Brien, 1958).

The conglutinating complement absorption test is not satisfactory because the anticomplementary titer of the antigen preparation usually approaches the antigen titer. The results of both tests with pigeon serum have been somewhat erratic (Hilleman, 1955).

Agglutination Tests

This antibody reaction had been studied only to a limited extent (Bedson, 1932; Lazarus and Meyer, 1939; Labzoffsky, 1946), but interest in it has been renewed. Formalin-killed, purified and concentrated suspensions of elementary bodies prepared from infected mouse lungs (Babudieri and Secchi, 1952; Giroud and Jadin, 1954), or from allantoic or even yolk sac material (Neal and Davis, 1958) have been specifically agglutinated by serum from infected turkeys, chickens, parrots, parakeets, or mammals. Allantoic fluid, harvested 3 to 4 days after inoculation with a virulent turkey isolate, is formalized, centrifuged, and the elementary bodies are resuspended in $1/10$ volume in Sorenson phosphate-buffered water (pH 6) and dispersed by forcing the suspension through a 24-gauge needle by syringe. Giemsa's stain is added, and the suspension permitted to stand at room temperature for 36 to 48 hours. Excess stain is removed by several washings with distilled water at pH 5 to 5.5. The elementary bodies are finally suspended in phosphate buffer at pH 6.0 and dispersed again. Final concentrations are determined by titration against serum of known indirect fixation titer.

Agglutination has been detected by two methods—rapid plate test and the more re-

liable capillary tube technique (Mason, 1959). Serums from infected chickens and turkeys have given good coarse agglutination. The aggregates with pigeon serum have been finer, and with psittacine serum, somewhat intermediate. There has been satisfactory correlation between the results of ICF and agglutination tests, both slide and capillary tube, with turkey and chicken serum. The results seem to be specific for measuring antibody to ornithosis in turkey serum. Reactions at dilutions of $1:16$ or less are considered to be of questionable significance. Findings to date suggest that the capillary tube test may be a valuable aid in screening turkey flocks in epizootic areas before marketing or in conducting epizootiologic surveys. As a rapid test it is useful at autopsies when a few drops of serum separated from the clot in the ventricle of the heart may be mixed with the antigen and a reaction read within 30 minutes.

Antibodies demonstrable by the capillary tube agglutination and CF tests using detergent antigen appear early in the disease. Complement fixing antibodies persisted longer in the blood stream of infected birds than did agglutinins (Mason, 1959; Page and Bankowski, 1960). Testing of 93 serum samples collected during surveys of infected flocks indicated a close correlation (70 per cent) between the results of the CTA and ICF tests. The CF test with detergent antigen gave only a 40.2 per cent correlation; some turkey serum samples reacting in dilution of $1:256$ in the ICF test failed to fix the detergent antigen (Mason, 1959; Meyer and Eddie, 1960, unpublished). For a practical application it must be emphasized that the serologic reactions determined by any one of these three reliable procedures (CTA, CF, ICF) usually do not become detectable for at least 10 to 16 days after infection. Early detection of ornithosis in a flock is of greatest importance in order to control spread of the disease and to prevent human infection. A sensitive specific test, for example, the capillary agglutination procedure or even a slide agglutination test,

can prove the existence of active infection with gross anatomical lesions several days before the bedsonia is isolated. Lack of a practical standard antigen has prevented routine laboratory use.

Intradermal Tests

Crude detergent extracts of the meningopneumonitis agent have been studied experimentally in chickens for the purpose of developing an intradermal test to detect ornithosis (Benedict, 1958a). Birds experimentally infected for less than 3 weeks showed either no reactions or reactions of varied intensity (Benedict et al., 1955; Benedict and McFarland, 1956b). The skin test used in naturally infected flocks yielded 85 per cent and the ICF test 92 per cent reactors, or 85 per cent agreement; in another less severely diseased group the agreement was 76 per cent (Benedict and McFarland, 1958). The claim by Soviet investigators and others that intradermal testing is the most practical for extensive ornithosis surveys is open to question (Terskikh, 1957a; Terskikh et al., 1962). For epizootiologic surveys the skin test requires repeated handling and examination of birds, some of which may be infectious and pollute the environment in which the personnel is exposed during the testing. The skin test to diagnose the infection in individual birds or man is unreliable; indeed it would be subject to the same criticisms as have been made against the intradermal test for diagnosis of other infections in man and animals. Individual birds and man may react though they were never infected with bedsoniae.

IMMUNITY AND ACTIVE IMMUNIZATION

The immunity is not completely understood. The immunity of many parrots after an attack is nonsterile, and it was formerly believed that persistence of the psittacosis agent was obligatory for the immunity. More recent studies indicate that latency is the sequel to incomplete or delayed autosterilization, due to host cell adaptation to new variants of the bedsoniae (Officer and Brown, 1960). In fact, considerable evidence supports the idea that the resistance is an innate constitutional one, reinforced by a short-lived infection. Individual squabs, chicks, parrots, or parakeets may resist massive injection of bedsoniae, readily destroy them and never become carriers. Others either succumb to small doses or recover and the infective agent remains in their organs for years. Since constitutional factors determine the ability of birds to resist infection, it should be possible through selective breeding to develop strains of birds that will not acquire a nonsterile immunity, so eminent a source of persistent infection in lofts and aviaries (Meyer and Eddie, 1962a).

Formalin-treated or ether-extracted, inactivated, concentrated bedsonia suspensions have conferred considerable immunity to mice, but have not completely prevented multiplication of the infector (Bedson, 1938; Meyer et al., 1942b). Mice hyperimmunized by the intraperitoneal route with killed 6BC and Borg bedsonia have resisted 10 homologous or heterologous intracerebral or intranasal LD_{50} (Wagner et al., 1946). Effective immunity has been established when immunizing and challenging doses have been given by the intraperitoneal route (Yanamura and Meyer, 1942). Concentrated tissue cultures treated with formalin, administered intramuscularly in as many as 7 injections, have protected ricebirds and parakeets against homologous challenge of 100 MLD. The immunity has not been strong enough to protect against massive challenge. Preliminary experiments failed to encourage hope that a practical safe method of active immunization of parakeets with inactivated bedsonia could be developed (Meyer et al., 1942b).

Hughes (1947) vaccinated alternate pigeons from the same nest when they were 3 weeks old and again 3 weeks later with a formalized, inactivated yolk sac pigeon ornithosis antigen prepared according to a modification of a method worked out by Smadel et al. (1913b). When the birds vaccinated by Hughes were exposed to natural infection for 4 months, 6 vaccinated

birds and 5 in the control group died of ornithosis.

In ewes, formalin-inactivated enzootic abortion bedsonia eliminated abortion if the vaccine, prepared from infected ovine fetal membrane, was incorporated in an adjuvant (McEwen *et al.*, 1955; McEwen and Foggie, 1956). This suggests that further efforts with vaccines in adjuvant might be rewarding.

In a critical review on the immunity against bedsonia infections several pilot experiments are described that suggest that psittacine birds could be immunized with concentrated formalin-inactivated psittacosis vaccine in adjuvant (Meyer and Eddie, 1962a). In search of a way to prevent acute ornithosis in turkeys, and in doing so reduce the risk of occupational infections, vaccination with formalin-inactivated vaccines in adjuvants was evaluated with the following results: (1) Three intramuscular inoculations 1 month apart conferred some immunity against intratracheal infection with a highly virulent strain: there were still gross lesions in a third of the turkeys sacrificed on the thirtieth day after challenge. The bedsonia was recovered from 14 of 101 vaccinated turkeys. Bedsonemia on the tenth day after challenge was, as a rule, not demonstrable in vaccinated birds. (2) Half of the unvaccinated had extensive gross lesions and the inoculated agent was recovered from 20 (47 per cent) of 42 surviving unvaccinated turkeys. (3) A single inoculation gave less protection. Concentration of the bedsonia doubtless would enhance immunogenicity, but with present production methods it would increase the cost beyond practicability (Meyer and Eddie, 1962a).

In the few studies in which it was tried a more effective immunity has been achieved with living bedsonia vaccines. In guinea pigs inoculated intradermally with virulent psittacosis or murine pneumonitis isolates, resistance to intratracheal challenge was developed against 40 respiratory LD$_{50}$ (Wagner and Victor, 1953). In earlier experiments (Rivers and Schwentker, 1934) monkeys were immunized against intra-

tracheal inoculation by intramuscular injection of small doses of a virulent psittacosis strain. Active immunization of fowl with living attenuated bedsonia even if successful is not practical and is of doubtful value in the control of ornithosis.

CHEMOTHERAPY

Early studies of the effects of antimicrobial drugs on certain bedsoniae revealed that they delay or stop multiplication but are not completely bedsonicidal. Tetracycline compounds have been effective in treatment, given in the dosage of 0.8 mg. in 2 injections daily for 14 days (Meyer and Eddie, 1954b and 1955). In chick embryos chlortetracycline is five times as effective as chloramphenicol on a molecular basis, and three times as effective on a weight basis (Cox, 1955). Chlortetracycline is the preferred drug for human infections caused by ornithine and psittacine bedsoniae (Fitz *et al.*, 1955). Symptomatic improvement in man is commonly prompt if treatment is begun immediately after the onset with 1 to 2 gm. daily and is continued long enough. Inadequate treatment or exceptional susceptibility may be followed by relapse. In one exceptional outbreak, broad-spectrum antimicrobial drugs did not control psittacosis contracted by infants through contact with pigeons (Berman *et al.*, 1955). It may be that in these cases the drugs, being only bedsonistatic, received little or no support from immunogenesis, which failed in the malnourished infants suffering from gastroenteritis and dehydration.

Early studies on treatment of latent avian psittacosis and pigeon ornithosis were discouraging, but in a later one daily parenteral or oral therapy with up to 100 mg. of tetracycline compounds per kilogram of body weight has improved the health of individual pigeons, reduced mortality, curbed epizootics, and reduced the hazard of infection in aviary personnel (Meyer and Eddie, 1955; Arnstein *et al.*, 1964). It does not always eliminate the carrier state in every bird, but if treatment of backyard flocks is repeated at intervals of one month,

the infection may be ultimately eradicated (Meyer et al., 1958).

Several field trials to eradicate ornithosis from squab farms with tetracycline compounds were disappointing. Intensive treatment by injection of aqueous solution or sesame oil preparations with tetracycline failed to free the latent carriers, or the isolation procedures were inadequate and favored heavy reinfection (Meyer and Eddie, 1955). Under controlled laboratory conditions the mortality rate fell during administration of chlortetracycline in a concentration of 80 gm. per gallon of water for a month, and squabs did not become infected. However on commercial breeding farms where chances of reinfection from a heavily soiled environment are ever present, it suppressed the bedsonia activity only temporarily and some birds have remained carriers (Shipkowitz et al., 1958).

Pigeons will eat a chicken scratch feed containing crude chlortetracycline SF 66 (4 per cent by weight of the feed). In small pilot experiments on naturally infected pigeons, 700 mg. of chloramphenicol per bird, administered orally continuously or interruptedly for 7 days, exerted a promising therapeutic effect (Jansen, 1955; Fritzsche et al., 1956). Parenteral administration of this drug is claimed to cause shock and death in pigeons; such side effects have not been observed when tetracycline compounds were used.

In a field trial clinically healthy but latently infected (serologically proved) 5- to 6-week-old ducklings (85 per cent infected) were offered feed that contained 0.5 mg. of chlortetracycline/gm for 11 days Only traces of the drug could be found in the blood during treatment. When the treated ducklings were dressed, 1 of 11 women employees (15 to 53 years old) contracted a subclinical infection (16-fold rise in titer). The 4 pools of spleen and liver prepared from 48 treated birds yielded the ornithosis agent. The 500 untreated control ducklings caused no infections, and only 2 of 56 organs pooled were proven infected with the agent (Strauss et al., 1961).

Extensive experiences in the treatment of psittacosis in parakeets and parrots suggest that the dosage and duration of chemotherapy were inadequate, particularly since the holding of the birds in large groups offered opportunity for continuous reinfection.

Experiences with chemotherapy of parakeets encouraged the use of tetracycline compounds to suppress ornithosis in turkeys. In 1952, epizootic ornithosis was treated with chlortetracycline at concentrations of 100 to 400 gm. per ton of feed. The epizootic subsided, but processing personnel contracted the infection in several instances. Subsequently pilot experiments with artificially implanted turkey poults were reported. Treatment with 400 and 800 gm. of drug per ton was instituted immediately for 7 days after infection and continued for 14 days, and this completely suppressed the infection (Davis and Delaplane, 1955). In a natural outbreak turkeys were given supervised treatment with 200 gm. of chlortetracycline per ton of feed for 3 weeks. Infection was suppressed, but at the time of processing, 288 of 1,856 toms were condemned because of aspergillosis. Residual lesions of ornithosis were present, but bedsonia was not recovered by the chicken embryo technique from tissues removed at the time of slaughter (Davis and Delaplane, 1958b). Treatment of epizootics in Minnesota caused by bedsonia of low virulence was also successful (Pomeroy et al., 1957).

These successes could not be repeated in the Oregon outbreaks. Three flocks were treated, during a progressive epizootic, with chlortetracycline and oxytetracycline at a dose of 200 to 400 gm. per ton of feed. The clinical response was favorable, but bedsoniae were isolated from organs of treated turkeys when processed after 32 or 39 days of continuous treatment. All 3 treated flocks, when processed, caused human infections. In systematic studies on normal and infected turkeys under supervision at a poultry experiment station the oral ad lib. intake of pellets containing 221 to 354 gm. of oxy-

tetracycline per ton failed in some cases to yield demonstrable antibiotic levels in the blood or organs, but these were found in the cloacal contents. The fecal material contained 96 to 480 micrograms of drug per gram. Therapeutically effective levels have been found in turkeys when the mash contained 2,800 gm. per ton and the calcium level of the feed was reduced with a chelating agent (6 gm. of sequestrin/pound of feed).

Because present knowledge is incomplete, no recommendations can be made. It is not unlikely that tetracycline compounds in economically practical dosage may be used to prevent severe infections and epizootics.

In transmission experiments ornithosis did not spread from artificially infected to healthy poults when the infected birds were fed 100 gm. of chlortetracycline/ton of feed. Beginning on the second, third or fourth day after intratracheal inoculation of 0.5 ml. of chick embryo material infected with a virulent Texas isolate, poults were offered feed containing 200 gm. of drug per ton. The infection was apparently aborted, mortality prevented, gross lesions were suppressed, antibodies did not develop, and the infected turkeys proved susceptible to reinfection. In another study adult turkeys that recovered from ornithosis with or without tetracycline therapy developed significant levels of ICF antibodies and proved resistant to subsequent challenge (Davis and Watkins, 1959). Oxytetracycline (terramycin) was unsatisfactory for therapy at 200 gm/ton, whereas this dose of chlortetracycline did eliminate the agent from the tissues. When the birds were fed 600 to 800 gm/ton for 3 weeks, infection was completely prevented. Terecephalic acid and low calcium diet enhanced the chemotherapeutic efficacy of tetracycline (Moore and Watkins, 1960). A crucial experiment to test the prophylactic efficacy of chlortetracycline in the low level of 10 gm/ton, an amount commonly incorporated in turkey feed for growth promotion under field conditions, has not been made. This low level has no inhibitive effect on the course of the infection induced by intratracheal infection even when treatment was begun immediately after infection (Davis and Delaplane, 1955).

Another later report (Francis, 1960) of a field observation is encouraging: A flock of 2,200 Broad-Breasted Bronze turkeys, 6 to 9 weeks old, lost 130 to 150 birds during the week before ornithosis was diagnosed. On the fifth day after treatment, with feed containing 200 gm. of chlortetracycline/ton being offered, the daily mortality dropped to 1 or 2 turkeys a day, and after 3 weeks no further deaths occurred. The epizootic was definitely arrested, and the total mortality in the flock was maintained at 300 birds. Of interest is the observation that drug intake for at least 3 weeks was required to arrest the ravages of the ornithosis agent.

Prolonged feeding of 200 to 400 gm. of drug per ton of feed has not freed the tissues of all diseased turkeys from bedsoniae. The infective agent has continued to be a risk to the processor, and birds not thoroughly and carefully eviscerated might endanger the person who prepares them for cooking. Some bedsoniae have acquired drug resistance in a variety of hosts; their tendency to chronicity increases their potentiality for developing drug resistance. This possibility is especially significant in connection with programs designed to eradicate ornithosis from poultry or psittacosis from psittacine birds by chemotherapy (Gordon et al., 1957). Apparently this risk is not great; several isolates from the organs of turkeys treated for 3 months and of parrots for 50 days have been drug sensitive (Meyer and Eddie, 1958b; Arnstein et al., 1963, unpublished).

EPIDEMIOLOGY

An estimate of the number of human infections acquired from contact with poultry is given in Table 23.1. In the United States between 1952 and 1956 the source of diagnosed psittacosis was sought in only half of the cases. In 1955 neither the occupation of the patient nor the source of infection was determined in 191

(57 per cent) of 333 cases (Andrews, 1957). Mild infections characterized by only malaise and minor respiratory symptoms undoubtedly go undiagnosed.

The sources of infection in man have changed since the outbreaks of 1929 and 1930 (Roger and Lépine, 1961).

Birds of Pleasure and Show

Since 1876 these birds have caused 4,000 reported apparent or inapparent infections. Exposure to cage birds in the home or occupational contact by bird breeders, dealers, pet shop owners, and employees in zoological gardens have been documented.

Oceanic Birds

Petrels were responsible for human outbreaks, principally among adult women on the Faeroe Islands; occasional infections have been traced to sea gulls (*Larus* sp.) and muttonbirds (*Puffinus tenuirostris*); egrets are suspected in the Louisiana outbreak of psittacosis. Human disease on the Faeroe Islands stopped when the killing and preservation of fulmars for food was discontinued.

Pigeons

Human psittacosis of pigeon origin has been traced to pigeon lofts or to flocks of racing pigeons (Meyer and Eddie, 1942; D. J. Davis, 1955). On the basis of serologic studies (Mohr, 1954; Meyer, 1958) it is estimated that around 50 per cent of pigeon breeders have significant serum titers. Few cases attributable to contact with feral pigeons have been reported. Pigeons in parks and streets constitute some hazard to people who come into contact with the dust from dried droppings (Levinson *et al.*, 1944; Mach *et al.*, 1950; Fallet, 1951; Lépine and Sautter, 1951; Fischer, 1955; D. J. Davis, 1955; Shaughnessy, 1955; Weyer and Lippelt, 1956; Babudieri, 1956; Berman *et al.*, 1955; Ephrati-Elizur and Bernkopf, 1956; Parry and Griffith, 1962). The history of exposure often incriminates dust of pigeon-roosting or nesting areas without direct contact with the birds

(Cohen *et al.*, 1946; Boucher and Sautter, 1951). The cleaning of wooden houses holding homing pigeons in the back yard of urban or rural dwellings constitutes an important risk (Meyer and Eddie, 1942; Dekking, 1950; Dekking and Ruys, 1951; Ellenbogen and Miller, 1952; Bacon, 1953; Deyke and Meyer, 1955; Schoop and Kauker, 1955; Semple, 1956; Monreal, 1959; Jansson, 1960).

Although there seems to be no evidence of widespread epidemic human infection of pigeon origin, the reports of fatal infections in infants (Berman *et al.*, 1955) and the relatively high incidence of sporadic, subclinical, mild-to-severe infections among pigeon fanciers and dealers indicate a public health hazard (Dekking, 1950; D. J. Davis, 1955; Shaughnessy, 1955; Parry and Griffith, 1962). In flocks responsible for human infections there has been a high proportion of reactors in the complement fixation test, and the ornithosis agent has been isolated from 50 of 60 and from 16 of 18 pigeons examined (Mohr, 1954; Kemmerer *et al.*, 1956). For enzyme studies two biochemists and two animal caretakers using the organs of one of seven pigeons all proved infected by isolation of the bedsonia, and students making psychological observations on visibly sick birds acquired confirmed clinical and subclinical infections. These group illnesses attest to the high contagiousness of pigeons in the acute stage of ornithosis. Repeated surveys of pigeons held for experiments in laboratories revealed CF titers greater than 1:32 in 30 to 50 per cent of the tested birds (Meyer and Eddie, 1947–62, unpublished observations).

Chickens

Infection has been contracted from chickens only when contact has been very close (Meyer and Eddie, 1942; Karrer *et al.*, 1950a; Duncan *et al.*, 1952). The recognition of a single case of psittacosis in a poultry processing plant in Connecticut led to an industrial survey and the discovery of 12 of 50 employees with high serum titers particularly among those hav-

ing direct contact (eviscerations) with chickens (Rindge et al., 1959).

Ducks and Geese

Histories of mild cases of atypical pneumonia among duck handlers were identified as psittacosis on Long Island (Korns, 1955) and in Virginia (Andrews, 1957). The many recent reports on human ornithosis in Central Europe document that ducks and geese play the same public health role in Czechoslovakia (Strauss, 1957; Strauss et al., 1961; Serý et al., 1961), East Germany (Kukowak, 1961a and b; Kukowak et al., 1960; Siegmund, 1960; Kielstein, 1961; Ortel, 1961, 1963), Austria (Fürst et al., 1957), Hungary (Derzsy, 1958; Varnai et al., 1960; Dömök, 1963), Poland (Parnas et al., 1961), Bulgaria Kuyumgieff, 1957), Roumania (Sarateanu et al., 1960), and the U.S.S.R. (Terskikh, 1954, 1957b) as turkeys have in the United States. In rural areas during small outbreaks, workers on small poultry breeding and fattening farms and then employees in poultry-processing plants are victims of the infection. Dr. Vladimir Serý contributed Tables 23.6 and 23.7 showing the places and numbers of human infections and the avian sources suspected of causing 1,072 cases of psittacosis

in Czechoslovakia during the past 10 years. Intimate contact with diseased ducks during picking and processing caused at least four times as many occupational illnesses in poultry plants as on farms. This relationship, conditioned by the more intimate and continuous exposure to the duck ornithosis agent, is illustrated by slightly different findings in a study of ornithosis in eastern Slovakia (Strauss et al., 1960). On a duck farm on which 1,350 of 7,000 ducklings died, 8 of 10 employees contracted psittacosis; 6 patients had pneumonitis and 2 had influenzalike attacks. Serologic surveys among 213 persons on 111 small poultry farms and poultry hatcheries revealed only 24 significant antibody titers. Twenty-one of the reactors who had histories of clinical illness (11 hospitalized: 8 pneumonitis, 2 influenza, 1 typhoidlike illness) belonged to the feeding and tending personnel in close contact with the ducks. Just as observed during the epidemiologic studies in Bohemia (Serý et al., 1957), only 3 members of duck-keeping families, without histories of illness, reacted with significant CF titers.

The Czechoslovakian epidemiologists stressed that ornithosis was relatively frequent in young women, and that it is

not always benign. The two-phase course of the disease is frequently complicated by meningeal manifestations and myocarditis.

More important are the frequent recrudescences that, according to Serý (1962), were recorded in 94 patients within 6 months, but more often within 1 month among 1,072 ornithosis cases. Many were relapses, since once the patients had had the disease they avoided contact with infected poultry. On the other hand, in 19 persons the attack 6 to 60 months after their first attack must be considered reinfection. They occurred during the annual seasonal outbreaks and only in workers who returned to the heavily contaminated environment of the farm or processing plants. Recrudescences were reported in persons who discontinued work in the poultry industry. During an outbreak of ornithosis in East Germany due to contact with ducks, 56 of 70 treated patients had one to three or more relapses from the first to third week after the body temperature had returned to normal (Gneuss and Koitzsch, 1961). Chloramphenicol and tetracycline in the total dose of 15 gm. (daily intake of 1.5 to 2 gm. for 7 to 10 days) was probably inadequate. Other factors, perhaps an unusual bedsonia, may

have been responsible for the high incidence of the relapses. Reinfections may reflect early treatment with antibiotics, hence no immunity conferred by the infections; they are not confined to the duck ornithosis agent but occurred in persons infected with psittacine and turkey agents (Meyer and Eddie, 1956c and 1962a; Irons et al., 1955). Care of recently hatched ducklings and cleaning of pens on a duck farm caused 6 cases of psittacosis in Austria (Fürst et al., 1957). The sporadic cases during April through June, 1945, on Long Island were all in persons who came in intimate contact with ducks (Korns, 1955).

Turkeys

The epidemiology of the explosive outbreaks due to exposure to sick and grossly diseased turkeys deserves detailed discussion. Since 1948, and particularly since 1952, persons processing adult turkeys have contracted ornithosis (Table 23.8). The CF titer in the tested sera of the workers who were ill increased 4- to 8-fold. Five outbreaks, consisting of at least 96 cases with 7 deaths, occurred in Giddings and El Campo, Texas, in 1948, 1951, 1952, and 1953. All illnesses affected workers who had been dressing young turkeys for the Thanksgiving or Christmas market or had

been handling adult birds marketed at the end of the egg-laying season. Illnesses ranged in severity from minor influenza-like attacks to fatal toxemia. In most cases in which X-rays were made, evidence of pneumonitis was observed.

The clinical attack rate in 135 presumably exposed workers was 33.6 per cent, despite the fact that scarcely more than three years earlier an outbreak of psittacosis had occurred in workers in this plant. Eight of 22 persons who had psittacosis in 1948 were again exposed as pickers or eviscerators in 1951. Five escaped (apparently immune) but 3 suffered reinfection.

Nine others apparently exposed in 1948 became infected again in 1951 or 1952.

Since 1952, use of broad-spectrum antimicrobial drugs has seemed beneficial, but relapses have been frequent in treated patients. In an outbreak from April through July, 1954, over 264 persons were infected, and one of them died (Irons et al., 1955). No cases were reported from September through December that year, and in the period there was an apparent low incidence of visibly diseased turkeys on the processing lines. Protective measures adopted by some plants may have helped keep the incidence low. The extent to

which acquired immunity of the workers might participate would be difficult to learn In 1965 the National Office of Vital Statistics, Public Health Service, U.S. Department of Health, Education, and Welfare, listed only 1, possibly 2, human infections resulting from contact with turkeys in Texas.

The processing of visibly diseased turkeys in California in 1954 did not cause infection in workers in the plant. Of 88 employees tested, the sera of 3 gave CF reactions. Sera from residents or employees of the turkey ranch where the infected flock was raised did not give CF reactions This is the first instance in which a bedsonia isolate of low virulence was found.

A thorough study of several outbreaks in Oregon disclosed the following: Of 13 workers on a farm where many birds had died of ornithosis, 2 were ill and I had died in February 1956. Of 9 workers on the other affected farm, 3 were ill when the epidemiologic investigations were undertaken The serologic reaction of 1 was positive and of the other 2 suggestive of psittacosis. At a rendering plant where dead turkeys from both farms were taken, 70 per cent of the employees (5 cases confirmed, 21 probable) had ornithosis. In a private home where some of the turkeys were dressed, the husband contracted severe psittacosis pneumonitis, proved by isolation of the bedsonia, and died; the wife recovered from a respiratory infection and had a CF titer.

During May, 1956, of 102 workers in a processing plant where apparently healthy turkeys from a third nearby farm were procesed, 52 developed signs of ornithosis. Complement fixation tests were positive in 7.

Of 86 persons who became ill (2 deaths) in the 1956 outbreaks in Oregon, 5 worked on turkey farms, 55 were employed as poultry processors, and 29 were employed in rendering plants. Hospitalization was required by 28, sometimes for several weeks. The infection was believed to have been air-borne, because many of the affected persons did not have physical con-

tact with turkey carcasses (Scruggs, 1957) The rendering (converting diseased carcasses into fertilizer) did create infective aerosols, as subsequent studies demonstrated (Spendlove, 1957). Diagnosis of psittacosis was based on the results of serologic tests interpreted with clinical and epidemiologic data. A total of 313 persons in contact with diseased turkeys or turkey products or exposed to aerosols and dust created by the handling, processing, or disposing of such birds, who contracted an illness like psittacosis were classified as confirmed, probable, or possible cases. Persons in direct contact who had no illness, but in whom a 4-fold or greater rise in CF antibody titers was demonstrated were classified as inapparent infections. Only 9 of the 95 serologically recognized infections were subclinical or inapparent. The attack rate ranged from 21.8 to 48.8 per cent in processing plants and was as high as 71 per cent in rendering plants. Exposure to a highly virulent bedsonia induced a higher incidence of clinical than subclinical infections.

In this respect it differed from that noted in poultry plants in which only ducks, geese, and chickens are processed. Though psittacosis acquired through exposure to ducks may be just as severe as psittacosis contacted from psittacine birds or turkeys, the relationship of 1 clinical to 2 subclinical infections lends some support to the contention that infections originating from water fowl and other poultry are milder. Generalization should be avoided, but the several observations (Graber, 1957, 1959; Meyer and Eddie, 1962a) imply that clinical cases are fewer when workers are exposed to turkeys infected with ornithosis agents of low virulence than when the strains are highly virulent.

Epidemiologists trying to analyze occupational ornithosis in processing plants have found it difficult to interpret the antibody titers of the employees since it was soon recognized that a variable percentage had titers at the time they contracted the illnesses that clinically were not typical for psittacosis. During the outbreaks

in Oregon, blood specimens routinely taken from the employees in several processing plants before they became involved in outbreaks furnished a serologic baseline that aided in diagnosing the illnesses among the workers.

Observations on serologic baselines led to the suggestion that a rough estimate of the degree of exposure or the incidence of ornithosis in poultry flocks at certain times of the year could be obtained if serologic tests were made at frequent intervals (McCulloh, 1955; Rosen, 1955; Osgood et al., 1956; Dickinson et al., 1957; Graber, 1957; Hines et al., 1957; Rindge et al., 1959). This reasoning is justified because with few exceptions illness among the employees has served as a sentinel for the unrecognized or often incorrectly diagnosed epizootics in turkeys that came to slaughter. Baseline antibody reactions are equally important to support decisions about whether an illness in a plant worker is acute psittacosis, a reinfection, or a relapse and whether he is entitled to compensation.

MODE OF TRANSMISSION

There are three known pathways of transmission from bird to man which are in order of importance, (1) through circulation of the bedsoniae in the air (Fig. 23.12), (2) through handling sick or dead birds or having contact with feathers, excreta, or nasal discharges of sick or latently infected birds and (3) through bite wounds. The ease with which inhalation of bedsoniae induces pneumonic lesions in susceptible mammals points directly to the respiratory tract as the principal entry. Handling of sick or dead birds or contact with feathers soiled with infective discharges or excreta or with droppings from latently infected flocks—all capable of creating bedsonia-carrying aerosols—are fully proved modes of infection (Rugiero et al., 1950; Mumme, 1955; Osgood et al., 1956; Spendlove, 1957). In experimental studies on primates (McGavran et al., 1962) the psittacosis agent was seen to be impinged along the respiratory bronchiole. It spread, perhaps along the lymphatics,

and lobular and confluent lobular pneumonia resulted from extension of the single focus. Recovery of bedsoniae from the blood, liver, and spleen emphasizes the systemic nature of the infection.

The clinical nature of the illness is related to the dose and virulence of the bedsonia (Gordon et al., 1957) and to the portal of entry. Little is known about the possibility of infection of man by the gastrointestinal tract. The bovine enteritis agent is excreted in the feces of cattle, and when it is fed to calves it induces illness, but the relation of this and the ornithosis and psittacosis agents, also excreted, to human disease is unexplored. It seems possible that the infector might be swallowed after hand to mouth transmission from the environment of an infected bird. As far as is known, human beings have not contracted psittacosis by ingestion of infected poultry. Bedsoniae are destroyed by heat, and poultry is ordinarily cooked long enough to destroy them. When concentrated highly infectious suspensions of the turkey ornithosis agent were spread on bread and given to mice they contracted generalized infections, most of them accompanied by pneumonia (Page, 1959a).

Poultry ornithosis can spread to any susceptible person in contact with an infected bird or its infective excretions. The probability of infection roughly parallels the extent of exposure, but high susceptibility, high virulence, or both may make even short exposure a risk.

The poultry flock in this country may be a small one raised by a farmer to supply his own family with food, or it may be an enormous commercial venture concerned with flocks numbering in the ten thousands. Those who may contract the infection from the flock are flockowners and their families and neighbors, anyone who visits the premises for any reason, flock caretakers, and anyone whom the flockowner may call in to ⟨...⟩ the flock when the illness becom ⟨...⟩ ive, such as feed company ⟨...⟩ products representatives, ⟨...⟩ spe-

cialists, and veterinarians (Irons *et al.*, 1955; Osgood *et al.*, 1956; Schmidtke, 1957; Strauss *et al.*, 1960).

The next group to be exposed comprises all who participate, even indirectly, in preparation of infected birds for food. Anyone who removes the feathers and viscera from an infected bird is under some exposure as is anyone on the premises while this is being done. This includes housewives, cooks, butchers, all processing plant employees, especially killers, pickers, and eviscerators, but also plant superintendents and office workers, poultry inspectors, and anyone who removes the viscera from New York-dressed poultry. Certainly the processing of large flocks of infected birds provides ample opportunity for the bedsonia to spread to human beings. If the plant is not well ventilated, high concentrations of bedsoniae can build up. Undirected air currents may carry them throughout the plant. People who kill and defeather the birds are likely to come into contact with the droppings, and if the birds struggle and flop around, the bedsoniae are likely to be dispersed into the air (Ortel, 1961; Otto, 1962).

Still another group, exposed rather more at the periphery, is composed of those who dispose of infected dead birds or parts not used for food. This includes rendering plant employees and those who dispose of feathers and entrails and those who clean feces from eggs. In Oregon, 29 of 43 rendering plant employees became ill. It seems possible that unclean duck or goose feathers could carry the bedsonia; in some processing plants they are treated with heat. In Czechoslovakia, the age at which the infected ducks were slaughtered (4 weeks) suggests use of the feathers rather than use of the bird for food.

The recent poultry plant outbreaks have followed the seasonal marketing of large flocks for the holiday season in October to December or the culling of the flock after the egg-laying period, in April through June, particularly when flocks with unusual mortality are processed to protect the owner from further losses. The former seasonal incidence of psittacosis from psittacine cage pets, related to the Christmas exchange of birds and the closed winter household, should not mislead suspicion with respect to poultry. During May to August, 139 (4 per cent) of 3,150 members of families who kept ducks after they were taken from the incubator of a poultry farm contracted psittacosis (Serý and Strauss, 1957). Benign psittacosis was observed throughout the year among persons directly or indirectly exposed to pigeons which are usually bred all year (Mohr, 1954; Mumme, 1955; Kittel, 1955; Weyer and Lippelt, 1956). Steele and Scruggs (1958) called attention to the peak incidence from May through July but could find no satisfactory explanation for the increase at this season, apparent even when the occupational infections were excluded.

In the processing plant outbreaks there has been no noticeable difference in the susceptibility of men and women. Exposure has been a more critical factor than either age or sex.

Laboratory Infections

The incidence of laboratory infections bears emphasis. During the height of the experimental investigations after the epidemics of 1929 and 1930, 38 laboratory infections were contracted and 5 of the infected died. In the United States from 1931 to 1956, 70 laboratory-acquired infections with 7 deaths remind scientific personnel and animal caretakers that utmost care must be taken in handling specimens suspected of carrying bedsoniae and in carrying out the diagnostic procedures (Moltke, 1932; Sulkin and Pike, 1949; Meyer and Eddie, 1958a). At the Statens Serum Institut in Copenhagen, among a staff of 5, 4 contracted psittacosis—a charwoman, a technician and 2 physicians. One of these physicians contracted the disease three times (Christensen, 1957a). Eight of the laboratory personnel working on the Texas outbreak became infected, some of them repeatedly (Davis and Delaplane,

1955), and workers handling turkey bedsoniae from Oregon and New Jersey have also become infected.

The case fatality rate for the outbreak of psittacosis due to contact with psittacine birds in 1892 was 35 per cent in France, and in 1929 and 1930 involving many countries, nearly 20 per cent. In some outbreaks it was 40 to 100 per cent, but with the recognition of mild infections the rate was about 10 per cent. Then with the introduction of antimicrobial drugs it has fallen to 5 per cent in the United States and to 3.5 per cent (86 cases) in Germany (Haussman et al., 1956) and on down to 0.5 per cent in 550 cases during 1955 to 1957 (Reinwein and Walther, 1961). Most of the patients who died were 40 to 60 years old. A recent analysis of the Faeroe Island outbreaks due to contact with infected petrels corrects previous statistics. It revealed that in the over-all reported mortality of 22 per cent (182 cases with 40 deaths), there existed a noteworthy difference in the fatality rates of nonpregnant and pregnant women. In men and nonpregnant women the rate was 16.2 per cent (154 with 25 deaths) but in 14 pregnant women with 11 deaths, it rose to 78 per cent (Vaag, 1959).

Under the title, "Domesticated pigeons do not carry or spread disease to human beings," the author of "The Pigeon," Wendell M. Levi (1960), repeats that pigeons are not potentially dangerous as spreaders of psittacosis, that the human fatality of 1 per cent misrepresents the case, and that children under 10 years old cannot catch psittacosis. Present knowledge contradicts these statements: (1) All recent studies and reviews, not all officially recorded, support the view that the pigeon is a noteworthy reservoir of ornithosis throughout the world, causing clinical and subclinical human infections (Jansson, 1960) (2) In the 164 cases of psittacosis proved epidemiologically and in some instances through isolation of a bedsonia of low virulence, 8 patients (4.8 per cent) died; some patients died even though they had been treated with antimicrobial drugs. (3) Infants and children may die of psittacosis (Berman

et al., 1955; Ephrati-Elizur and Bernkopf, 1956); in fact, the case fatality rate in 24 cases epidemiologically assumed to be due to contact with pigeons was 33 per cent.

The mortality in poultry–particularly turkey–processing plant employees has certainly not been negligible: 2 of 22 in one outbreak, 4 of 44 in another (Irons et al., 1955), 2 of 86 in another (Osgood et al, 1956), and 1 of 41 in two plants in Texas (Leachman and Yow, 1958). The deaths occurred in cases not clinically recognized as psittacosis; broad-spectrum antibiotic therapy either was not instituted at all or was much delayed, or the injury to the liver and kidney was by then so extensive that treatment was ineffectual (Yow et al., 1959). Despite the low death rate of 1.3 per cent in 150 cases observed during some outbreaks due to contact with ducks, ornithosis is a serious disease; the convalescence may be long and tedious. Even after a year of convalescence, working capacity may be restricted and it may lead to severe involvement of the cardiopulmonary system (Strauss, 1957).

PROPHYLAXIS, SUPPRESSIVE AND CONTROL MEASURES

Prophylaxis and control of ornithosis in poultry must take into consideration (1) prevention of epizootics and spread of infection among poultry, (2) protection of the flockowner and workers in processing and rendering plants, and (3) the consumer. In the United States, the official steps taken can be applied to poultry in general, though they were adopted as measures against occupational human psittacosis due to diseased turkeys. German veterinarians recommend that ornithosis in pigeons be suppressed by reducing the feral pigeon population in cities and by treating racing pigeons with antimicrobial drugs at regular intervals (Monreal, 1963).

Measures to Prevent Ornithosis on Poultry Farms

The United States Department of Agriculture, according to a regulation passed on April 9, 1957, prohibits the movement

of poultry, carcasses, and offal from premises where the existence of ornithosis has been proved by isolation of the bedsonia. The Agricultural Research Service, U.S. Department of Agriculture, and the Food and Drug Administration forbid movement of all birds from infected flocks in interstate commerce.

Until the means by which this infection spreads has been learned, the flockowner can only apply the general principles of control of infectious diseases. He should be informed about this disease through agricultural authorities and trade journals. If he finds evidence of disease during daily observation of his flock, he should at once isolate any sick birds and submit dead birds to a poultry laboratory. This is very important because sick birds excrete bedsoniae and the environment can become hopelessly contaminated as an epizootic progresses. Early isolation of the sick birds might go a long way toward checking its spread throughout a flock.

The acquisition of infected poultry is a means of introducing the disease into a flock. All breeders should make every effort to acquire any new stock from flocks known to be free from this infection.

Immunization has not been considered warranted. It would be necessary first to develop an effective immunizing preparation, a potentially difficult research problem, and then to solve the problems, technical and economic, of commercial production. This would be a major undertaking, and it is questionable whether a vaccine could be produced at a cost low enough to permit its routine use. The outlook is not very promising.

Once the infection has been diagnosed another difficult control problem is apparent. Treatment with antibiotics in the feed or water does reduce morbidity and mortality, but it is expensive and, with the dosage and treatment schedule recommended, of uncertain effectiveness. For the time being, if virulent ornithosis has been proved to exist on a farm it is imperative to depopulate the entire premises of birds in a manner to be decided by the agricultural disease control agency in consulta-

tion with the local or state health department. Dead birds should be disposed of in some way that insures that the bedsoniae will not be spread, either to other birds or to man. The methods have been described by Bodenweiser and Peterson (1958). Eggs from infected flocks should be thoroughly disinfected and hatched in separate incubators. There are no restrictions of the movement of eggs from infected flocks. Hatcherymen have refused to handle eggs from farms where the infection may be widespread; no assurance can be furnished that they are not unknowingly handling eggs from infected flocks. Poults should be under observation and supervision by the poultry division of the state department of agriculture. All poultry quarters should be thoroughly disinfected with hot lye solution after the disposal of the infected flock. The cost to the flockowner and the cost of continuous supervision make it seem unlikely that ornithosis-free flocks can be established.

The poultry industry should stimulate greater interest in the specific diagnosis of poultry diseases, and it may be found necessary for more diagnostic laboratories to include tests for ornithosis. This already seems warranted. Any excess of serum samples collected for *Salmonella pullorum* tests could be used. The existence of ornithosis can be readily established through serum tests and examination of a few sick birds. Although neither the clinical course nor the gross lesions are characteristic enough to allow diagnosis without bedsonia isolation, or at least serologic tests, the existence of a diarrheal or respiratory infection causing oxidation on organs of the peritoneal cavity should provoke suspicion. Agricultural agencies should insist that poultry inspection services report any suspicious lesions observed on the processing line (Meyer, 1955).

Protective Measures Against Human Infections in Processing Plants

Any poultry diagnostic laboratory that recognizes ornithosis in poultry should at once notify public health authorities so that they can advise physicians in the

area of the possibility of human infection. The flockowner must be informed that he, his family, flock caretakers, and anyone who comes on the premises may be under exposure and at risk of infection. The symptoms of the oncoming disease should be described so that medical attention will be sought early in the course. Care of a flock undergoing a severe epizootic requires extra work, and this may lower the resistance of the caretakers.

Unfortunately the processing plant group has been the first point at which the infection in the flocks has been recognized, especially in the turkey outbreaks. Ideally, if the infection had already been diagnosed in the flock this group would never come into contact with the bedsonia. When flocks with high infection rates caused by highly infective bedsonia are processed, the incidence of disease and latent infection among processing plant personnel will be high. The plants can be expected to refuse to process flocks in which the infection is suspected rather than subject plant personnel to the risk. If the plant were to send out inspectors to observe the flock before it is moved into the plant, the inspector might notice signs of the infection such as droopiness of the birds and evidence of extensive diarrhea in yellowish droppings. Although this alone cannot be relied on to reveal the infection, it is a necessary part of the inspection. General sanitation and ventilation in the plant might lower the risk, but exposure in certain phases of the processing is likely to be extensive. If the flock is to be processed despite the suspicion of infection, the personnel must take pains to minimize distribution of the infective particles adherent to the wings and in the organs, but particularly the exudates and feces should be regarded as highly infections (Meyer, 1964).

The poultry meat inspector must promptly notify his superior and the plant manager when he encounters gross lesions suggestive of ornithosis. Laboratory tests must decide whether the lesions are caused by bedsonia or other agents.

Unfortunately, most of the processors have already been exposed when the diagnosis is made. Then the personnel must be informed of the possibilities and all physicians in the area must be notified. Now that effective treatment is possible, serious illness or death can be prevented in most cases if treatment is given early enough. The problem has been that the infection has not been recognized, sometimes not until after several people have died of psittacosis pneumonitis.

In districts where turkey ornithosis annually appears as latent epizootics of varying intensity, contact with grossly diseased carcasses passing through processing plants where the birds are dressed is unavoidable. Employees of such establishments should be under constant public health and occupational hygiene supervision; serologic tests should be made at frequent intervals. If they have been exposed to diseased birds they should remain under medical supervision and care. In case they contract psittacosis they must be treated thoroughly with antibiotic drugs.

To protect rendering plant employees, such as truck drivers and plant workers, one problem is to prevent formation of heavily infected aerosols during plant operations. The bedsonia is destroyed within 3½ to 5 minutes at 132.8° F. (56° C.), so that after proper cooking the byproducts can be considered safe. Rendering plants should install any special equipment needed, the plants should be well ventilated, and the ventilation system should be constructed so that they constitute no risk (see Oregon State Board of Health: Joint Statement of Policy, etc., 1956).

Protection of home processors is considerably more complicated, but this group should be observed, especially if processing plants reject flocks and unscrupulous poultry raisers are left to dispose of their flocks in any way possible.

Protection of the Consumer

So far as is known the infection has not been contracted through ingestion. The danger of infection in market poultry is in the eviscerating, and it has been con-

tracted in the dressing of even frozen birds (Bowmer, 1958). The U.S. Department of Agriculture Regulations Governing the Inspection of Poultry and Poultry Products (1961) recommended that the sale of birds from which the viscera have not been removed be prohibited, and if this recommendation were followed, the person who prepares the birds for the table would be protected. The finding of antibodies against the group antigen in people who have had no known contact with psittacine birds suggests that poultry dressing may have introduced the infection and that it went undiagnosed. It is fairly certain that ornithosis has been prevalent on pigeon and duck farms for some time, and doubtless thousands of infected birds have been distributed through commercial channels without recognized harm to the consumer.

Early public actions prompted by outbreaks of psittacosis among the personnel on breeding and fattening farms of water fowl, particularly ducks and geese, mainly in eastern Europe, devoted considerable speculation to preventive measures (Kielstein, 1961). After the war, keeping and fattening of ducks became a profitable undertaking since a breed of ducks was developed that, under optimal conditions of feeding, was ready for consumption within 8 to 9 weeks. The rapidly growing industry presented many new problems and risks to the operators and employees of processing plants. Since the early investigators were epidemiologists and public health workers their interest focussed on prevention of the workers; they unanimously agreed that the establishment of ornithosis-free duck breeding and fattening farms would eliminate human disease. Subsequent investigations by veterinarians showed that this would be difficult because of the complexities of the already known and the many unknown factors on the farms. According to the latest reports of experts, the hygienic measures must take into consideration the following: proper intensive and diversified feeding, avoidance of crowding of the birds on stagnant polluted water, installation of running water, drainage through concrete-lined interchannels, and repeated serologic examination of duck blood samples in order to gauge the extent of the ornithosis in the flocks. These measures may check the progressive epizootization of the duck population and in turn reduce the number of infected birds that reach the poultry processing plant. Heavily infected flocks should be promptly slaughtered and processed under veterinary and medical supervision.

Complete eradication of ornithosis is not anticipated in the near future. Every reasonable means, however, should be adopted to keep the infection rate of the flocks low. Attention must be paid to ducklings infected in the egg. When visibly sick, they must be isolated. The risk of infection to duck flocks through contact with wild birds is considered minimal (Voigt et al., 1962). To reduce the build-up of the bedsonia infection within the duck population and their environment, Wolff (1961) recommended chemotherapy and prophylaxis similar to that used in the U.S.A. on turkey farms. The experiences with attempts to free pigeon flocks from ornithosis (Meyer and Eddie, 1955; Shipkowitz et al., 1958) should warn the proponents that this type of prophylactic measure, even if partially effective, is economically and administratively impractical. All control measures must adapt themselves to the prevailing epizootic, regional, and economic situations.

Until the measures outlined have been tested and proved effective, the German physicians and veterinarians insist that no efforts be spared to protect the poultry farmers, their families, and the workers in the poultry plants by breaking the transmission chain from ducks and geese to man. Efforts should be made to recognize the epidemic and sporadic human cases through constant medical supervision and prolonged chemotherapy (Grantova and Milek, 1962). Of special interest are the following actions taken: Regulations have been promulgated to enforce prolonged scalding of the carcasses at temperatures

above 60° C. (140° F.) (Grahneis and Horn, 1961), mechanical plucking of feathers, and evisceration in order to reduce infective aerosols. This procedure does not prevent contact or "smear" infections. Continuous disinfection within the processing plant and proper spacing of the employees on the working benches in the installations is considered important. Since personnel continuously exposed to bedsonia may acquire some resistance it is recommended that inexperienced susceptible housewife brigades should not be drafted in emergencies for service in poultry processing plants. To minimize concentration of the infective agent the flock should be observed antemortem and any visibly sick birds

eliminated. Distant transportation and holding of the birds without food and water in crowded cages for long periods before slaughter, particularly during July to October when ornithosis is prevalent, should be avoided. Combinations of environmental stresses contribute to the conversion of latent to active infection with heavy shedding and dispensing of the infective agent within and without the bird delivered to the plants (Wolff, 1961; Thamm, 1964).

Early recognition of ornithosis in poultry, in particular turkey and duck farms, is essential and basic in providing effective hygienic and prophylactic measures to prevent losses and human infections.

Avian Encephalomyelitis
(Epidemic Tremor)

Avian encephalomyelitis (AE) is a viral infection which affects primarily young chickens and is characterized by ataxia and tremor, especially of the head and neck. Jones (1932, 1934) first described and designated this disease as epidemic tremor. However, later the name infectious avian encephalomyelitis was given to this malady by Van Roekel *et al.* (1938, 1939). In 1939 the binomial, avian encephalomyelitis, was recommended by the Committee on Poultry Disease Nomenclature of the American Veterinary Medical Association (Beach, 1939).

HISTORY AND DISTRIBUTION

Jones (1932, 1934) first encountered the disease in May, 1930, in 2-week-old Rhode Island Red chicks received from a commercial flock. Only tremor, but no ataxia, was observed in this outbreak. In April, 1931, a second outbreak was observed in 1-week- and 4-week-old chicks on two different farms, but originating from the

same breeding flock. Tremor and ataxia were noted in these two outbreaks. During the ensuing two years, the author saw an increasing number of outbreaks which occurred in Connecticut, Maine, Massachusetts, and New Hampshire. Since then, an increasing incidence of the disease has been reported by others from widely separated areas.

Recent surveys in this and other countries reveal that the distribution of the disease, while limited, presents an interesting geographical picture. Responses to the survey revealed that the disease had been observed in Australia (Seddon, 1952), Canada (Anon., 1958), England (Markson and Blaxland, 1955), Japan (Kuba, 1964), Korea (Lee, 1958), Scotland (Wilson, 1958), Sweden (Lindgren *et al.*, 1957), and Union of South Africa (Coles, 1956). The geographical distribution of this disease has been reported on every continent in the world. Information obtained from the Animal Health Yearbook, Food and Agri-

culture Organization of the United Nations, reveals that there are countries on each continent where the disease is either suspected or has been confirmed (Animal Health Branch, 1963). This is not surprising since many countries in the various parts of the world have received stock from the United States where the disease is widespread. The virus may be egg borne and hence disease may be disseminated via the egg or through young chicks. Its behavior is very similar wherever it occurs and may be a serious economic problem in the broiler industry, hatcheries, and in certain breeding establishments. Its sudden appearance, often with great severity and unpredictable duration, are reasons for great concern on the part of the breeder, hatcheryman, and broiler producer. While not a major threat to the industry at large, it may be of great economic significance to those individuals who experience the disease in their flocks. Adjustments for chick losses from the disease have been very costly to hatcherymen and hatching-egg producers.

ETIOLOGY

Jones (1934) was the first to propagate successfully the causative agent of the disease in susceptible chicks by intracerebral (IC) inoculation with brain material from spontaneous cases. Experimental infections in chicks revealed signs of the disease 6 to 44 days, with an average of 12 to 28 days, after intracerebral inoculation. The disease was produced more readily upon increased serial passage of the agent in the chicks. Similar observations have been reported by other workers (Olitsky, 1939; Van Roekel et al., 1938; Jungherr, 1939). Jones (1934) demonstrated that the agent was filterable through Seitz and Berkefeld N filters and that the virus in brain tissue could be preserved in 50 per cent glycerin for at least 69 days. Van Roekel et al. (1938) confirmed the filterability of the agent through Seitz and celloidin filters, and Olitsky (1939) reported the agent capable of passing through Seitz 1 and 2 disc filters and

Berkefeld V and N candles. Later, by gradocol membrane filtration, the virus was reported to have a diameter of 20 to 30 mμ (Olitsky and Bauer, 1939). In sedimentation of the virus through centrifugation, Jungherr and Minard (1942) were successful in obtaining a noninfective supernate at 20,000 r.p.m., while the sediment induced infection. Olitsky (1939) was unsuccessful in demonstrating complete sedimentation of the virulent virus after angle centrifugation at 5,400 and 12,000 r.p.m. for one hour.

Fresh hatching eggs and embryonating eggs, 5 to 17 days old, inoculated with virus brain suspensions by various routes, have produced chicks with signs of the disease (Van Roekel et al., 1939, 1941). Among 807 fresh hatching eggs inoculated in nine different trials, and then incubated, only 149 chicks hatched, of which 71 showed signs of AE, some as early as on the day of hatching. Among 370 embryonating eggs inoculated at 10 to 11 days of age, 206 chicks hatched and 44 manifested signs of the disease. These observations were confirmed in part by Jungherr and Minard (1942), but they reported that inoculation of the agent via the chorio-allantoic route failed to produce evidence of the disease in the hatched chicks. Likewise, Kligler and Olitsky (1940) could not demonstrate the virus in the allantois 4 days after inoculation. On the contrary, Feibel et al. (1952) were able to demonstrate the presence of the virus in the allantoic fluid in dead and live embryos 7 days post inoculation.

Recently, the successful propagation of the virus in embryonating eggs via intraocular, allantoic cavity, and yolk sac routes has been reported (Jungherr et al., 1956; Wills and Moulthrop, 1956; Sumner et al., 1957a). The behavior of this virus in chicken embryos will be described under pathogenesis.

Multiplication of the virus in Maitland type cultures of minced whole embryo tissue in vitro in the presence of chick serum has been reported by Kligler and Olitsky (1940). Virus growth was not de-

tected in this medium when embryo brain was substituted for whole embryo tissue. Propagation of the virus in tissue culture has not been reported.

Olitsky (1939) also investigated the behavior of the virus of eastern equine encephalomyelitis in chickens and found that it differed from AE virus.

PATHOGENESIS

Primary isolation of the virus by chick inoculation may yield variable or negative results even though brain material is used as inoculum via the IC route. Jones (1934) inoculated 91 chickens IC with brain and spinal cord suspensions and obtained positive evidence of the disease in only 5 birds, 3 developing symptoms and 2 manifesting only lesions. She concluded that the infective agent was present in the brains in only a small proportion of the chicks selected for the inoculum. Jungherr and Minard (1942) found that among 19 spontaneous cases of AE, 11 takes were obtained in inoculated chicks on first passage and only 5 could be passaged regularly. The percentage of takes on first passage varied from 53 to 100 with an average of 41. The incubation period varied from 18 to 70 days with an average of 28 days, and the titers of the strains ranged from 10^{-2} to 10^{-3}. These workers also stated that the virus concentrations in original material were either low- or sub-infective. However, these viewpoints may not be entirely valid in the light of more recent knowledge that the stock used for inoculation may have had either a passive or active immunity (Sumner et al., 1957a, 1957b).

Van Roekel et al. (1938) noted that in a series of 42 passage experiments with a composite of 2 field strains of virus, the percentage of takes increased from 59 to 88 and the incubation period was shortened from 23 to 9 days. Also the period from first symptom to death decreased with increased serial passage of the virus. It is quite evident that primary isolation of the virus by IC chick inoculation may fail to produce signs or lesions of the disease, but

as the virus becomes adapted in the chick, the disease is readily reproduced even with a decimal dilution of infective brain suspensions as high as 10^{-6} (Olitsky, 1939).

The intracranial route of inoculation has given the most consistent results in reproducing the disease in chickens. Other routes by which the infection has been established in the chicken are the intraperitoneal, subcutaneous, intradermal, intravenous, intramuscular, intrasciatic, intraocular, and intranasal (Olitsky, 1939; Van Roekel et al., 1939; Jungherr and Minard, 1942; Feibel et al., 1952; Schaaf and Lamoreux, 1955). Unsuccessful trials to reproduce the disease via the oral route have been reported by Jones (1934) and Olitsky (1939).

The brain and spinal cord are the most promising sources for virus isolation, although other tissues and organs produced evidence of the disease when inoculated into chicks (Jungherr and Minard, 1942; Van Roekel et al., 1938).

The isolation of the virus from other tissues of the body, aside from the brain and cord, is logical to expect since histopathological evidence of the disease is seen in many tissue sites in spontaneous cases. Jungherr and Minard (1942) observed that feces from adult AE affected flocks contained a filterable factor which is capable of producing brain lesions which were indistinguishable from spontaneous AE virus infection. Feibel et al. (1952) were able to demonstrate the presence of virus in allantoic fluid in embryonating eggs 7 days post inoculation, but were unsuccessful in producing a death pattern after at least 6 "blind" serial passages.

More recently, successful propagation of the virus in embryonating eggs, inoculated via the allantoic and intraocular routes, has been accomplished (Jungherr et al., 1956; Sumner et al., 1957a). Virus passed by the intraocular route produced a titer of 10^{-6} after 11 serial passages; whereas, the allantoic route passed virus attained a titer of 10^{-2} after 9 passages. Wills and Moulthrop (1956) were also successful in propagating the virus in embryos using

FIG. 24.1 – Avian encephalomyelitis, 19-day-old embryos: (left) uninoculated, normal; (right) inoculated, shows a marked stunting and muscular dystrophy.
the yolk sac route of inoculation. This route of inoculation was adopted later by other investigators (Sumner et al., 1957b; Calnek and Jehnich, 1959a; Moore and Flowers, 1959; Taylor and Schelling, 1960). The advantages of embryo over chick propagation of the virus have been emphasized, which should greatly facilitate the investigations concerning the disease.

The salient signs and lesions observed in AE embryos are decreased movement and occasionally retardation of growth. Live infected embryos examined at 20 days of age may show a persistent heart beat, but the voluntary muscles would be partially or completely immobilized (Jungherr et al., 1956) (Fig. 24.1) Calnek and Jehnich (1959a) made similar observations concerning the behavior of the virus in embryos. The isolation and propagation of the virus in eggs selected from susceptible flocks is recommended. It also has been emphasized that the isolation and propagation of a field virus be passed in susceptible chicks before attempting to adapt it to susceptible embryos (Poultry Disease Subcommittee, 1963). Calnek and Jehnich (1959a) found that the virus could be detected in the brains of inoculated

embryos 2 to 4 days post inoculation and peak titers (log 5.7 to 6.1) were found 6 to 8 days post infection. The histopathology in the embryo revealed changes that were uniform in character but variable in intensity and location and consisted of encephalomalacia and muscular dystrophy. Among 48 embryos inoculated, 45 exhibited lesions in the central nervous system and 43 showed lesions in the skeletal muscles. The neural lesions were characterized by severe local edema, gliosis, vascular proliferation, and pyknosis. The muscular changes consisted primarily of eosinophilic swelling and necrosis, fragmentation and loss of striations of affected fibers with rare sarcolemmal proliferation and heterophil infiltration (Jungherr et al., 1956).

EPIZOOTIOLOGY

The disease may be observed in all seasons of the year, although it has been suggested that a minor seasonal incidence may occur in November and December and a more pronounced increase from January to June (Jungherr and Minard, 1942). The time and frequency of occurrence of the disease presents a challenging question as to the source of the infection.

In young chicks the disease can nearly always be traced to susceptible parent stock that has experienced a recent infection. In such parent stock one may find, in retrospect, a decline in egg production that usually is transient and may or may not be marked. Taylor and Schelling (1960) reported that susceptible breeding flocks which exist at 5 months of age that some may not encounter the infection for a period of 13 months. At 5 months of age approximately 56.8 per cent of the flocks were immune and at 13 to 18 months of age 95.7 per cent were resistant to the virus based on the embryo susceptibility test. This means that as mature breeding flocks become infected, the virus may be eliminated in the egg and passed on to the chick. The source and mode of spread of the infection to adult breeding flocks is not understood at present (Jungherr and Minard, 1942; Schaaf and Lamoreux, 1955). Naturally infected chicks up to 7 weeks of age have been reported (Jones, 1934). Chickens of all ages are susceptible to the infection by experimental inoculation (Olitsky, 1939; Van Roekel et al., 1939; Feibel et al., 1952).

Evidence of morbidity of the natural disease has been observed only in young stock, although inapparent infections do occur in mature flocks. The usual morbidity rate has been in the range of 10 to 20 per cent with a maximum limit of 60 per cent (Jungherr and Minard, 1942). A high incidence of the disease has occurred in all breeds and under many types of management. The average mortality rate is around 10 per cent and may exceed 50 per cent (Van Roekel et al., 1938).

Natural transmission of the disease has presented a baffling problem. Earlier investigations failed to demonstrate the disease in progeny hatched from eggs obtained from breeders that survived a natural infection (Jones, 1934; Bottorff et al., 1936; Van Roekel et al., 1941). Considerable field evidence and some experimental results show rather conclusively that the infection is egg borne (Van Roekel et al., 1941; Jungherr and Minard, 1942; Schaaf

and Lamoreux, 1955; Taylor et al., 1955; Calnek et al., 1960).

Transmission of the disease by direct or indirect contact, either with naturally or experimentally infected chickens, has been reported. Calnek et al. (1960) suggest that avian encephalomyelitis is an enteric infection in growing and adult birds. The virus may be eliminated in the droppings in sufficient concentration to infect young susceptible chicks by the oral route. Chicks placed in a battery in a contaminated poultry house became infected but to a much lesser degree than chicks in direct contact with infected chicks. Clinical signs occurred among susceptible chicks in contact with infected chicks 11 days after hatching. With the virus strain used, the minimum incubation period following oral administration of the virus-contaminated feces was 11 days. It was suggested that in the field most of the chicks hatched from susceptible dams may become infected as the result of contact with a few egg-borne infected chicks. Attempts to transmit the infection by aerosol means, using a modified Horsfall unit, yielded negative results. Richey (1962) incriminated a ready-to-lay pullet flock housed in the same building but in a separate pen as the source of the infection for outbreaks that occurred in several susceptible breeding flocks 45 weeks of age. Previous history of the pullet flock revealed that it had experienced an acute outbreak of the disease at 3 weeks of age. It was suggested that a "carrier" existed in the pullet flock. While certain aspects of transmission of the disease have been well established, there are other phases that remain unanswered.

Schaaf and Lamoreux (1955) stated that incubator transmission of the disease does not occur, and Jungherr and Minard (1942) reported that hatchability was not affected. On the contrary, Taylor et al. (1955) reported a high embryo death pattern during the last three days of incubation. The percentage of hatchability declined from 78.6 preinfection level to 59.6 during the clinical stage and in-

creased to 75.4 post infection. Eggs produced just prior to and during the period of depressed egg production showed a decreased hatchability and an increased embryonic mortality during the last three days of incubation. Furthermore, the chicks from the hatch with depressed hatchability were the only chicks to show signs of the disease, while the chicks hatched prior to and after the affected hatch appeared normal. Similar observations have been reported by other workers (Calnek *et al.*, 1960; Richey, 1962).

Calnek *et al.* (1960) demonstrated that transmission of the infection can occur in the incubator. Three groups of susceptible eggs were selected. One group was inoculated at 6 days incubation, a second group was uninoculated, but the 2 groups incubated in the same incubator. A third uninoculated group was hatched in a separate incubator. Upon removal of the chicks from the incubators the 2 groups hatched in the same incubator were distributed in wire batteries as well as the uninoculated control group hatched in a separate incubator. The chicks from the inoculated group manifested signs on the first day of age and by the sixth day 49 of 52 showed clinical evidence of the disease. The chicks from the uninoculated group first manifested signs on the tenth day and 15 of 18 chicks exhibited clinical evidence. The control group of 19 chicks remained negative.

Birds recovered from natural and experimental infection develop antibodies in their serum capable of neutralizing the virus (Olitsky, 1939; Jungherr and Minard, 1942; Feibel *et al.*, 1952; Sumner *et al.*, 1957a; Calnek and Jehnich, 1959a, 1959b; Moore and Flowers, 1959; Taylor and Schelling, 1960). In a flock survey for embryo susceptibility to the virus, Sumner *et al.* (1957b) found a wide range in the titration end points of the AE virus in eggs received from 119 flocks. A majority of the tested flocks had no history of AE but produced embryos resistant to the virus, suggesting a mild infection. It was suggested that in an immune flock not all

hens are immune to a degree measurable by the test. Olitsky and Van Roekel (1952) reported that chicks inoculated with an active virus and which failed to show clinical signs of the disease may not be rendered resistant.

The AE virus appears to have a limited host range, including the chicken, pheasant, and Coturnix quail, which have succumbed to natural infection. Hill and Raymond (1962) were able to produce clinical signs of avian encephalomyelitis in quail chicks 1 to 14 days of age. The experimental chicks were maintained in the same room with the adult breeding quail. Fifteen days after the chicks were inoculated, the adult flock manifested a decline in egg production and hatchability. Clinical evidence and mortality were observed among the chicks hatched from eggs collected during the outbreak of the disease. Ducklings, turkey poults, young pigeons, and guinea fowl have been infected experimentally. Mice, guinea pigs, rabbits, and monkeys were refractory to the virus introduced intracerebrally (Van Roekel *et al.*, 1939, 1940; Olitsky and Van Roekel, 1952; Mathey, 1955).

In view of the limited investigations concerning host susceptibility, it would appear most desirable that further studies be undertaken with the improved methods to evaluate the status of the various animal and avian species concerning avian encephalomyelitis.

SYMPTOMATOLOGY

This disease presents an interesting syndrome which may be characterized as follows:

The disease usually makes its appearance in natural outbreaks when the chicks are 1 to 2 weeks of age. Affected chicks have been observed at the time of hatching. The incubation period of the experimental disease varies from 5 to about 40 days, with an average period of 9 to 21 days. Affected young chicks, as a rule, will show first a slightly dull expression of the eyes which is followed by a progressive ataxia or incoordination of the leg

muscles. This ataxia may be detected readily by exercising the chicks. As the ataxia grows more pronounced, the chicks show an inclination to sit on their haunches. When disturbed, such chicks may move about, exhibiting little control over the speed and movement of their gait, and finally come to rest on their haunches or fall on their sides. Some chicks may refuse to move or they may walk on their hocks and shanks. The dull expression becomes more pronounced, accompanied with a weakened cry or an inability to cry. Tremor of the head and neck may become evident. The frequency and magnitude of the tremor may vary. Exciting or disturbing the chick may bring on the tremor, which may continue over various periods of time and recur at irregular intervals. The ataxic signs, as a rule, appear before the tremor, but in some cases only tremor has been observed or may occur prior to the ataxic signs. Jungherr (1939) states that of the histologically positive field cases, 56.9 per cent showed ataxia, 18.3 per cent showed tremor, and 35 per cent both; 9.2 per cent showed no clinical signs. The ataxia usually progresses until the chick is incapable of moving about, and this stage is followed by inanition,

prostration, and finally death (Figs. 24.2 and 24.3). Chicks with marked ataxia and prostration are frequently trampled upon by their pen mates thus hastening death. Some chicks with definite signs of AE may survive and grow to maturity, and in some instances the signs may disappear completely. Among 83 naturally infected chicks reared at the laboratory, only 24 survived after a period of 8 months. Seven of the 24 survivors developed a blindness as the result of an opacity or bluish discoloration of the lens of one or both eyes (Fig. 24.4). A few progenies from these survivors, as they became mature, developed an eye condition that resembled the condition observed in the naturally infected dams. The gross pathology consisted of an apparent enlargement of the eyeball, a marked opacity of the lens, seemingly fixed pupil, and total blindness in some cases. No characteristic signs of AE were detected in these progenies (Van Roekel *et al.*, 1936, 1937). Somewhat similar observations have been reported by other workers (Peckham, 1957; Bridges and Flowers, 1958).

While the disease has been reported to occur in adult flocks, as substantiated by a decline in egg production, positive sero-

FIG. 24.2 — Avian encephalomyelitis in experimentally inoculated chicks. Chick 1 appears normal; chicks 2, 3, and 4 show various stages of the disease.

logic evidence, and presence of the disease in its progeny, it is of interest that typical signs of AE as seen in chicks do not occur in natural outbreaks in mature birds. Since seminature and mature chickens fail to manifest signs of the disease, one might suspect spread of the virus to occur constantly in a population, and such a process can be detected most readily by serological means.

PATHOLOGY

The lesions are only microscopic. The principal histopathologic changes are distributed among the central nervous system as manifested by gliosis, perivascular infiltrations, neuronal degeneration, and in the viscera as hyperplasia of the lymphoid follicles involving primarily the myocardium, proventricular and ventricular

FIG. 24.4 — A mature pullet having survived an attack of avian encephalomyelitis shows an opacity of the lens.

muscles, and the pancreas (Jones, 1932; Olitsky, 1939; Jungherr and Minard, 1942). No meningeal reaction except a perivascular infiltration of the vessels was observed by Olitsky (1939). Neuronal degeneration was most striking and common among lesions distributed throughout the central nervous system, especially in the pons-medulla and anterior horn cells of the spinal cord in the region of the lumbo-sacral enlargement. The progressive changes consist of an enlargement of the neuron and its nucleus, nuclear eccentricity, tigrolysis, and clearing of the cytoplasm of the Nissl bodies, and in the advanced stages the neuron may disappear completely. In early stages of the infection, there may be occasionally no other sign of involvement of the nervous tissue, especially no inflammatory reaction. The latter, however, is likely to occur in the anterior horns of the cord. Jones (1934) reported the occurrence of severe degeneration of Purkinje cells, while Olitsky (1939) claimed that these cells are usually well preserved and that only here and there some cells show degeneration, especially in the later stages of the disease. Also, in chronic ataxia some indications of neuronophagia and satellitosis may be found. Perivascular reaction may be very pro-

nounced throughout the entire brain, especially in the cortex, pons-medulla, and cerebellum (Figs. 24.5 and 24.6). Perivascular changes were essentially absent in the cord. Demyelinization was not observed, although Jungherr (1939) did note occasionally myelin degeneration in the sciatic nerve. Jungherr and Minard (1942), in a study of 283 spontaneous cases, found the focal lesions in the central nervous system to be comparatively mild and quite independent of the severity of the symptoms.

The visceral lesions consist of hyperplasia of the lymphoid follicles, which are normally quite irregularly distributed throughout the tissues (Fig. 24.7). The hyperplastic follicles are of two types — the one having an irregular outline without a definite boundary, and the other being oval or circular in shape and surrounded by a delicate, capillarized, connective tissue membrane. These focal lesions may be seen in many tissues but seem to have diagnostic significance when they occur in the ventriculus, proventriculus, pancreas, and heart and when accompanied by specific lesions in the central nervous system (Jungherr and Minard, 1942). These same authors also stated that in correlating pathologic evidence with the

symptoms, in spontaneous cases, 11 per cent manifested symptoms but revealed no lesions, and, on the contrary, 8 per cent of the symptomless cases revealed typical lesions.

The pathology of experimental cases was quite similar to that of the spontaneous, except that the perivascular reactions in the central nervous system frequently showed massive development, especially in the cerebrum. Visceral lesions

were much less pronounced and frequently absent.

IMMUNOLOGY

Chickens that have been exposed to the live virus will manifest an immunologic response that can be measured with the standard virus neutralization test (Sumner et al., 1957b; Calnek and Jehnich, 1959a). The Van Roekel embryo-adapted strain is recommended to determine the neutrali-

ing capacity of the serum or plasma. The undiluted serum or plasma is mixed with tenfold dilutions of the virus and the resulting mixtures are inoculated via the yolk sac into susceptible 6-day-old embryonated chicken eggs. The embryos are examined 10 to 12 days post inoculation for lesions characteristic of the virus. The neutralization index is calculated as the log difference between EID_{50} virus titer and EID_{50} virus-serum titer. A log index of 1.1 or greater is considered as positive evidence of previous exposure to the virus. Among samples from a recently exposed flock, the log index may vary from 1.5 to 3.0. Neutralizing antibodies may be detected as early as the second week after exposure and remain at significant levels for at least several months. Calnek and Jehnich (1959a) reported that in many instances birds having no detectable neutralizing antibodies (NI of less than 1.1) would resist intracerebral challenge with as many as ten thousand EID_{50} of virus.

Another method used to determine the immunity of a flock is the embryo susceptibility test. Sumner et al. (1957b) first employed this test as a means to determine which breeding flocks had experienced the infection. A small sample of fertile eggs is selected from each flock and the eggs are inoculated after 6 days of incubation with the egg-adapted virus via the yolk sac. Ten to 12 days post inoculation the embryos are examined for characteristic lesions of the virus. If 0 to 50 per cent of the embryos show no signs of infection, the flock is considered immune. If more than 50 per cent but less than 100 per cent of the embryos are affected, it strongly suggests a recent exposure to the virus. If all embryos are affected, the flock is susceptible. Adequate controls should be included in conducting the embryo susceptibility test. This test serves as a useful tool under certain circumstances, but it is used to a very limited degree. The availability of susceptible eggs has been a deterrent in the wider usage of this test.

DIAGNOSIS

In spontaneous cases a tentative and frequently a definite diagnosis of disease can be made when a complete history of the flock and typical specimens of the disease are furnished the diagnostician. Histopathologic evidence of gliosis, lymphocytic perivascular infiltration, the axon type of neuronal degeneration in the central nervous system, and the hyperplasia of the lymphoid follicles in certain visceral tissues usually can be considered as a basis for a positive diagnosis. The isolation of the virus or the serum-virus neutralization test gives a more specific diagnostic result. Recently the latter method has been employed more extensively and with further refinements and improvements should furnish a very useful tool for the specific diagnosis of avian encephalomyelitis. Caution should be given that this disease may be confused with other avian diseases manifesting similar clinical signs. Among such diseases may be included Newcastle disease, equine encephalomyelitis infection, nutritional disturbances (rickets, encephalomalacia, and riboflavin deficiency), and avian leukosis complex. Specific diagnostic criteria have been described for these diseases in other chapters of this text.

PREVENTION AND CONTROL

No satisfactory treatment is known for acute outbreaks in young chicks. It is advisable to check the management in order that the chicks will receive adequate nutrition and a suitable environment. The removal and segregation of affected chicks may be indicated under certain conditions, but generally it is advisable to kill affected specimens since they will not develop into profitable stock. If the disease appears frequently in progeny from the same flock, it is advisable to cease hatching from such a flock for a brief period of time.

It appears that once a flock has experienced an outbreak of the disease no fur-

ther evidence of the disease is likely to be observed (Schaaf and Lamoreux, 1955). Natural specific antibodies for the virus have been detected in the sera and in the yolk of fresh eggs obtained from survivors of the disease (Sumner et al., 1957b).

Within recent years effective immunization procedures have been developed to protect breeding flocks against outbreaks of the disease and in turn prevent the spread of the virus to the progeny via the egg-borne route (Schaaf, 1958, 1959; Calnek et al., 1961; Butterfield et al., 1961; Van Roekel et al., 1961). Schaaf (1958) first recognized that chickens exposed to the virus developed an immunity and that such birds should not produce infected progeny. This observation formed the basis for a program of vaccinating growing birds with the wing-web method prior to sexual maturity. Among more than one million chickens vaccinated with the live virus, no evidence of avian encephalomyelitis was observed in progeny produced by these vaccinated birds.

Calnek et al. (1961) were successful in immunizing immature birds by using a satisfactory vaccine strain which was ad-

ministered by the oral route. It was observed that by vaccinating only a small percentage of the birds the remainder of the flock would develop a satisfactory immunity. Since progeny from vaccinated or naturally infected flocks may retain passive antibodies for approximately 8 weeks, they should not be vaccinated until 10 weeks of age or older. It is recommended that all replacement stock for breeding flocks be immunized against the disease.

Effective inactivated vaccines for avian encephalomyelitis have also been produced (Calnek and Jehnich, 1959b; Schaaf, 1959; Butterfield et al., 1961). At the present time the inactivated vaccine may be applicable for susceptible breeding flocks that are in production and for breeding flocks located in areas where the disease incidence is low.

A commercial live virus vaccine, administered in the drinking water, is available at the present time. An effective immunization program applied to all breeding flocks should eliminate clinical outbreaks of the disease in the chick population.

Equine Encephalomyelitis Virus in Birds

A few years after the viral etiologies of equine encephalomyelitis were established, naturally occurring diseases of birds were shown to be due to eastern equine encephalomyelitis (EEE) virus. Fothergill and Dingle (1938) reported the isolation of this virus from a pigeon submitted by a breeder in Massachusetts during the 1938 epidemic, which involved both man and horses. Simultaneously, ring-necked pheasants in Connecticut were found to be naturally infected with the eastern virus by Tyzzer et al. (1938) During the same year, Van Roekel and Clarke (1939) isolated the eastern virus from a ring-necked pheasant submitted to them by a game breeder in New Jersey. Since that time, recurring epidemics of eastern equine encephalomyelitis have been reported from New Jersey and Connecticut by Beaudette and Hudson (1945), Beaudette and Black (1948), Cohen and Sussman (1957), and Luginbuhl et al. (1958). Western equine encephalomyelitis (WEE) virus has not

been reported as producing clinically evident, naturally occurring disease in domestic poultry or game birds.

Etiology. Two antigenically different viruses cause encephalitis in horses in North America. Because of the geographical distribution of the disease in horses, these are called eastern equine encephalomyelitis (EEE) virus and western equine encephalomyelitis (WEE) virus. These viruses are spherical in shape and are 40 to 50 mμ in diameter. They are readily inactivated by a number of chemical agents such as ether, chlorine, phenol, etc. These viruses are most stable in a menstruum containing 10 per cent or more serum, a low salt concentration, and buffered to pH 7.6 or above. They may be preserved in 50 per cent glycerin buffered to pH 7.6 for short periods or frozen at -70° C. for periods of several years.

These viruses have a wide host range, readily infecting most laboratory animals when inoculated intracerebrally. Mice and

guinea pigs are especially susceptible, dying of encephalitis within 2 to 5 days when inoculated with the eastern virus and in 4 to 7 days when inoculated with the western virus. The eastern virus is more infective for mammals by peripheral routes of inoculation than is the western virus. Both viruses cause death of chicken embryos within 18 to 72 hours after inoculation by any route. The amniotic route of inoculation is more sensitive than other routes. The embryos present a purplish hemorrhagic appearance when death is due to specific virus infection. A number of tissue cultures show cytopathic changes when infected with these viruses. Chicken and duck embryo fibroblast and hamster kidney cultures have received the most widespread use in diagnostic work.

Symptoms. Chickens more than 4 weeks of age show no clinical signs of disease when infected by these viruses. The effect of infection upon egg production is not known. Day-old chicks succumb rapidly to infection by these agents without showing signs of central nervous system involvement (Chamberlain et al., 1954). Signs of disease in young chicks consist of diarrhea and extreme prostration. Histologically, myocarditis is the outstanding lesion (Tyzzer and Sellards, 1941).

Only eastern equine encephalomyelitis virus has been shown to cause clinical disease in ring-necked pheasants. In this species the outstanding signs of infection are referrable to central nervous system involvement and consist of leg paralysis, torticollis, and tremors. No prominent gross lesions are seen upon postmortem examination. The mortality among clinically ill pheasants is approximately 75 per cent. Recovery from the acute phase of the disease may be accompanied by sequelae consisting of incoordination or muscular weakness. Pheasants may also experience clinically inapparent infections with eastern equine encephalomyelitis virus.

Native wild birds usually experience inapparent infections with these viruses (Kissling et al., 1954). Clinical disease and death may result in introduced species such as the English sparrow (Stamm and Kissling, 1956) and domestic pigeon.

Transmission. Both viruses are transmitted among wild birds principally by mosquito vectors. Not all species of mosquitoes are capable of transmitting these viruses. Virus is circulated in the blood of infected birds for periods of 2 to 5 days. Small passerine birds tend to circulate virus in higher concentrations than do larger birds and therefore are potentially more important sources of virus for mosquito infection.

Eastern equine encephalomyelitis virus is transmitted chiefly by Culiseta melanura among the wild bird population under endemic conditions (Chamberlain, 1958). This mosquito is found only in areas of fresh water swamps. Although its biology is not known completely, it is thought to be preferentially a bird feeder. During epidemic periods, other mosquito species such as Mansonia spp. and Aedes spp. may become important transmitters of the virus (Chamberlain et al., 1954). Culex species of the eastern United States are extremely poor transmitters of the eastern virus. Since Culex pipiens and related species are the common mosquitoes found near poultry houses, this may explain the low incidence of antibody to EEE found in chickens.

There is ample evidence that direct transmission of EEE may occur among pheasants during the acts of feather picking and cannibalism. The virus is present in the blood, feather quills, and mouth secretions of infected pheasants. Pheasants may be experimentally infected by oral administration of the virus (Holden, 1955; Satriano et al., 1958).

WEE virus is transmitted chiefly by Culex tarsalis in the western part of the United States. In the eastern United States, WEE virus usually shares the same habitat as EEE virus and is probably transmitted by the same vectors.

These viruses may occasionally be transmitted mechanically by biting insects due to contamination of their mouth parts

with virus. Transmission by mosquitoes depends upon a cycle of virus development within the arthropod, and, once infected, such insects may remain infected for life.

Diagnosis. Since pathological examination reveals no pathognomonic lesions and clinical signs may be confused with Newcastle disease, definitive diagnosis must be made by isolation and identification of the virus.

Although a variety of laboratory animals are suited for isolation of EEE or WEE virus, chicken embryos and freshly hatched chicks are more sensitive indicators of virus than any other host. Embryos 9 to 14 days of age are satisfactory for use. Inoculation should be into the amniotic cavity. Freshly hatched chicks should be less than ½ day of age and are inoculated subcutaneously. In pheasants the brain is the most likely tissue to yield virus, while in other species the liver, spleen, and heart are more likely to contain virus than is the brain. The tissue emulsion may be treated to control bacterial contaminants by the addition of 1,000 units of sodium penicillin G and 2 mg. of streptomycin sulfate per ml. When the inoculum contains virus the embryos should die within 18 to 72 hours after inoculation and present a hemorrhagic appearance.

Specific identification may be made by serological methods, either neutralization or complement fixation (CF). The allantoic fluid from the infected embryos may serve as antigen in either case. In the complement fixation test the allantoic fluid is tested against serum known to fix complement in the presence of EEE antigen. The CF reactivity of the fluid is usually

rather low, and expected titers are generally in the range of 1:2 to 1:8. Appropriate controls to determine anti-complementary and nonspecific reactions are necessary.

For the neutralization test the infected fluid must be diluted to contain 1,000 to 100 embryo LD_{50}, and it is incubated with specific immune serum before inoculation of the test hosts. Infected allantoic fluids usually contain 10^8 to 10^9 LD_{50} per 0.1 ml. Chicken embryos, mice, or tissue cultures may be used as hosts in the neutralization test for identification purposes. Appropriate controls, using normal serum in place of the immune serum, are necessary.

Birds recovering from EEE infection develop specific neutralizing and hemagglutinin inhibiting antibodies against the virus.

Although WEE is not known to cause clinical disease in poultry, the diagnostic procedures are similar to those for EEE.

Prevention. Protection against mosquitoes will prevent the introduction of EEE virus into pheasant pens. Where this is impractical, debeaking or other methods of preventing cannibalism and feather pulling will check the spread of virus should it be introduced by mosquito bite.

Prophylactic immunization using products designed for equine use may lower the mortality rate should the virus be introduced. These vaccines are usually diluted 1:5 for pheasant use.

Where possible, rearing pens for pheasants should be located away from the margins of fresh water swamps, since it is in areas such as these that the virus is found endemically in wild birds.

Fowl Pox

Synonyms. Chicken pox, avian pox, bird pox, contagious epithelioma, sorehead, avian molluscum, avian diphtheria, bird pox diphtheria, canker, *Geflügelpocken* (German), *variole aviaire* (French), *viruela aviar* (Spanish), *difteria aviar* (Spanish), *bouba* (Portugese).

Etiology. Fowl pox has been observed in avian species from time immemorial. Excellent reviews are presented by Goodpasture (1928) and by Beaudette (1949, 1953). The causal agent is a filterable virus, as was first demonstrated by Marx and Sticker (1902) Carnwarth (1908) and others showed that the virus is responsible for both the cutaneous and diphtheritic forms of the disease. There appear to be at least four different viruses or strains of virus causing pox among birds. These are classified by van Rooyen (1954) as *Borreliota avium* (fowl pox virus), *Borreliota meleagridis* (turkey pox virus), *Borreliota fringillae* (canary pox virus) and *Borreli-*

ota columbae (pigeon pox virus). *Borreliota avium* is the type species of the viruses of the animal pox group. Each virus is infective for its homologous host and in some instances for heterologous hosts.

The identification of the common etiology of the pox viruses has been attempted by passage of the viruses through homologous and heterologous hosts and using the criteria of immunogenesis and pathogenesis for the interpretation of the results. In many investigations, quantitative determinations of the virus content of the vaccines were not taken into consideration, and it seems obvious that an accurate assessment of the antigenic properties of such preparations would be impossible.

The present knowledge of avian pox does not allow an adequate classification of the pox viruses without reference to host origin. Some avian pox viruses may

be mono-, bi-, or tri-pathogenic with respect to transmission to certain species of birds.

Gallagher (1916) described an outbreak of fowl pox in quail transmissible to chickens. Ward and Gallagher (1920) stated that pox occurs naturally among geese, ducks, and guinea fowl, and that pheasants and various wild birds are also susceptible. Te Hennepe (1926) reported that of 268 ducks examined by him during 1924, 17 were affected with mouth lesions and 14 with cutaneous lesions of fowl pox. Later, te Hennepe (1927) did not observe fowl pox infection in 304 ducks examined during 1925–26. Doyle and Minett (1927) were unable to infect ducks or a seagull with fowl pox virus. Pigeons are generally resistant to infection with fowl pox virus, but Doyle and Minett were able to adapt a strain of the virus to the pigeon by frequent serial passage.

Irons (1934) studied the immunological relationship of several strains of fowl, turkey, and pigeon pox viruses and suggested that some strains may be rendered "bi-pathogenic" by passage through a series of heterologous hosts, e.g., fowl pox virus passaged through pigeons. All the pigeon pox strains studied were found to be infective for chickens. Negative results were obtained in attempts to infect pigeons with turkey virus. Crows, hawks, owls, ducks, guinea fowls, starlings, and several other species were refractory to the fowl and pigeon strains of virus. Chickens were susceptible but pigeons were refractory to turkey virus. One strain of pigeon pox virus proved infectious for the English sparrow and certain related species. After a single passage in chickens the virus of pigeon pox was greatly attenuated for the pigeon. Repeated passage of pigeon pox virus in chickens, with one possible exception, failed to destroy the infectivity of the virus for pigeons. One strain of fowl pox virus was transmissible with gradually increasing virulence in pigeons but was temporarily attenuated for chickens. Two other strains of fowl pox virus were noninfectious for pigeons.

Beach (1939) classified avian pox according to the host—fowl, turkey, pigeon, and canary—with a list of the species in which it occurs or to which it has been transmitted.

Syverton and Cowan (1944) reported the recovery of fowl pox virus from the sooty grouse. They state that although avian pox is reported to have occurred under natural or experimental conditions in a wide variety of birds, more conclusive evidence appears to be limited to the chicken, pigeon, turkey, guinea fowl, canary, partridge, quail, and pheasant.

A natural outbreak of pox in mourning doves transmissible to other mourning doves and a ring dove through cohabitation was reported by Kossack and Hanson (1954) to be caused by pigeon pox virus.

The virus of turkey pox usually has been considered to be the same as that of fowl pox, but the results obtained by some investigators indicate certain strain differences between viruses causing pox in these two species. Brunett (1934) studied the immunological and pathological relationship between a strain of pox virus obtained from a natural case of the disease in turkeys and a strain of fowl pox virus. No differences were observed in the effect of the two viruses on turkeys, chickens, and pigeons except that the disease was of a longer duration in turkeys and chickens inoculated with fowl pox virus, as compared to inoculation with turkey pox virus. Immunity studies showed that turkeys and chickens inoculated with turkey pox virus or fowl pox virus were immune to subsequent inoculations with these viruses. Pigeon pox virus produced a severe reaction on turkeys, but it failed to produce any immunity to turkey or fowl pox viruses.

Brandly and Dunlap (1938) inoculated chickens with a strain of pox virus obtained from a natural case of the disease in turkeys and observed only a mild cutaneous reaction. No infection was produced at the fifth passage of the virus in chickens.

Beaudette and Hudson (1941) reported

that a strain of turkey pox virus studied by them produced a more severe local and systemic reaction and a higher percentage of secondary head lesions in chickens than fowl pox virus. The lesions consisted of a typical scab of considerable thickness as compared to the atypical scab formation and decreased virulence of the turkey strain studied by Brandly and Dunlap (1938). The turkey virus was less lethal for embryonating chicken eggs than was the fowl pox strain. In cross-immunity tests, Brandly and Dunlap used canary, pigeon, turkey, and fowl pox viruses for a study of the immunological relationships of these viruses and concluded ".. that canary virus immunizes against itself and against pigeon virus to a high degree. The canary virus seems to produce no immunity against turkey virus but apparently a slight immunity to the fowl virus. Similarly, pigeon virus protects against itself and canary virus but does not give complete protection against turkey and fowl viruses. Turkey and fowl viruses give almost complete protection against the four viruses used."

Kikuth and Gollub (1932) found in their work on bird malaria a virus capable of producing a highly fatal disease of canaries. This virus has been the subject of controversy concerning its relationship to the avian pox viruses.

Burnet (1933a) concluded that Kikuth's virus was a member of the bird pox group. The virus was not pathogenic for day-old chicks, half-grown fowls, pigeons, and parrots (budgerigars). Sparrows were susceptible to infection.

Burnet and Lush (1936) showed by the embryonating chicken egg technique that fowl pox and Kikuth's strain of canary pox, although not identical, are serologically related. They stated that "if canary-pox and fowl-pox are serologically almost identical, it is more than likely that all bird-pox strains are similarly related."

Burnet (1933b) was able to infect canaries with pox material collected from a spontaneous outbreak in wild sparrows. The disease in the canaries was similar to that produced by Kikuth's canary virus, but the difficulties in filtration of the virus and the agglutinative tendencies of the virus particles resembled fowl pox virus

McGaughey and Burnet (1945) studied three cases of avian pox in wild sparrows and concluded that the virus resembled canary pox in causing a fatal disease in sparrows and canaries and localized lesions in fowls and pigeons.

The strain of canary pox virus studied by Reis and Nobrega (1937) was "tri-pathogenic" as it infected chickens, pigeons, and canaries. The virus did not dissociate into mono-pathogenic strains after serial passage through chicks, pigeons, and canaries. Typical inclusion bodies were found in the infected birds, and those which recovered developed immunity against the homologous virus as well as fowl and pigeon pox viruses. Birds vaccinated with either fowl pox or pigeon pox viruses developed immunity against the canary pox strain. The canaries from which the strain was isolated suffered from a severe pox disease in which the mortality was 98 per cent.

Grosso and Prieto (1939) have reported a "tri-pathogenic" canary virus which produced only a mild, transitory, localized lesion in chicks and pigeons.

Antoniotti and Romat (1940) studied a canary pox virus which was pathogenic only for canaries.

Durant and McDougle (1938) conducted studies of the immunological relationship of canary pox virus to fowl pox virus with the following conclusions: "Chickens, turkeys, and quail when inoculated with canary pox virus, though fairly typical gross lesions are produced, later when inoculated with fowl-pox virus will develop typical lesions, indicating that no immunity to the fowl-pox virus had been developed by exposure to the canary-pox. This would seem to indicate that canary pox virus is a different type of virus with a different degree of virulence for other bird species than the canary."

Coulston and Manwell (1941) reported that canary pox virus was found to be in-

fective for English and song sparrows but not for cowbirds, starlings, or chickens. Canaries which had been vaccinated with the virus attenuated through long storage did develop an immunity which protected them to some degree, but not completely, against exposure to fully virulent virus. Vaccination with the virulent virus was always fatal.

Jansen (1942) reported infection of a jackdaw with canary pox virus. Fowls, pigeons, and canaries were susceptible to the virus. Immunity against the jackdaw strain was not produced by vaccination with fowl pox virus or pigeon pox virus but was demonstrated with canary virus.

Jactot et al. (1956) isolated canary pox virus and showed that it was pathogenic for the sparrow, fowl, and pigeon, but in the latter two species the disease was local and recovery was spontaneous. The virus did not immunize pigeons against pigeon pox, and pigeons immunized against pigeon pox were susceptible to the virus. Fowl pox and pigeon pox immune fowl were susceptible to the virus.

Pox in the mourning dove has been reported by Kossack and Hanson (1954) and by Locke et al. (1960).

Pathology. Detailed descriptions of the pathological processes in fowl pox are reported by Goodpasture (1928) and Hutyra et al. (1938).

Fowl pox is characterized by the appearance of cutaneous eruptions or wart-like nodules on the unfeathered parts of fowl and diphtheritic membranes of the mouth. The lesions are observed particularly about the head region, but they may also appear on the legs and feet, around the cloacal aperture, and under the wings. The characteristic lesion of the cutaneous form is a local epithelial hyperplasia involving both epidermis and underlying feather follicles with the formation of nodules. The cutaneous nodules may be very numerous or few in number, and they do not necessarily erupt at the same time. At first, the nodules appear as small, whitish foci which rapidly increase in size

and become yellowish in color as they develop. In some instances, closely adjoining lesions may coalesce, and the larger developing lesions are rough, and gray or dark brown in color. After about two weeks of development, sometimes sooner, the lesions may show areas of inflammation at their base and become hemorrhagic. The lesion then undergoes a process of desiccation and scab formation which may last for another week or possibly two weeks. In uncomplicated cases the process ends with desquamation of the degenerated parts of the epithelial layer. If the desiccated scab is removed in the meantime, a moist, sero-purulent exudate is found underneath, covering a bleeding, granulating surface. When the scab drops off, a smooth scar may be present, although in milder lesions there may be no noticeable evidence of scar tissue. The specific process is often modified by the invasion of bacteria which propagate in the degenerated epithelium and may reach the deeper layers of the mucous membrane where they cause suppurative or necrotic processes with the formation of fibrinous deposits.

The eruptions on the mucous membranes are white, opaque, slightly elevated nodules. These processes rapidly increase in size, often coalescing to become a yellowish, cheesy, necrotic material with the appearance of a pseudomembrane. When these pseudomembranes are removed they leave bleeding erosions. The invasion by contaminating bacteria aggravates the diphtheritic form of the disease. The inflammatory process may extend from the mouth region into the sinuses, particularly the infraorbital sinuses, resulting in a tumorlike swelling, and may extend into the pharynx, resulting in respiratory disturbances.

Stafseth (1931) reported that naturally infected pigeons showed typical pox lesions on various parts of the body. Most of the scabs were found on the feet, legs, and near the base of the beak. A few pigeons showed cankers in the mouth. Hutyra et al. (1938) reported that in pi-

FIG. 26.1—Epithelial changes in fowl pox. ×460. (Biester, Iowa State University.)

geons the pox lesions develop chiefly on the borders of the eyelids, the angles of the mouth, and on the feet.

The characteristics of the canary disease of Kikuth and Gollub (1932) show little resemblance to fowl pox, but Burnet (1933a) and Burnet and Lush (1936) presented evidence that the virus was a member of the bird pox group and classified it as canary pox. Intramuscular injection of the virus produced an inflammatory necrotic local lesion and a generalized viremia. The postmortem appearance resembled that of a subacute bacterial cellulitis. Hemorrhages under the serous membranes, edema of the lungs, and pericarditis were observed. The difference between the pathological manifestations of fowl pox infection and Kikuth's canary pox infection was the capacity of the canary pox virus to multiply within the cytoplasm of the cells derived from all three primary germinal layers. Mononuclear cells were infected and spread the infection in many respects comparable to the spread of a pyogenic bacterial infection.

Durant and McDougle (1938) observed that in canaries the external pox lesions affected the entire body. Scab formation was not as distinct as in chickens, although there was a tendency toward this condition in the advanced stages of the disease. Cheesy exudates were found in the commissures of the mouth and the entrance to the larynx.

Canary pox, as reported by Coulston and Manwell (1941), may be manifested by lesions about the margin of the epithelium of the eye and elsewhere on the head, and by lesions of the toes and legs.

The significant feature of the histological picture of fowl pox is the presence of intracytoplasmic inclusion bodies in the affected epithelial cells (Fig. 26.1). Goodpasture (1928) states that only squamous epithelium of the skin and mucous membranes seems to be susceptible to the virus and that the basal layer of the epithelium shows little change from the normal. The early stages of the inclusion bodies appear peripheral to the basal layer. The cells in which they are present are enlarged, and the cytoplasm appears edematous. The material constituting the inclusion body appears first about the periphery of one or more vacuoles situated at the proximal pole of the cell. The inclusion body increases rapidly in size, in some cases becoming as large as the original cell.

Nearer the surface, the altered cells become larger, and there is evidence of change in position of the inclusion bodies so that they come to lie more frequently at the distal pole of the cell. As the surface of the lesion is approached, the cells show evidence of disintegration, and the inclusion body may become more or less isolated in the cytoplasm. The increasing size of the inclusion body is accompanied by the ultimate destruction of the nucleus and the death of the cell. Extruded nuclear particles may appear in the cytoplasm. On the surface of the lesion there are great alterations of the cells from desiccation.

Inclusion bodies in the affected cells of cutaneous eruptions of fowl pox were first discovered by Rivolta (1869). Bollinger (1873), through histological studies, differentiated the lesions of fowl pox and variola and classified fowl pox among the tumors as epithelioma contagiosum. This term unfortunately exists today but is an erroneous terminology, although the gross lesions of the disease do have some macroscopic similarity to epitheliomata. Guarnieri (1892) demonstrated certain characteristic intracellular bodies in the lesions of variola differing from those of fowl pox. These studies of Bollinger and Guarnieri presented convincing pathological differentiations between the two diseases as distinct entities.

Borrel (1904) discovered, in smear preparations from the cutaneous lesions of fowl pox, myriads of minute coccuslike structures apparently small enough to pass through the pores of a Berkefeld filter. This discovery suggested that these bodies might be the etiological agent.

Burnet (1906) confirmed Borrel's observations and showed that these bodies were derived from the same cell in which inclusion bodies could be demonstrated in stained preparations. Goodpasture (1928) reported that these bodies were about 0.25μ in diameter.

The experiments of Woodruff and Goodpasture (1929) on inclusion bodies of fowl pox presented conclusive evidence as to the etiological agent. These authors discovered that a 1 per cent solution of trypsin in 0.2 per cent sodium bicarbonate would dispel completely the cellular material of a fowl pox lesion in about 30 minutes, leaving the inclusion bodies free and separable from the tissue debris. The inclusion bodies were small, oval, occasionally bean shaped or irregular, and varied from 2 or 3μ to perhaps 50μ. In their internal structure, they ranged from discrete granules to hyalinelike, homogeneous bodies. Inclusion bodies had an elastic, semipermeable membrane of lipoproteid composition and responded to osmotic influences. Inclusion bodies could be washed free of trypsin by centrifugation and resuspending the bodies in saline. Woodruff and Goodpasture showed that a single inclusion body inoculated into the skin of a susceptible chicken produced a typical fowl pox lesion containing the characteristic inclusions.

Woodruff and Goodpasture (1930) showed that an inclusion body may contain as many as 20,000 elementary bodies, each of which was capable of inciting the disease.

Studies by Woodruff and Goodpasture (1931) of chorio-allantoic membranes of chicken eggs infected with fowl pox virus showed a marked susceptibility of ectodermal cells to infection, although entodermal cells could be infected. Inclusion bodies were usually less numerous and hyperplasia was less marked in entodermal cells than in ectodermal cells. Further indication that entoderm was less susceptible than ectoderm was seen in the fact that entodermal derivatives of the adult hen were rarely infected.

Brandly (1941) concluded from studies of infected chorio-allantoic membranes that "both fowl- and pigeon-pox viruses produced microscopic retrograde changes in all three germ layers of the chorio-allantois. Fowl-pox strains produced more severe alterations in the ectodermal and entodermal layers, while with the pigeon virus the reactions were more marked in the mesoderm (cellular infiltration and

edema). The development of cytoplasmic inclusions (Bollinger bodies) produced by fowl strains appeared to be associated with necrosis of the limiting cellular layers. As a rule, these inclusions in the ectoderm and entoderm were larger and more readily demonstrated than those occurring in pigeon-virus lesions Entodermal involvement by pigeon virus was invariably slight."

Groupé et al. (1946) showed by electron microscopy that the elementary bodies of fowl pox closely resemble those of canary pox and have many characteristics in common with the elementary bodies of vaccinia. The bodies were approximately rectangular, occurred singly, in pairs, and in short chains, and were most frequently attached to one another at the corners.

Groupé and Rake (1947) stated that "Although the elementary bodies of fowl pox are somewhat larger than those of vaccinia, the similarities between the two are striking. The particles of both appear to be approximately rectangular in shape and possess large central moundlike elevations. ... That classic examples of both avian and mammalian strains should so closely resemble one another morphologically adds still another link to the chain of evidence that has bound the viruses of the pox group together. The presence of forms suggesting unequal division of elementary bodies, together with the characteristics mentioned above, supports the suggestion of Green et al. (1942) that the pox viruses have morphological characteristics that approach those of the bacteria rather than those of the plant viruses." (Fig. 26.2.)

Burnet (1933a) observed well-marked cytoplasmic inclusion bodies in the epithelial cells of skin overlying lesions produced by Kikuth's canary pox virus. There was a considerable resemblance of these inclusions to the Bollinger bodies of fowl pox. On the chorio-allantoic membrane the virus produced massive inclusions in
FIG. 26.2 — Fowl pox virus shadowed with gold. Electron micrograph. 2.3 x 12,400X. (Groupé and Rake, 1947.)

the proliferating ectoderm, but changes in the mesodermal and entodermal layers appeared to be purely secondary and no inclusion bodies were observed.

Durant and McDougle (1938) reported the findings of their histological studies of canary pox as follows: "Microscopic studies of the stained sections from canary pox lesions in canaries, chickens and turkeys showed distinct differential characteristics. In the sections from canaries numerous typical virus inclusion bodies are present with very few if any polymorphonuclear eosinophils with rods. In the section from chicken lesions there are no virus inclusion bodies evident and only a few polymorphonuclear eosinophils with rods. In the case of turkeys the sections showed a marked infiltration of polymorphonuclear eosinophils with rods with small bodies resembling virus bodies which are usually seen in the canary pox or fowl pox lesions. These are observed only in the deeper tissues. . . ."

Coulston and Manwell (1941) observed typical cellular inclusions in canary pox.

A variant strain of canary pox virus studied by Siegel and Leader (1957) produced cutaneous papular eruptions when introduced into the scarified, defeathered areas of the skin of the chicken, turkey, and canary. In the chicken and turkey the lesions were characterized by marked inflammation in the corium and subcutaneous connective tissue with the epithelium remaining essentially normal. In the canary there was massive proliferation of epithelium with numerous intracytoplasmic inclusions as well as severe subcutaneous lesions. The gross lesions in the chicken and turkey were mild and transitory, but in the canary they became confluent and formed thick scabs.

An excellent review of the literature on canary pox is presented by Beaudette (1953).

Diagnosis. The presence of cutaneous lesions typical of fowl pox in chickens usually warrants a diagnosis of the disease. A diagnosis is not so readily made when mouth cankers or coryzalike lesions and symptoms are seen. Several diagnostic tests may be employed, viz., infectivity tests, protection tests, microscopic examination of lesions, and serological tests as described by Brandly and Dunlap (1938).

With infectivity tests it may be necessary to utilize heterologous as well as homologous hosts for an accurate diagnosis of the type of pox virus present in the bird. Fowl pox virus may be demonstrated readily by the application of a suspension of the material to the skin of susceptible chickens by scarification of the comb or by the "stick and "feather follicle" methods described later. If the virus is present the chicken will develop typical cutaneous lesions in from 5 to 7 days. In atypical cases microscopic examinations should be made of scrapings from the base of the lesions for detection of Bollinger bodies.

Protection or immunity tests with fowl pox immune and susceptible chickens may be used simultaneously with infectivity tests and microscopic tests. The original fowl pox suspected birds which recover from the infection may be tested for immunity to a known fowl pox virus.

Microscopic examinations of smears and histological preparations of suspected lesion material are of diagnostic value. Smears may be prepared according to the method of Goodpasture (1928): "If the surface of such a lesion be slightly scraped and the scrapings moistened with water and pressed under a cover glass, the virus bodies may be easily recognized under the microscope. . . . In smears stained with Loeffler's flagella stain, or better with carbol-anilin-fuchsin for 1 minute, after mordanting an equal period with ¼ per cent potassium permanganate (Goodpasture), they are readily demonstrable. They are round or slightly oval, sometimes arranged in short chains or in diplococcal and biscuit forms. They are colored a distinct pink by the latter method, and are Gram-negative. These bodies may be studied equally well in darkfield preparations. They measure about 0.25μ in diameter, and have the appearance gener-

ally of a minute, nonmotile microorganism."

Brandly and Dunlap (1938) utilized the method of Morosow (1926) for preparing and staining direct smears from suspected lesion material. These authors have successfully used this method of examination to facilitate rapid diagnosis of suspicious field cases.

Angstrom (1951) reported that Bollinger bodies are readily demonstrable in fresh, unstained preparations from recently formed lesions.

Sevoian (1960) described a rapid, histological method using a solution which fixes and dehydrates tissues simultaneously. Using hematoxylin and eosin stains, intracytoplasmic inclusions for avian pox were demonstrated readily within 3 hours.

Stained histological preparations should reveal the presence of Bollinger bodies and the typical microscopic lesions observed with fowl pox.

Serological tests of the suspect virus with known fowl pox antiserum may be conducted with living hosts and also with embryonating chicken eggs as described by Burnet (1936b) and Burnet and Lush (1936) for neutralization tests. Burnet and Lush (1936) produced fowl pox antiserum by inoculation of susceptible birds on the scarified comb and intramuscular injection of an emulsion of fowl pox infected chorio-allantoic membrane material. A course of three more intramuscular injections of infected membranes was begun 3 weeks after the initial inoculation. Blood was collected from the birds 10 days after the last inoculation.

Dalling et al. (1929) were successful in producing fowl pox antiserum by immunizing susceptible chickens through application of the virus to the scarified comb. After "takes" were no longer produced by subsequent application of the virus to the comb, a course of four to six increasing doses of active virus was injected intramuscularly. The protective value of the antiserum could be estimated by two methods — scarification and intravenous injection. With the scarification method,

equal amounts of the test-dilution virus and antiserum were admixed, incubated at room temperature for 1 hour, and then applied to the scarified comb. It was possible to test as many as twelve samples on the comb of one bird. With the intravenous method, varying amounts of antiserum were injected intramuscularly, and on the following day each bird received the test-dilution of virus intravenously.

Neutralization tests utilizing embryonating chicken eggs would necessitate the recovery of the virus in a bacteria-free inoculum. Techniques are discussed under the section Cultivation of avian pox viruses. Isolation and propagation of the virus in eggs with the appearance of typical lesions on the chorio-allantoic membrane would offer presumptive evidence of the identity of the virus. Identification of the virus requires neutralization tests using the embryo technique, protection or immunity tests, or serological tests.

Ledingham (1931) demonstrated agglutination of the elementary bodies of fowl pox virus with sera in dilutions as high as 1:160 from recovered and hyperimmunized chickens. Agglutination did not occur with normal sera. Quantitative experiments (Ledingham, 1932) showed that the agglutinin response was slow after inoculation with the virus. Sera from hyperimmunized birds showed titers as high as 1:300.

The agar gel precipitation test can be used for the diagnosis of fowl pox and its differentiation from certain other respiratory diseases of chickens according to Jordan and Chubb (1962) and Woernle (1963). The test is relatively simple to perform and can be completed within a few days in comparison to the longer time and more technical aspects of using chicken embryo methods.

Cultivation of avian pox viruses. Fowl pox virus like other viruses can be cultivated only in living cells. These requisites may be supplied by the host, avian embryos, and tissue culture.

Cultivation of fowl pox virus in the host may be accomplished by application

of the virus to the scarified comb of a susceptible chicken and collection of the scabs. Brandly and Bushnell (1932) reported that lesion material harvested the tenth and eleventh days after inoculation was the most virulent and produced the most extensive cutaneous lesions. The scabs should be desiccated, powdered, and stored under refrigeration until used for the next passage. Pigeon pox virus may be propagated, according to Graham and Brandly (1940), by the application of a freshly prepared 1 per cent aqueous solution of powdered pigeon pox skin lesion material to a defeathered area of the ventral surface of the breast of pigeons. Inoculated pigeons were killed when moribund, usually about the sixteenth day, and the affected skin and scab removed. This material was desiccated, cut into small pieces, ground to a fine powder, and refrigerated until used for the next passage.

The technique of avian embryo culture of viruses requires bacteria-free inoculum. Woodruff and Goodpasture (1931) successfully cultivated the virus of fowl pox on the chorio-allantoic membrane of chicken eggs. Woodruff and Goodpasture (1931) and Beaudette and Hudson (1938) described certain aseptic techniques for collection of bacteria-free, virus-infected materials from birds. Penicillin and streptomycin, however, can be used to render such material bacteria-free. Variable amounts of these antibiotics have been employed but, as a general rule, 1,000 to 10,000 Oxford *units* of penicillin and 1 to 10 mg. of streptomycin per milliliter of suspended material are satisfactory. No brega and Reis (1949) used 5,000 Oxford units of penicillin to free suspensions of pigeon pox virus-infected skin of bacterial contamination.

The Bierbaum and Gaede (1935) method of intracerebral inoculation passage through pigeons and/or chickens of pigeon pox lesion material for obtaining bacteria-free virus inoculum has been utilized successfully by Brandly and Dunlap (1938), and Brandly (1941). This method consists of introducing the material intra-

cerebrally, and after 8 to 12 days incubation the bird is sacrificed and the brain removed aseptically. Brandly (1941) reported that in two instances a pure pox virus was obtained from the first passage, and rarely were three or more intracerebral passages necessary to free the virus from bacteria.

Avian embryo culture offers an economical and convenient means for the pursuit of many fundamental virus investigations as well as the source of materials rich in virus for the production of vaccines free of bacteria. Consideration must be given to the species of embryos, as certain viruses fail to propagate in embryonating eggs of all domestic fowl. The temperature of incubation and the age of the embryos also influence the action of the virus, as well as the route of inoculation (Cox, 1952; Cunningham, 1963).

There are two general methods, with modifications, for preparing eggs for inoculation of the chorio-allantoic membrane with virus (Cunningham, 1963). The Brandly (1935, 1936, 1941) method consists of introducing the inoculum between the inner shell membrane and the chorio-allantoic membrane.

The Burnet (1936a) method consists of the production of an artificial air cell on the side of the egg where the inoculum is deposited on the chorio-allantoic membrane.

The amount of inoculum depends upon the particular problem under consideration. Inoculum of 0.05 cc. or more has been used by various investigators.

A technique which permits, in a single injection, a combination inoculation of the chorio-allantoic membrane, allantoic chamber, and yolk chamber has been described by Gorham (1957).

Woodruff and Goodpasture (1931) used 10- to 15-day-old embryos for their investigations of fowl pox virus. They were, however, successful in cultivating the virus on the chorio-allantoic membrane of 6-day-old, and, in one instance, 4-day-old embryos. Slight abrasion of the skin of the embryos resulted in successful growth of

the virus, but the trauma resulting from this method was so great and the mortality so high that this method was abandoned.

Burnet (1936a) reported that for the study of inclusions 10-day-old embryos are best suited, while for virus production 11- or 12-day-old embryos are preferred. Brandly (1936, 1937, 1941) used 10- to 14-day-old embryos, but 12-day-old embryos were preferred for critical observations of the action of the virus.

Brandly (1937) studied the susceptibility of duck, guinea fowl, and turkey eggs to fowl pox virus as compared to chicken eggs. The eggs were of various ages from 10 to 18 days with the control chicken eggs 12 days old. Infection was obtained in all species of eggs employed but a ten- to thirty-fold greater end-point concentration of the virus was necessary to initiate infection in duck eggs. This was interpreted as a lower degree of susceptibility of duck-egg membranes to infection with fowl pox virus. An appreciable increase in the resistance of duck eggs was noted after the fifteenth day of incubation. Infection was not noted in duck eggs inoculated on the eighteenth day, while slightly more than half of the eggs inoculated on the sixteenth day showed evidences of infection. Turkey eggs of the same age as the duck eggs and inoculated with the same virus preparation showed infection of 80 per cent of the eggs. With chicken eggs it was found in some instances that infection was obtained in 10- and 12-day-old eggs with virus concentrations approximately 10 to 30 times smaller than was required to infect 14-day-old eggs. A tendency to metastasis of pock lesions was noted on the membrane of the 10- and 12-day-old eggs when dilute suspensions of virus were used. Large confluent lesions confined to the large pole of the egg were found in about equal numbers of the eggs of the different ages which received concentrated virus. Differences in the survival time of the embryos in eggs of various ages that developed pox infection did not appear consistent or significant. The infec-

tive concentration of fowl pox virus was not materially influenced by adsorption when powdered Pyrex glass and quartz sand were used as abrasives for grinding infected egg membranes. Repeated egg passages through 20 successive series of eggs did not change the virus insofar as the appearance of skin lesions in vaccinated birds was concerned. It was recommended that all harvested material be rapidly dehydrated at a low temperature if the material was to be held an appreciable length of time.

Brandly and Dunlap (1939) reported that passage of one strain of fowl pox virus through 68 series of eggs did not influence the virulence for chickens or for the chorio-allantoic membrane. The membranes of 12-day-old eggs were found to be more susceptible to fowl and pigeon pox virus than was the skin of chickens 6 to 12 weeks old.

Brandly (1941) conducted extensive experiments on the propagation of fowl and pigeon pox viruses in chicken eggs and the utilization of these viruses in immunization studies. Inoculated 12-day-old embryos were incubated for 4 to 5 days and the chorio-allantoic membranes were collected. Gross lesions were visible as early as 48 hours after inoculation. The pigeon pox viruses had the tendency to localize over the area inoculated. The fowl pox viruses tended to metastasize rapidly. According to Brandly, "The nature of the lesions induced in developing chicken eggs by fowl pox and pigeon pox viruses differed considerably among the strains studied. Grossly, the pigeon virus lesions were typically pale yellow to white, with a nacre or pearly tint, whereas the fowl virus infected membranes were usually reddish gray and quite heavily congested. Individual pocks . . . were globular in form in the case of pigeon virus, compared with the somewhat thinner and relatively flat fowl pocks." (Fig. 26.3.)

Thorning et al. (1943a) presented evidence of fowl pox virus in the embryo proper and yolk as well as in the chorio-allantoic membrane. The greatest concen-
FIG. 26.3 — Fowl and pigeon pox lesions on chorio-allantoic membrane: (A) metastatic fowl pox lesions, (B) diffuse fowl pox lesions, (C) focal pigeon pox lesion. (Brandly, Ill. Agr. Exper. Sta., Bul. 478.)

tration of the virus was in the chorio-allantoic membrane, a lower concentration in the yolk, and a still lower concentration in the embryo proper. They (1945b) stated that "Available evidence does not indicate that multiplication of fowl pox virus occurs in various parts of the embryo exclusive of the chorioallantois, and until further evidence is presented, it appears that the virus content, as well as its immunogenic activity, is related to the virus content of the chorioallantois."

In Beaudette and Hudson's (1938) report on the cultivation of pigeon pox virus on the chorio-allantoic membrane of chicken eggs, it is stated that the lesions did not differ in appearance from those of fowl pox virus. The most extensive involvement was seen when the inoculum was rich in virus and the eggs were incubated more than 5 days following inoculation. Membranes removed from eggs near the hatching date contained little or no virus. One trial with 8-day-old pigeon eggs showed by inoculation of chickens with the harvested membrane that the virus was active, but there was no evidence of the growth of the virus on the membrane since lesions were not produced. Fowl pox virus was apparently lethal to 12-day-old Muscovy duck embryos whereas it had but little effect or lethal action on chicken embryos. Duck embryos were red, but the membranes were not thickened

According to von Reischauer (1906), the virus resists dry heat for 15 to 30 minutes at 80° C. and moist heat for 5 minutes at 100° C. The virus is inactivated in 5 minutes by 1 per cent potassium hydroxide, 1 per cent acetic acid, and bichloride of mercury 1:1,000. Loewenthal (1906) exposed the virus to radium and found it active after 5¼ hours. An emulsion of scabs was active after 1¼ hours in 1 per cent phenol but not in 2 and 2½ per cent phenol according to Marx and Sticker (1903), Graham and Barger (1936) found that 1 per cent aqueous suspension of fowl pox virus on sterile cotton squares, on the feet and down of day-old chicks, upon being subjected to routine incubator fumigation, survived 30 minutes, often 45 and 50 minutes, but was consistently noninfective after 90 minutes. The infectivity of the virus suspension fumigated for 30 and 45 minutes was not appreciably altered as demonstrated by infectivity tests with susceptible chicks.

Graham and Brandly (1940) reported that 1 per cent suspensions of virus containing 0.025 to 0.5 per cent formalin, 0.5 per cent phenol, 2 per cent saponin, and 0.5 per cent tricresol were completely inactivated when stored for 48 hours at icebox temperatures. Coulston and Manwell (1931) found that canary pox virus in the dried form was virulent for 7 months but not for 11 months. Beaudette (1941) reported that a dry scab removed from a wild turkey and stored in an electric refrigerator contained active virus approximately 8 years later.

McCulloch (1915) enumerates several factors to be considered for an assessment of the virucidal properties of physical and chemical agents. The author reported that 95 per cent and 75 per cent solutions of ethyl alcohol inactivated the virus in less than 10 minutes, 50 per cent ethyl alcohol inactivated the virus in 30 minutes but not in 10 minutes, and 25 per cent ethyl alcohol was without effect. These tests were made at 20° C. with 1,000 infective doses, and the broth in which the virus was tested was at pH 7. The virus was found to be inactivated by 50 parts of available chlorine per million when the material was suspended in F.D.A.[1] broth. The virus was able to withstand a 20-minute exposure to 3 per cent formaldehyde solution at 20° C., although the incubation period in chickens inoculated with the treated virus was prolonged. A commercial solution of hexylresorcinol (1:1,000) inactivated the virus when diluted 1:4 but not when diluted 1:8. Tincture of iodine diluted 1:400 inactivated the virus, but a 1:800 dilution was without effect. A 1 per cent aqueous solution of mercurochrome was without effect, while a 2 per cent solution inactivated the virus at 20° C. at pH 7. The virus was able to withstand 3 per cent phenol for 10 minutes at 20° C. but not for 30 minutes. A 1:500 dilution of sodium hydroxide at 20° C. inactivated the virus in 10 minutes, but a 1:600 dilution was without effect. When the virus was suspended in F.D.A. broth pH 7, at 20° C., 1:1,000 crystal violet inactivated the virus in 10 minutes, 1:50 acriflavine in 10 minutes but not 5 minutes, while 1:100 acid fuchsin failed to inactivate the virus in 30 minutes. In each inoculum there were approximately 1,000 infective doses. A 1:400 dilution of liquor cresolis at 20° C. inactivated the virus in 10 minutes but not in 5 minutes, while at 20° C. a dilution of 1:5,000 was as effective as the same dilution at 40° C.

A suspension of 100,000 infective doses of the virus in F.D.A. broth was inactivated in approximately 5 minutes at 60° C., in 15 to 20 minutes at 55° C., and resisted for longer than 1 hour at 50° C.

Graham et al. (1939) reported that irradiation of aqueous suspensions of fowl pox virus with hard X-rays in dosages up to 888 r units had no effect. The virus was inactivated by ultraviolet light from a mercury vapor lamp in 2 hours at 20 cm. and attenuated when exposed for 15 to 90 minutes. The addition of methylene blue in a concentration of 1:50,000 reduced

[1] Food and Drug Administration

the time necessary for inactivation to 5 minutes, while 2½ minutes irradiation markedly attenuated the virus.

Robbins (1944) reported that neither penicillin nor patulin were effective against the virus as shown by infectivity tests on the chorio-allantoic membrane of chicken eggs.

Beaudette et al. (1948) found that fowl pox virus propagated in chicken eggs was active after being held in the dried state up to 3,598 days, while the same strain adapted to duck eggs was active up to 1,928 days. Pigeon pox virus passaged in chicken eggs and in duck eggs was active up to 3,605 and 1,099 days, respectively.

Epizoology. Fowl pox is prevalent wherever poultry is raised. The incubation period of the spontaneous disease varies from 4 to 6 days, according to Goodpasture (1928), and from 6 to 14 days, according to Delaplane (1943). While the disease may make its appearance at any time, the greatest incidence is during the fall and winter months. Under natural conditions, the disease usually makes its appearance in young stock at about the time they are housed in laying quarters. Following this it may reach serious proportions. During the fall and early winter, the cutaneous form predominates in most outbreaks, while during the winter months the diphtheritic form is usually most common. The epizoological picture is similar to that of other contagious diseases in that variations in virulence may be observed. If nothing is done to control an outbreak, it may persist in a flock throughout the winter. The course of the uncomplicated disease is usually about 3 to 4 weeks, but if complications are present the duration may be considerably longer. Recovered birds are immune to further infection.

Chickens affected with the cutaneous form of the disease are more likely subjects for recovery than chickens affected with the diphtheritic form, particularly when the lesions involve the respiratory tract, eyelids, and nasal sinuses. A flock in good physical condition usually war-

rants a favorable prognosis, while the prognosis is unfavorable if the flock is affected with other infectious or parasitic diseases or is subject to poor nutrition and management.

The mortality rate is variable. In laying flocks the egg production will be temporarily retarded. This is associated with an increasing number of emaciated chickens. The mortality in laying flocks may assume serious proportions.

Individual symptoms of fowl pox may be manifested in one of three forms or a combination of these forms, depending upon the virulence and pathogenicity of the strain of virus involved: (1) localization of typical cutaneous pox lesions on the comb, wattles, and face region (Fig 26.4); (2) localization of the infection in the mouth region with the appearance of typical diphtheritic lesions; and (3) localization of the infection in the nasal chambers with accompanying coryzalike symptoms. While pox lesions are not commonly observed on the feet, legs, and body of chickens, these lesions may be observed if chickens are reared on wire floors. Other than the typical cutaneous and diphtheritic lesions there are no characteristic lesions to be found at postmortem examination of affected chickens.

Chickens of all ages, sexes, and breeds, unless previously exposed, are equally susceptible to the virus by inoculation Under natural conditions there seem to be possible breed differences in susceptibility. Cary (1906) reported that chickens with large combs seem to be more susceptible to infection than chickens with small combs. Johnson (1927) has reported that Leghorns appear to be more susceptible to natural infection than are Barred Plymouth Rocks because of the large comb area.

The disease is not commonly seen in young chickens, although Beaudette (1929) and Johnson (1938) have observed outbreaks in battery brooded chicks. In the latter report, the chicks were 6 weeks old, and the lesions in practically all cases

FIG. 26.4 — Severe case of fowl pox. (Brunett, Cornell Vet.)

were found on the feet and legs. The absence of lesions on the combs and wattles was attributed to the lack of development of these organs at this age.

Fowl pox virus is unable to penetrate intact epithelium. Doyle and Minett (1927) were unable to induce infection by the daily application of virus to intact epithelium of the combs of chickens. Injection of virus subcutaneously, intramuscularly, intraperitoneally, and instillation in the conjunctival sac resulted in infection. Intravenous injection of the virus produced the disease in three forms: (1) generalized infection with skin or mouth lesions; (2) slowly progressive emaciation without lesions; and (3) immunity without lesions or loss of condition. From transmission experiments, the authors concluded that infection of the skin resulted from injuries sustained in picking, and that mouth lesions were the result of injuries produced by eating of grit. The intimate cohabitation of chickens in most flocks enhances the possibility of spread of the infection since most chickens in a flock present injured skin surfaces so that there is no lack of suitable portals of entry of the virus.

The possibility of "carrier" chickens serving as foci of fowl pox infection has been the subject of considerable speculation and research work. According to Doyle and Minett (1927) and Doyle (1930) several investigators have indicated that pigeon pox virus may localize in certain internal organs and may persist for a considerable length of time in these organs in recovered pigeons. Doyle (1930) stated it is possible that the frequently repeated statement that fowl pox virus acts in a similar manner is based on this work. Doyle and Minett (1927) found that fowl pox virus could be demonstrated in variable quantities in the blood of chickens throughout the course of the disease following intravenous injection or application of the virus to scarified areas of the comb and in the mouth. In no instance was the virus demonstrable in

the internal organs of recovered chickens or on the comb after complete disappearance of lesions.

According to Burnet (1906), if feathers are plucked or the skin is scarified after intravenous injection of the virus, specific lesions will develop at the site of the cutaneous injury. The author concluded that the requirements for the development of eruptive lesions are a viremia and a susceptible point for the lesion.

Beaudette (1941) stated that in a small percentage of birds (usually less than 5 per cent) secondary lesions may appear on the head as a result of viremia.

That fowl pox was transmitted by intermediary carriers has been reported by several investigators. Cary (1906) stated that "Mosquitoes — and other insects — may sometimes be the real carriers of the real virus." Kligler et al. (1929) have shown that Culex pipiens and Aedes aegypti are capable of transmitting the disease from infected chickens, as lesions developed in from 5 to 10 days after the infected mosquito was allowed to feed on a susceptible chicken. The mosquitoes were considered to be mechanical carriers of the virus as they were capable of transmission of the disease immediately after feeding on infected chickens. In one case the mosquitoes remained infectious for at least 14 days.

Kligler and Ashner (1929) studied the transmission of fowl pox by Culex pipiens and Aedes aegypti and showed that the same mosquito may produce a number of consecutive infections for at least 16 days. Infected mosquitoes were capable of transmitting the infection despite intermediate feeding on guinea pigs. The virus appeared to be localized on the proboscis of the mosquitoes, which may remain infective for 16 to 19 days. Only rarely could the disease be transmitted by inoculation of other parts of the mosquito's body. The virus behaved in the same manner as on infected pins as on the proboscis. Blanc and Caminopetros (1930) showed that infected Culex pipiens could transmit the infection for at least 58 days and from pigeon to

pigeon for at least 38 days. Matheson et al. (1932) showed that the virus could be transmitted by Aedes vexans for at least 27 days.

Stuppy (1932) presented evidence that Culex pipiens and Stegomyia fasciata were capable of transmitting fowl pox for at least 39 days. The incubation of the mosquito-transmitted infection was from 6 to 8 days. The infection was sufficient to produce immunity. It was believed that the transfer of virus was not simply mechanical and that it was possible that the mosquitoes remained infective for life. The virus was present in the body of the mosquitoes.

The incubation period of Kikuth and Gollub (1932) canary pox is about 4 days, the canaries dying from 7 to 12 days after infection. Durant and McDougle (1938) observed that canary pox apparently occurs in cycles of about 21 days in young canaries, with a mortality of about 100 per cent of all birds affected. Death occurred quite regularly from the tenth to the fourteenth day after exposure. Recovered canaries were refractory to subsequent exposure to a virulent virus. According to Coulston and Manwell (1941), canary pox was uniformly fatal to canaries after a week or 10 days when the lesions were localized other than on the toes and legs. In the latter form the disease was chronic, but it also killed the canary after a period of some weeks or months.

Prevention and control. Graham and Brandly (1940) and Beaudette (1949) present extensive reviews of the literature on immunization. Much of the early work was conducted with virus which had been attenuated, and in some cases inactivated, by physical or chemical means, or virus modified by passage through heterologous hosts. The immunogenic properties of these preparations were subject to wide variations. The ineffectiveness of these vaccines prompted exploration of the possibilities of utilizing virulent fowl pox virus obtained from cutaneous lesions. De Blieck and van Heelsbergen (1929) were probably the first to use on a large

scale the fully virulent virus for cutaneous immunization. That vaccination of chickens with fully virulent virus is an effective immunizing agent has been reported by many investigators who have also emphasized that certain potential postvaccination hazards may accompany this method of immunization. A review of the reasons for failures in immunization against fowl pox has been presented by Beaudette (1941).

Two types of vaccines are available for immunization of domestic fowl against pox: fowl pox vaccine and pigeon pox vaccine. The success of a program with these vaccines depends upon their utilization only under the conditions where indicated, and upon the potency and purity of the vaccines and their application.

Vaccines were formerly of two types: "chicken origin" or "pigeon propagated," and "chick-embryo origin" or "egg-propagated," depending upon the method of preparation. According to Hejl (1957), licensed laboratories in the United States are not permitted to use fowls in the production of poultry vaccines due to the possibility that the causative agents of other diseases may be contained in the crude material obtained from chicken and pigeon tissues.

Fowl pox vaccine. "Chick-embryo origin" or "egg-propagated" vaccine is prepared by propagation of the virus on the chorio-allantoic membrane of chicken eggs. The infected membranes are collected, desiccated, ground to a fine powder, distributed in suitable containers, and stored under refrigeration. The best type of containers are glass vials or ampoules in which the virus can be hermetically sealed *in vacuo* for maximum retention of potency of the virus. A suspension of 40 mg. of virus in 2 cc. of diluent is satisfactory for vaccination of 100 chickens according to Beaudette (1911).

Thorning *et al.* (1943a, 1943b) and Kerlin and Graham (1944a, 1944b) reported that fowl pox vaccines prepared from the entire chicken embryo possess immunogenic properties. Bryan (1949)

prepared a satisfactory vaccine consisting of 5 per cent fowl pox virus-infected, undesiccated entire embryo suspended in 50 per cent buffered glycerol at pH 7.6. When stored at 14° C., the vaccine was active for 8 months. When stored at 5° C., the vaccine was viable for 2 years.

Prier (1951) prepared a mixed Newcastle disease-fowl pox whole embryo vaccine in 50 per cent glycerol that immunized chickens against both diseases.

Brandly and Dunlap (1939) and Sabban (1954) present conclusive evidence that egg-propagated vaccines represent a distinct and desirable refinement over chicken-propagated vaccines. Zargar and Pomeroy (1950) isolated Newcastle disease virus from commercial fowl pox and laryngotracheitis vaccines. These findings emphasize the necessity for adequate precautions to exclude contamination of vaccines with extraneous viruses.

Pigeon pox vaccine. "Chick-embryo origin" or "egg-propagated" vaccine is prepared and processed as previously described for fowl pox vaccine. A suspension of at least 80 mg. of virus in 4 cc. of diluent for vaccination of 100 chickens is recommended by Beaudette (1941).

Nobrega and Reis (1949) reported that fowl pox vaccine prepared with whole embryo from eggs inoculated with pigeon pox virus by the allantoic cavity route gave results as satisfactory as those obtained by propagation of the virus on the chorio-allantoic membrane.

Vaccination. Fowl pox vaccine is used to vaccinate chickens and turkeys, and it may also be used for pheasants. Fowl pox vaccine is not to be used on pigeons, and it is never to be used on laying birds.

Pigeon pox vaccine is used to vaccinate chickens, turkeys, pigeons, and pheasants. It is used on chickens and turkeys when these birds are laying or when the flock is debilitated through the presence of other diseases or improper nutrition and management.

Fowl pox vaccines of adequate potency contain the causal agent and when improperly used are capable of producing

the disease in a severe form in chickens. When properly used, the vaccine is equivalent to a mild attack of the disease. Vaccination differs from the natural disease only in that the vaccine is applied to a small area, the extent of the lesion is less than that encountered in the natural disease, and it is given to the chicken at an age when postvaccination reactions are less likely to occur than in the natural disease.

All vaccines should be mixed away from the poultry house and precautions should be taken not to spill any of it. The vaccine should be mixed just before use and only enough prepared for one day's operation. If it is necessary to hold vaccine overnight, it should be kept frozen. After the vaccine is mixed, the hands should be washed to prevent contamination of the birds since the vaccine should be kept away from all parts of the bird except the site of vaccination. When vaccination is completed, the unused vaccine and all containers should be burned. The "stick" instruments should be boiled if they are to be kept for further use.

Since the flock will have to be examined for "takes," it is well to be consistent in the site of vaccination so that no confusion will occur in a false interpretation of the reaction to the vaccine.

Chickens may be vaccinated with fowl pox vaccine by one of two methods: the "stick" method and the "feather follicle," or brush, method, since the virus has a predilection for cutaneous epithelium and follicular cells. Chickens may be vaccinated successfully with pigeon pox vaccine by the "feather follicle" method only, since pigeon pox virus has a particular affinity for follicular cells.

In the "stick" method the vaccine is introduced into the cutaneous epithelium by sticking the skin with a sharp-pointed instrument that has been moistened with the vaccine. The sites of application may be the skin of the leg, the under surface of the web of the wing, or the breast. The under surface of the web of the wing is probably the most convenient area. In baby chicks the vaccine is introduced into the skin of the flank region. The vaccinating instrument may be of any type that will insure adherence of the virus for its introduction into the skin. Most manufacturers supply an instrument with the vaccine.

When the "stick" method is used, the vaccine should be in a container with a mouth wide enough to allow entrance of the instrument so that the points can be moistened easily with the vaccine. As an added precaution to prevent spilling of the vaccine, a small piece of wood, 2 inches by 4 inches by 6 inches long, with holes large enough to receive the container of vaccine, should be prepared. The instrument should be moistened with vaccine before each application.

With the "feather follicle" method the vaccine is applied to defeathered follicles with a brush. The brush should be stiff enough to withstand repeated usage without deterioration, and the bristles should be of a suitable length and number. Most manufacturers supply a brush with the vaccine. When vaccine is applied, only three or four follicles should be infected, as the reaction of the vaccine increases in proportion to the number of follicles infected. Usually, the most convenient vaccination area is the anterior or lateral aspect of one leg about midway between the hock joint and the femoro-tibial articulation of the leg. The bristles of the brush should be moistened with vaccine before each application and directed into the open follicles for proper deposition of the vaccine.

When pigeon pox vaccine is used, the area should be considerably larger than that with fowl pox vaccine, since the degree of immunity produced is in direct proportion to the size of the vaccination lesion, and pigeon pox virus does not produce a systemic reaction in chickens. The feathers should be plucked from an area of about 1 by 2 inches on the leg, and the exposed follicles over the entire area infected with the vaccine by directing the brush against the openings of the follicles. This is of particular importance in

view of the affinity of pigeon pox virus for follicular cells.

The method of vaccination is a matter of personal preference. There are certain distinct advantages of the "stick" method over the "follicle" method which make the former more desirable when using fowl pox vaccine. According to Johnson (1934), some advantages of the "stick" method are as follows: uses less virus; permits more rapid vaccination; requires less help by eliminating feather plucking; results in less contamination of fowls and premises; results in less virus at "take"; standardizes vaccination procedure; results in less exposure of the "takes"; and provides a method applicable to fowls from a day old to maturity.

Reaction to fowl pox vaccine and evidence of a successful vaccination consists of a scab or "take" which may be readily detected in a week at the site of vaccination by either the "stick" or "feather follicle" method. The flock should be examined for "takes" between the sixth and tenth day following vaccination. If the vaccine was applied to the web of the wing by the "stick" method, two small scabs will be observed where the points of the vaccinating instrument were introduced into the skin and usually two small scabs on

the outer surface of the wing where the points emerged (Fig. 26.5).

With the "feather follicle" method there will be a swelling of each follicle and the formation of a scab (Fig. 26.6). These scabs will enlarge during the course of a week or 10 days and may coalesce to form a single scab covering the entire vaccination area.

A "take" following vaccination with pigeon pox vaccine is indicated by a swelling of the follicles which may be evident as early as the fifth day. Scabs are not produced in chickens immunized with this vaccine. A flock examination for "takes" should be made at about 10 to 12 days following vaccination. "Takes" with both fowl and pigeon pox vaccines subside and disappear about the third week following vaccination. The scabs dry and drop off the birds immunized with fowl pox vaccine.

The immunity developed following vaccination with fowl pox vaccines endures throughout the life of the chicken. With pigeon pox vaccine the duration of the immunity is not as long nor as well established as that from fowl pox vaccine (Seegar and Price, 1956).

Vaccination provides no protection during the first two or three weeks, and birds

FIG. 26.5 — Web of wing of chicken. Six-day "takes," fowl pox vaccine, "stick" method. (Brunett, Cornell Vet.)
FIG. 26.6 — Leg of chicken. Six-day "takes," fowl pox vaccine, "feather follicle" method. (Brunett, Cornell Vet.)

may become infected with the natural disease. Maximum immunity is usually attained by the end of the fourth week. Vaccination is only a prophylactic measure and not a treatment. If vaccination is to be done when the disease has just made its appearance, all visibly affected birds should be removed from the flock and isolated to prevent spread of the infection from this source. Medicinal treatment of chickens against fowl pox is of no value.

When properly applied, a vaccine of adequate potency should produce "takes" in all vaccinated birds. Failure to obtain "takes" may be the result of the application of a vaccine of inadequate potency (one used after expiration date or subjected to deleterious influences), improper application of the vaccine, or use on immune birds In the event that "takes" are not obtained (except in birds previously immunized or recovered), the flock should be revaccinated at once.

The age of the bird receiving fowl pox vaccine is important. In certain areas day-old chicks are vaccinated, but the severe systemic reactions and high mortality rate following vaccination do not make birds of this age satisfactory subjects The preferable age is from the sixth to the twelfth week according to Delaplane (1943) and from the eighth to the tenth week according to Beaudette (1941). As as rule the chickens should be at least 1 month old. Chickens should not be vaccinated within 1 month and preferably 2 months before production is expected to start in order to allow ample time for them to recover from the effects of the vaccination. The upper limit for light breeds would be from 3 to 3½ months and for heavy breeds from 4 to 4½ months.

With pigeon pox vaccine the upper age limit for vaccination is not important since this vaccine does not produce a systemic reaction in chickens. In young chickens, however, the age limit depends upon the feathering of the bird since the vaccine is applied only by the "feather follicle" method. Generally, chickens should be at least 6 weeks old, and it is preferable to

have all birds in the flock well feathered before vaccination.

When pigeon pox vaccine is applied to pigeons, only four or five follicles need to be infected, since this virus is as pathogenic for pigeons as fowl pox virus is for chickens. Follicles of either the breast or leg of the pigeon may be inoculated. The bristles of the vaccinating brush should be directed against the openings of the follicles to insure the deposition of the vaccine in the follicles. Pigeons should be vaccinated at about 4 to 6 weeks of age. Vaccinated pigeons should be segregated from nonvaccinated pigeons to prevent spread of the infection.

Goldhaft (1956) has described a method of spray application of pigeon pox vaccine to chickens. The degree and duration of immunity was, in general, directly related to the number and area of follicles infected by the vaccine. The vaccine was used successfully with adult chickens and day old chicks.

Prophylactic vaccination. Prophylactic immunization of chickens against fowl pox consists of vaccinating susceptible chickens with fowl pox vaccine prior to the time when the disease is likely to appear. Vaccination is usually done during the spring and summer months in those areas where the disease appears during the fall and winter months. In tropical climates, where the disease may make its appearance throughout the year, vaccination may be done at any time when warranted without regard to seasonal periods.

Vaccination is indicated in three types of flocks which present themselves in the problem of prophylaxis against fowl pox:

1. Vaccination is indicated as a routine prophylactic measure in a flock that has been infected the previous year and when the owner wishes to prevent such an occurrence in the new susceptible population. All young stock, produced on the premises or introduced from other sources since the outbreak, should receive fowl pox vaccine. When several lots of birds are raised during the year, each lot should be vaccinated at the appropriate age. Vac

cinated birds should be maintained under strict isolation as they are *a source of infection* for the nonvaccinated birds. If vaccination with fowl pox vaccine is delayed beyond a reasonable limit to expect the establishment of immunity prior to housing of the pullets, then pigeon pox vaccine should be used. This practice, however, should not be necessary.

2. If fowl pox was present the previous year but pigeon pox vaccine was used to check the spread of the disease at that time, vaccination is desirable. Since pigeon pox vaccine does not induce a durable immunity in chickens, the old birds should be revaccinated with fowl pox vaccine.

3. *In certain congested poultry districts* where fowl pox is prevalent, the owner should immunize the flock through the application of fowl pox vaccine to protect the flock against infection from the neighboring flocks. Delay under these circumstances may result in the infection being established at a time unfavorable for vaccination.

Prophylactic vaccination of pigeons with pigeon pox vaccine is indicated if the infection was present on the premises the previous year and if the loft is in a congested pigeon district.

Vaccination of canaries against pox with canary pox virus has not been successful according to Burnet (1933a) and Durant and McDougle (1938). The latter authors observed that canaries recovered from the natural disease were refractory to further infection. Coulston and Manwell (1941) reported that canaries which had been vaccinated with the virus attenuated through storage did develop an immunity which protected them to some degree, but not completely, against exposure to fully virulent virus. As a therapeutic measure, 1 to 3 per cent mercurochrome in 70 per cent alcohol, to which a trace of acetone was added, was applied once or twice daily to the infected pox areas. The duration of the treatment varied with the severity of the disease. The authors concluded that "This method of treatment is successful in nearly all cases, unless they are very advanced. Recovered birds exhibit a strong immunity to reinfection, particularly if they have been infected to begin with by a virulent virus."

Beaudette (1949) reported that favorable results had been obtained by vaccination of young canaries by the wing "stick" method using a suspension of the most advanced passage of an egg-propagated strain of canary pox virus. Beaudette (1953) has compiled an excellent review of the literature on modification of canary pox virus and vaccination of canaries.

Fowl Plague

Fowl plague (fowl pest, *peste aviaire*, *Geflügelpest*) is an acute, highly infectious, generally fatal virus disease of fowls and sometimes of water birds.

History. Fowl plague was described first by Perroncito (1878) in Italy, and later studied by Rivolta and Delprato (1880), who found it to be different from fowl cholera and called it *typhus exsudativus gallinarum*. Subsequently, it was discovered in enzootic form in southern Europe and has been observed in many countries of the world. It has been widespread in Austria, has been found in Switzerland, Rumania, and Russia, and occasionally has spread to France, Holland, and Great Britain. The disease is indigenous in Egypt, has extended widely in Asia, particularly in China and Japan, and has occurred also in South America.

Fowl plague was reported first in North America in 1924–25 and again in 1929. The first severe losses appear to have occurred in the poultry market of New York City, and others later in the poultry markets of New Jersey and Philadelphia. Dr. John R. Mohler, Chief of the United States Bureau of Animal Industry, reported the existence of the disease in the United States in December, 1924. Its occurrence in New York was reported by Brunett (1925) and in Pennsylvania by Stubbs in the same year. Later in 1925, Beaudette reported the presence of fowl plague in New Jersey; Julien, in Indiana; Boughton and Tunnicliff, in Illinois; and Johnson, in Michigan. An outbreak, reported by Beaudette and associates in New Jersey in 1929, was confined to a few flocks in one locality and was eradicated promptly.

Etiology. Centanni and Savonuzzi (1900) demonstrated the cause of fowl plague to be a filterable virus, and later their results were confirmed by other workers. Weineck (1940) reports that the infectivity of tissues containing fowl plague virus is destroyed by extraction with alcohol ether,

alcohol, benzene, and chloroform but not by acetone or ether. Weineck considers this as evidence that the virulent component of the virus is lipoid in nature. The disease attacks chickens and related species, but chickens and turkeys are found affected most frequently and are considered most susceptible. With few exceptions, which seem to be immune, chickens are infected easily by subcutaneous, intramuscular, intraperitoneal, or intravenous injections of amounts even as small as one millionth of a cubic centimeter. Feeding infection also succeeds. Introduction of the virus through injuries to the skin or by instillation into the eye produces the disease. After such infection, chickens die in 36 to 72 hours and may or may not show symptoms.

Natural infection among pigeons is not found so commonly, water birds, such as ducks and geese, often remain free when chickens are attacked severely. It is a curious fact that this disease is confined frequently to a single species, and that other fowls on the same premises are not infected. Artificial infection, even by large amounts of virus from the species in which it has occurred naturally, often fails when injected into other species. Thus, on premises where there is great mortality among chickens, waterfowl usually are resistant. Injection of the virus into the central nervous system succeeds more frequently among pigeons and water birds, in which case the disease usually gives rise to nervous symptoms, such as convulsions and paralysis.

Mammals are considered immune, as artificial infection has been unsuccessful, and it is believed that this disease is not dangerous to man, as there are no recorded cases. Morcos (1946) reports the successful transfer of the virus of fowl plague from birds into mammals by using defibrinated infected fowl blood injected subdurally into white mice in which the virus became fixed after the fifth passage. The intracerebral injection was made just above and posterior to the eye, and after the fifth passage produced death in about 3 days. At the same time, the virus became attenuated in fowls with a period of incubation of 6 days instead of the previous 3 day period. The mouse brain virus treated with ether was antigenic, and Morcos believes it is promising as an immunizing agent.

Symptoms. Fowl plague appears with sudden onset. Chickens may die without showing any symptoms. Usually there is weakness and an inclination to stay on the roost or in some secluded place to avoid disturbance. Dullness and inappetence are present. Hens stop laying, the feathers are ruffled, and the birds stagger (Fig. 27.1).

Cyanosis develops, with the comb and wattles becoming dark red or blackish. The eyes are dark, the eyelids close, the conjunctiva is red and swollen. There is fever, the body temperature rising to 110°-112° F., and gradually lowering until it is subnormal (100°-103° F.).

Edema of the head, consisting of an exudation of serum into the subcutaneous tissues, marked around the eyes, ear lobes, and wattles, with a tendency to extend

FIG. 27.1 — Fowl plague. Dullness, listlessness, ruffled feathers.

downward along the throat toward the breast, frequently appears. Edema of the glottis may develop, followed by difficulty in respiration. The chickens may open their beaks for air and breathe with a rattling sound; suffocation may occur (Fig. 27.2). Mucus exudes from the nostrils, with a gray or reddish, blood-tinged exudate, which may cause the chickens to shake their heads in an effort to expel the obstructive discharge. Similar exudate may be found in the pharynx, which may contribute to the gasping and rattling sounds. The mucosa of the mouth may show small hemorrhages, and fibrinous exudate may be observed. Diarrhea also may be present, usually profuse and watery. Finally, the head cannot be raised from the ground, coma develops, the respiration becomes more labored, and death results, usually within 2 days.

Many modifications of symptoms may be noticed. Nervous disorders frequently are associated, particularly in cases that do not die early, with excitation, convulsions, rolling, or circling movements. There also may be ataxia and blindness.

In 1946, Jungherr and associates reported that in experimental work with the Dutch East Indies strain of virus, the first symptoms were usually observed within 18 to 50 hours after inoculation with 100 or more minimal lethal doses of virus. Death occurred within the next 24 hours. The first evidence of the disease was a decrease of sensitivity to sensory stimuli. There was a pronounced general malaise, congestion of comb and wattles, and closing of the eyes, with the head resting on the breast or on the floor of the cage. Loss of appetite was evident, while the desire to drink remained, so that birds frequently would fall asleep while drinking and let the water run from the mouth. Whether birds recovered or whether death occurred later, small focal or confluent areas of necrosis often were found on the comb and wattles. Inappetence, marked dehydration, loss of flesh, and in some cases severe torticollis with starvation were found. The corneas showed focal or diffuse opacities in rare cases.

Pathology. The virus of fowl plague is present throughout the body and in the blood, the nervous system, all the tissues and tissue fluids, is secreted from the glands, and is found in the nasal and oral secretions, the intestinal and urinary excretions, and in the mucous and serous exudates. The virus, or materials containing it, is highly infectious in very small amounts; and the blood is so rich in virus that 0.000,000,1 cc. may be infectious for the chicken. The virus appears to be in close contact with the blood cells, while plasma or material free of cells is less infectious. It is killed easily; exposure to direct sunlight or to a temperature of 70° C. for a few minutes renders it inactive. Moses et al. (1947) report the virus is destroyed within one hour at pH of 4.0. Its activity is destroyed quickly by the common antiseptics and disinfectants. Cold, however, promotes longevity of the virus, and it may be preserved for long periods under refrigeration. Desiccation or glycerination preserves the virus so that it retains its virulence for years. Blood from chickens suffering from the disease, preserved in sealed test tubes, remains infectious for a long time. Filtrates retain their virulence with less uniformity than unfiltered material. Purchase (1931) showed that the virus of fowl plague re-

FIG. 27.2 — Fowl plague. Chicken's head, swollen about eyes, wattles, and ear lobes.

tained its activity in flesh for 237 days, and in the bone marrow for 303 days when kept at chilling temperature. He believes the disease may be spread by feathers, since he found that the virus survived on feathers for 18 days after being plucked from a chicken dead of fowl plague. Burnet and Ferry (1934) have reported the propagation of the virus by inoculation of the chorio-allantoic membranes of developing chicken embryos. Jungherr et al. (1946) studied the inoculation of the Dutch East Indies strain into embryonating chicken eggs. Death was caused, and, regardless of age or route of inoculation, bright to dark red discoloration indicative of congestion of the embryonic tissues, especially the skin and less so of the musculature, occurred. Scattered punctiform hemorrhages were found in the skin and skeletal musculature with renal congestion in 12-day-old or older embryos. Minimum doses of virus in some eggs caused slower death of embryos, which showed tumefaction and sometimes pinhead-sized, gray focal areas in the spleen and rarely in the liver. Variant viruses were obtained from such spleens which, in further egg passages, produced congestive and hemorrhagic lesions similar to the parent strain.

Histopathological studies were made on embryonating chicken eggs. Inoculation into the allantoic sac usually failed to show any specific lesions. Inoculation of the virus onto the chorio-allantoic membrane was followed in about one-fourth of the cases by shallow hemorrhagic ulcers in the ectoderm, filled with disintegrated red cells and heterophils, and delimited by an intensely congested and fibrotic zone of the mesoderm. The lesions in the embryo were multiple capillary hemorrhages, particularly in the skeletal muscles and in the spinal cord and brain as well as the myocardium and the gizzard wall.

Hotz and Schafer (1955), using thin histologic sections of allantoic membranes from infected chicken embryos in the electron microscope, demonstrated deviations from the normal picture beginning 4–5 hours after infection. At the sixth hour,

particles resembling elementary bodies were observed at the cell surface, but not within the cell.

Shinnin et al. (1957) report serial propagation and cytopathogenic effect of fowl plague virus is the same in cells of pig kidney as in cells of chicken embryos.

Waterson (1958), reports fowl plague virus in agar suspensions of chicken embryo cells form plaques in numbers directly proportional to the quantity of the inoculum. The plaque count is not affected by allowing time for adsorption of virus before mixing with the agar.

Franklin (1958), using fluorescent antibody technique, studied the growth of fowl plague virus in cultures of macrophages derived from chicken leukocytes and found a soluble antigen multiplying in the nucleus. These studies indicated that soluble antigen does not multiply in cells undergoing mitosis. Hemagglutinating antigens were found only in the cytoplasm and were detected later than the soluble antigen.

The changes found at postmortem examination are those of septicemia. The lesions cannot be depended upon entirely for diagnosis but are somewhat characteristic and usually quite uniform. Rigor mortis sets in early and is complete. There is cyanosis of the head; the face, comb and wattles are dark; and the conjunctiva is swollen, often petechiated. The nostrils and beak show accumulation of mucus, frequently stained or streaked with blood. There may be edematous swellings of the head; and the fluid, clear and straw-colored, may be most marked in the face, about the eyes, in the ear lobes, the wattles, or in the subcutaneous tissue of the neck and breast (Fig. 27.3).

Removal of the skin shows engorgement of all blood vessels. The flesh is red. Hemorrhages are widespread and vary from the smallest possible petechiae to ecchymoses. Those that are small and widely scattered may be overlooked easily but are conspicuous when grouped, as in the proventriculus or over the abdominal fat. They may be found in any tissue, but are

FIG. 27.3 — Fowl plague. Chicken's head showing swollen wattles.

frequently in the muscles of the breast. Very distinct petechial hemorrhages, quite characteristic and appearing to have been sprayed on with an atomizer, are found on the inner surface of the sternum when the breast is removed. Hemorrhages usually are found in the fat about the abdominal cavity, and petechiae frequently are sprinkled over the fat tissue forming the bottom of this cavity. Petechial hemorrhages also are particularly noticeable in the abdominal fat over the proventriculus, gizzard, and mesentery, and in the thoracic fat over the heart.

The most characteristic lesion is the hemorrhagic alteration in the proventricu-

lus, which can be seen after the whitish mucus is washed off the mucous membrane. Such hemorrhages, usually ecchymoses, may be observed between the conical elevations or secreting glands of this portion of the stomach and are more noticeable when they occur as bright red blotches on the mucous membrane where it becomes smooth on entering the gizzard (Fig. 27.4).

Petechiae or ecchymoses also are seen in the gizzard after the rough membrane or cuticle has been removed. The intestine frequently shows hemorrhagic changes, especially in the duodenum. These hemorrhages, petechiae or ecchymoses on the serous or mucous coat, are accompanied by catarrhal enteritis. The hemorrhagic enteritis usually present in fowl cholera is not found in fowl plague and may be helpful in differentiating these diseases.

The liver, spleen, and lungs do not show much change. Congestion may be found, and also hemorrhagic fluid in the peritoneum and pericardium. Exposure to the air results in clotting, and in some cases fibrinous exudate is already present. This is spoken of sometimes as the exudative form. The ovary, when functioning, shows highly engorged blood vessels, especially in the large follicles. The oviduct often shows gray exudation, and the wall is swollen.

Microscopically, the chief changes are congestion and hemorrhages. Perivascular round-cell infiltrations have been noted. Some have described necrosis in brain tissue and the presence of bodies which

FIG. 27.4 — Fowl plague. Hemorrhages of proventriculus (chicken).

strongly resemble intracellular inclusions.

Beaudette and associates, reporting the outbreak of fowl plague in New Jersey in 1929, recorded the occurrence of vesicles on the comb and wattles of chickens artificially infected. These vesicles were observed in cases that ran longer than the usual course and varied in size from a pinhead to 4–5 mm. in diameter. The same investigators also reported the occurrence of edema of the feet and tibiometatarsal joint, and spots of violet color on the scales of the shanks and feet, some as mere spots and others as blotches 4–5 cm. in length.

Jungherr et al (1946) in experimental work with the Dutch East Indies strain reported a variety of postmortem changes. The acute cases showed congestive, hemorrhagic, and transudative changes. Congestion was evident in the skin, the comb and wattles, musculature, oropharynx, larynx, trachea, and the abdominal viscera. Punctiform hemorrhages were most often found in the coronary fat beneath the epicardium, especially the left auricle and around the roots of the large vessels. Intestinal hemorrhages were discrete, scattered along the serosa in the walls of the intestine and in the mucosa of the proventriculus, and in the region of the Peyer's patches and the cecal tonsils. Transudative changes were less frequent and showed moderate to severe edema of the lungs with congestion or hemorrhage and consolidation. Pericardial fluid that jellied on exposure to the air was sometimes found, and in a few cases subcutaneous edema of the hocks, feet, breast, neck, and head was present. Usually the spleen appeared small and anemic, often almost white except for stellate areas of capillary injection near the mesenteric attachment.

Jungherr et al. also studied the histopathological changes in over 100 experimental cases of different ages while experimenting with the Dutch East Indies strain. They considered the basic lesion roundish but not sharply delimited, foci of necrosis of various organs. The young

foci were recognized by acidophilic staining. The cellular architecture was at first undisturbed, but in well-developed foci the tissue cells were swollen and vesicle-like, with the cell membrane prominent and the nucleus small and marginated, leaving a large cytoplasmic space containing eosinophilic granules or globules. The necrotic foci did not show pyknosis or karyorrhexis, did not become confluent, but remained scattered. The foci were rarely numerous but were found in a variety of the organs such as the spleen, lung, thymus, liver, gallbladder, kidney, heart, pancreas, proventriculus, intestine, comb and wattles, iris, and occasionally in the gonads. The spleen showed the highest incidence of necrotic foci, and it was estimated that more than three-fourths of the cases showed spleen involvement, with the other organs in a falling order of frequency.

The necrobiotic foci in various organs were often accompanied by hemorrhages, congestion, and edema. Hemorrhages were found in the submucosa of the secondary pulmonary bronchi, in the alveolar tissue, in the proventricular mucosa, in the thyroid, subepicardium, myocardium, and elsewhere. The lungs often showed edema and variable degrees of congestion with some proliferation, capillary congestion, and edema, and occasionally fibrinous thrombi were found in the region of necrotic foci.

Diagnosis of fowl plague may be returned when an acute, plaguelike infectious disease resembling fowl cholera is encountered, accompanied by cyanosis and edema of the head and hemorrhages in the proventriculus, gizzard, and abdominal fat. In questionable cases, doubt is removed by negative bacteriological examinations, negative results from inoculations into mammals, and filtrates producing typical symptoms with characteristic lesions in chickens. Differentiation from other acute infectious diseases, particularly fowl cholera, is difficult. Both diseases present similar symptoms and lesions: rapid onset, cyanosis, prostration,

diarrhea, high mortality, and especially hemorrhagic alterations. The losses from fowl plague are regular and extensive, while from fowl cholera the mortality is likely to be irregular. In the recorded natural outbreaks of fowl plague in this country, where chickens are associated with waterfowl, such as ducks and geese, the latter are not affected; while in fowl cholera, ducks and geese are highly susceptible and show the disease in a marked and highly fatal form. European literature indicates that young geese sometimes are affected. In numerous necropsies of fowl cholera cases, areas of focal necrosis appearing as whitish-yellow points are observed scattered over the liver. Such changes have not been found in fowl plague. The hemorrhages of fowl cholera more often are confined to the heart and intestine, while in fowl plague the hemorrhagic lesions are more likely to be scattered throughout the body.

Placidi and Santucci (1956) report fowl plague virus agglutinating the erythrocytes of the chicken, camel, horse, donkey, and mule.

Grausgruber (1958) reviewing the various serologic methods of diagnosis, advocates the agglutination test, using fowl erythrocytes sensitized by suspensions of infected organ material. He states this gives the most reliable results in dead birds.

In cholera, culture examination is positive; inoculation into rabbits, mice, and pigeons produces death, and filtrates do not cause the disease. Where there is recourse to laboratory procedure in fowl plague, culture examination and inoculations into rabbits, mice, and pigeons are negative, while filtrates will produce the disease in chickens.

Newcastle disease may be found in chicks, in growing chickens, and in mature fowl. The disease in chicks frequently begins with gasping, wheezing, or coughing, and the same changes are also found in older birds. It spreads very rapidly and may go through an entire group in 1 or 2 weeks. Later many different kinds of nervous symptoms and paralysis may

be found. Shivering, incoordination, convulsions, and chronic spasms of the head or neck and body have been noted. Twitching of the head or tail may be seen, with birds walking in circles, forward or backward. Alternating periods of excitation and depression may be found. Birds may stand motionless with the head drawn back and eyes fixed. The head may be drawn toward the ground. The presence of respiratory difficulty followed by nervous symptoms points to Newcastle disease. Mortality may be high in young birds and slight or none in mature birds. Layers show an abrupt drop in egg production followed by irregular shells, discolored shells, and soft shells. Varying lengths of time are required for resumption of production.

Differential diagnosis. Doyle in England has described a disease similar to fowl plague from which it is difficult to differentiate. He discovered the malady near Newcastle and named it "Newcastle disease." It also has been described in other places as "pseudo-fowl plague." The symptoms are quite similar, and there is high mortality, but the pathologic changes are not nearly so marked. It can be transferred readily by blood, brain, organ emulsion, oral discharges, and feces, as well as by filtrates of these materials. The hemorrhages present in this disease are not nearly so marked as in fowl plague, and the period of incubation is longer (about 1 week or more). Experimental infection by contact often does not succeed in fowl plague, whereas in Newcastle disease contact infection appears easier.

Apoplectiform septicemia and sleeping sickness cause symptoms and lesions similar to fowl plague but can be differentiated by the demonstration of a streptococcus in the blood stream. These diseases produce depression, staggering, prostration, coma, and death. Postmortem examinations disclose hemorrhages and hemorrhagic discolorations which are rather widespread. There may be lung congestion and hemorrhage, and usually a hemorrhagic pericarditis. Peritonitis is

frequent and also catarrhal or hemorrhagic enteritis.

Phosphorus poisoning produces hemorrhagic lesions in the proventriculus and may be confused with fowl plague. Phosphorus, highly poisonous to chickens, causes depression, weakness, trembling, thirst, and sometimes diarrhea, and may result in sudden death. Postmortem examinations may show hemorrhages in the proventriculus, usually with erosions, and extending more deeply into the tissue than in fowl plague. In phosphorus poisoning there is usually severe enteritis, particularly in the upper portion of the intestine. If such poisoning is suspected, attention should be directed to the detection of the phosphorus vapor that may be noticed as a transient cloud when the crop, proventriculus, and gizzard first are opened. The contents also have the distinctive odor of phosphorus, and if such material is taken into a dark room or mixed with dilute acid, the characteristic phosphorus luminosity is seen.

Botulism may be attended by sudden onset and cause high mortality. It may attack a flock with overnight suddenness, but the clinical picture is so striking that it should not be confused with any other disease. Usually no lesions are found in botulism.

Edema of the wattles, usually an infection of one or both wattles, with listlessness, inappetence, and marked depression, may be confused with fowl plague. Some cases show a slight swelling, while in others the wattles become enormous and occasionally rupture. The swelling first contains an edematous fluid which gradually thickens and becomes caseated. The mortality is not high unless the disease reaches the sinuses or spreads systemically. It is frequently due to the organism of fowl cholera.

Prognosis. The course of fowl plague is quite rapid in chickens, which often live only a few hours. After artificial injection the fowls usually die in 36 to 72 hours. Death frequently takes place after a short struggle, and the victim often is found dead on its back. Occasionally recovery occurs, and such survivors are solidly immune.

Epizootiology. The virus is found in many European countries, and the disease occurs where conditions are favorable for it. Fowl plague may be spread rapidly under certain conditions and usually disappears after a time, due in part to its high mortality; thus the disease is somewhat self-limiting.

The diseased bird is the most dangerous factor in the spread of the disease, so the introduction of one or more infected chickens may cause an outbreak. Usually the newly purchased birds die first, although this is not always the case, since carriers are known to exist. Losses begin within 1 or 2 days after the disease has been introduced.

The virus is present in the eye, nasal secretions, in the mouth, feces, and urine. The feed, drinking water, and soil become contaminated, and the virus may be spread on the shoes of attendants. Livestock dealers provide excellent opportunity for the spread of the disease as they travel from place to place. Chickens may ingest the virus with contaminated feed or water and with substances picked up from the soil, while the virus also may enter through the respiratory tract. The virus is present in the blood, so many believe vectors play a part in the natural spread of the disease. It is a commonly held opinion that susceptible chickens in close association with infected chickens often do not contract the disease, but when injected frequently succumb. This lends support to the belief that vectors are instrumental in transmitting fowl plague. It is also the common experience that healthy chickens placed in uncleaned, undisinfected cages in which others have died of fowl plague frequently do not contract the disease. This is attributed to rapid destruction of the virus except under conditions favorable to its existence.

Wild birds and semiwild birds that commonly associate with farmyard fowls also may spread the disease. Thus, pigeons, sparrows, and similar birds under some circumstances disseminate the di-

ease. Fowl plague may also be spread by streams. In certain instances it has been noted that chickens on farms downstream from infected areas have contracted the disease, presumably from the water.

Immunization. Fowl plague is highly fatal. The few birds that recover appear to be solidly immune. The serum from recovered chickens shows serum neutralizing and hemagglutinating inhibiting antibodies and will protect susceptible birds, but only for a short time, and is impractical. Generoso and San Agustin (1947) report a vaccine of fairly good protective power against Philippine avian plague using oils and saponin solution as vehicles. Daubney et al. (1949) state "no very great success has hitherto attended the efforts of workers to devise a satisfactory technique for artificial immunization." Their experiments indicated that adjuvants and the use of killed acid-fast bacilli, together with formalized vaccines, seemed to enhance immunization. These workers stated that a strain was found that when passed through pigeon embryos was apathogenic for chickens, but gave solid immunity against virulent fowl plague virus.

Hallauer and Kronauer (1960) report variants of fowl plague virus isolated from human explants (amnion, HeLa, KB cell strains) showed a high degree of attenuation, allowing inoculation by various routes of maximum doses without danger to the bird, and excellent immunizing activity.

Control and eradication. Outbreaks should be reported immediately to livestock sanitary authorities. Poultrymen should be warned against the addition of fowls to flocks. If additions are necessary, the added fowls, regardless of source, should be isolated until proved healthy. Sick fowls should be destroyed, carefully examined, and carcasses burned or properly buried. Frequent, diligent cleaning of premises, coops, crates, and carriers, followed by thorough disinfection, is essential. Flückiger (1950), reporting for the International Commission for the Control of Fowl Plague, recommends that fowl plague be a reportable disease in all countries and that all birds on infected farms be destroyed.

Outbreaks of fowl plague in the United States have always been eradicated with methods designed to limit and destroy the disease. In many instances the disease was self-limiting, inasmuch as entire flocks succumbed, leaving no survivors. Since the disease spreads most easily and rapidly through the intermingling of fowl, exposure to infected premises, coops, crates, and other containers and carriers, the best procedure is the destruction of all birds in the infected flock and the disinfection of houses and equipment.

It is fortunate that the outbreaks of fowl plague in the United States have been recognized and measures for control instituted promptly. It is perhaps the most fatal of fowl diseases, capable of causing such destruction to the poultry population as to be of economic importance in diminishing the food supply. The dangerous character of the disease has warranted the radical methods employed in each outbreak so that complete eradication was effected within a few months. Quarantines were imposed, embargoes placed, and poultry shipping restricted. Slaughter, sanitation, and disinfection aided in the control program.

Federal disease restrictions were applied to the poultry industry for the first time in the United States during the 1924–25 outbreak. Federal and state employees supervised the cleaning and disinfection of 2,718 plants, 8,140 cars, 352,525 coops, and 124,997 pieces of miscellaneous equipment.

Infectious Synovitis

Infectious synovitis is recognized as a separate disease entity of chickens (Olson *et al.*, 1954; Wills, 1954a) and of turkeys (Snoeyenbos and Olesiuk, 1955). The disease is observed primarily in growing birds 4 to 12 weeks of age in the broiler-growing areas of the United States. It has been reported from England (Carnaghan, 1959), Canada (Bigland and Brown, 1955), Norway (Badstue, 1961), Germany (Burtscher, 1961), France (Guillon *et al.*, 1963), South Africa (Cole, 1964) and is probably worldwide. The morbidity is variable with reports of 2 to 75 per cent. Mortality usually is low and ranges from less than 1 to 10 per cent. Successive flocks on the same farm, following an outbreak, generally do not show the infection. The infection spread slowly. Kerr *et al.* (1963) found birds from 2 to 20 weeks old were equally susceptible. The disease has been seen in egg birds with increased frequency. On one occasion signs were not noted until the birds were in production.

Symptoms. The first observable signs in an affected flock are pale comb, lameness, and retarded growth. As the disease progresses, the feathers become ruffled and the comb shrinks. In some cases the comb is bluish-red. Swellings usually occur around the joints, and breast blisters are common. The hock joints and foot pads are principally involved, but in some birds all joints become affected. However, birds are occasionally found with a generalized infection but not having apparent swelling of the joints. The birds become listless, dehydrated, and emaciated (Fig. 28.1). Although birds are severely affected, many of them continue to eat and drink if placed near feed and water. A greenish discoloration of the droppings, which contain large amounts of uric acid or urates, is frequently seen.

Gross lesions. In the early stages of the disease necropsy reveals a viscous, creamy to gray exudate involving the synovial membranes of the joints, keel bursae, and

FIG. 28.1 — Experimental birds with infectious synovitis. Contact control bird (standing) and three typically infected birds in the advanced stage of the disease

tendovaginal sheaths (Fig. 28.2). As the disease progresses, this exudate becomes caseous. Caseous exudate is occasionally found over the skull, along the neck, and rarely extends into the muscles and air sacs. When birds become severely emaciated and dehydrated before caseous exudate develops, there is occasionally no fluid about the joints. In chronic cases the surfaces of the affected joints are frequently yellow to orange.

In the early stages of the disease, splenomegaly generally occurs. The liver is frequently enlarged, occasionally mottled, greenish or dark red. The kidneys are usually swollen, mottled and/or pale.

FIG. 28.2 — The foot of a 7-week-old turkey showing the purulent exudate in the foot pad 22 days after experimental inoculation. Similar exudates are seen in chickens.

These changes occur in approximately 50 per cent of the birds and become more pronounced and frequent as the severity of the disease increases. Even though some birds are severely affected, their internal organs appear normal. In experimental foot-pad-inoculated birds the infection frequently localizes in the inoculated foot, and no gross internal lesions are noted.

The microscopic lesions (Sevoian et al., 1958) of the brain consist of vascular endothelial thickening and adventitial proliferation in the cerebrum, cerebellum, optic lobe, degeneration of some of the Purkinje cells, and occasionally cerebellar lesions similar to those of encephalomalacia. In the liver, perivascular, periportal, and interparenchymal cellular hyperplasia of the reticular cells of the reticulo-endothelial system occur. The sinusoids are dilated and the parenchymal cells are atrophied. There is proliferation of the bile duct epithelium. The connective tissue framework of the heart, gizzard, and interlobular septa of the lungs reveals a similar reticular cell hyperplasia. Occasionally focal mononuclear infiltration and necrosis of the myocardium and a fibrinous inflammation of the pericardium are seen. A reticular cell or lymphocytic hyperplasia, or both, decrease the sinusoidal areas of the spleen. A granulocytic hyperplasia of the bone marrow occurs, and atrophy of the thymus and bursa of

Fabricius results from lymphoid degeneration in the medulla and cortex.

The embryo response (Casorso and Jungherr, 1959) to infectious synovitis is similar to that described in birds.

Giemsa stains of smears made from creamy synovial fluid reveal many large macrophage cells, lymphocytes, plasma cells, and heterophils. In many cases the heterophils predominate. No bacteria are found.

The changes in the blood components have been studied (Olson *et al.*, 1956, 1957c; Shelton *et al.*, 1957; Sevoian *et al.*, 1957). Average determinations for 31 experimentally inoculated birds were as follows: erythrocytes, 1,680,000 per mm.^{3}; leucocytes, 80,810 per mm.^{3}; hemoglobin, 6.5 gm. per 100 ml. of blood. Differential count gave the following percentages: lymphocytes, 41.9; heterophils, 31.9; monocytes, 19.3; eosinophils, 0.23; basophils, 1.1; immature leucocytes, 6.1. The thrombocyte count increased and hematocrit decreased. The gamma globulin is increased (Shelton *et al.*, 1957). The blood abnormalities increased as the severity of infectious synovitis increased, generally reaching a maximum shortly before death. The changes were most severe between the 6th and 26th day following foot-pad inoculation. In severely affected birds the erythrocytes showed anisocytosis, poikilocytosis, polychromatophilia, and achromia. Immature erythrocytes of varying degrees were present. When the birds showed signs of recovery, the blood changes showed evidence of returning to normal. Similar blood changes have been noted in experimentally infected turkeys.

Host specificity. The disease has been reported from turkeys and chickens. Pheasants and geese (Sevoian *et al.*, 1958) were experimentally infected by the intravenous route. Rabbits, rats, guinea pigs, mice, pigs, and lambs are not susceptible to experimental inoculation.

Etiology. Infectious synovitis was thought to be caused by a large particle virus or rickettsia (Wills, 1954b; Lecce *et al.*, 1955; Cover *et al.*, 1956; Olson *et al.*, 1956). Electron micrographs (Lecce *et al.*,

1955) revealed coccobacillary elements, 0.2 to 0.5μ in size, containing what appeared to be a limiting membrane. Pleuropneumonialike organisms (PPLO) (*Lecce*, 1960) were noticed growing as satellite colonies to micrococcus colonies on PPLO agar. This was confirmed by Chalquest and Fabricant (1960) who subsequently grew the organism on PPLO broth (Difco) that contained 0.1 per cent beta diphosphopyridine nucleotide (DPN), 0.1 per cent cysteine, 10 per cent heat inactivated swine serum, 0.05 per cent thallium acetate, and 1,000 units of penicillin per ml. A PPLO agar was used in a similar medium but without the cysteine, and incubation in a candle jar was required. Chalquest (1962) reported that the infectious synovitis-derived (ISD) PPLO grew better in a medium containing 0.01 per cent DPN, 0.01 per cent cysteine HCl, 0.5 per cent soluble starch, and 0.05 per cent trypticase. The ISD-PPLO fermented dextrose and maltose, but not lactose, sucrose, or mannite. Six isolates were not inhibited by hyperimmune rabbit serum prepared against *Mycoplasma gallisepticum* using *Edward's technique* (1954) as revised by Fabricant (1960). The morphology of the ISD-PPLO in Giemsa-stained smears and the colonial characteristics were similar to M. gallisepticum.

Seven broth passages and one agar passage were made before inoculation of ISD-PPLO into poults, chickens, and embryos. A typical synovitis was produced in these birds and ISD-PPLO were reisolated from swollen joints (Chalquest and Fabricant, 1960). There is little doubt that the infectious synovitis described in this report is caused by a PPLO which is serologically distinct from M. gallisepticum, the cause of CRD. This was confirmed by Olson *et al.* (1961b) and the name *Mycoplasma synoviae* proposed for the etiological agent of infectious synovitis. A large number of bacteria have been isolated from arthritic conditions in chickens and turkeys. Olson (1956) found that inoculation of the fowl pox virus into the foot pad of chickens caused the growth of the virus in the synovial

membranes with enlargement, but Newcastle disease, infectious bronchitis, or laryngotracheitis did not. Also, a synovitis has been produced experimentally by PPLO (Wasserman *et al.*, 1953), and *M. gallisepticum* have been isolated from some field outbreaks (Olson *et al.*, 1956), and from breast blisters (Domermuth, 1962).

Passage of the agent in embryonating chicken eggs, using 0.25 ml. of a 1:10 dilution of inoculum, results in mean day of death of the embryos as follows: yolk 6.7 days, amniotic 8.6 days, chorio-allantoic membrane 12 days, and allantoic 12.9 days (Lecce *et al.*, 1955). The yolk sac route of inoculation is preferable for cultivation of the agent in embryonating eggs. Those embryos which die 4 to 10 days post infection are edematous and hemorrhagic (Fig. 28.3). The hemorrhages of the skin are not obvious in those that die later. The liver, spleen, and kidneys are enlarged, and the liver is frequently mottled or contains necrotic foci. Petechiae on the chorio-allantoic membrane

(CAM) frequently appear. Plaques were produced on the CAM by two of nine isolates and by the isolate described by Thayer *et al.* (1958). Recent studies (Olson *et al.*, 1964) have established the presence of three separate entities in synovitislike conditions: (1) infectious synovitis caused by *Mycoplasma synoviae*, (2) *Mycoplasma gallisepticum*, and (3) an unidentified arthritis-producing agent.

Transmission. Low morbidity in many flocks suggests an agent that spreads slowly. This was confirmed in laboratory trials where the incubation period in contact controls was 24 to 80 days. Spread occurred more frequently to uninoculated birds when the principles are inoculated intrasinusly (Skamser and Seeger, 1960). Birds are susceptible to the respiratory route of inoculation and following such inoculation birds develop agglutinins without showing signs of infectious synovitis. This respiratory infection was not exalted to systemic disease by the exposure to infectious bronchitis (Olson *et al.*, 1964a). In
FIG. 28.3 — Two 15-day-old embryos. The infectious synovitis-inoculated embryo on the left is edematous and has numerous hemorrhages in the skin. The embryo on right is normal.

birds experimentally infected by inoculation, at 3 to 6 weeks of age, with joint exudate from infected birds or yolk from infected embryos, the order of susceptibility and incubation period is as follows: foot pad, 2 to 10 days; intravenously, 7 to 10; intracranially, 7 to 10; intraperitoneally, 7 to 14; intrasinusly, 14 to 20; conjunctival instillation, 20. Birds are also susceptible to intramuscular and intratracheal inoculation. The incubation period varies with the amount and pathogenicity of the inoculum. Sevoian *et al.* (1958) reported an incubation period as short as three days in intravenously inoculated birds. The agent has been found in nearly all body tissues but not in bile or intestinal contents (Cover and Benton, 1957). In intravenously inoculated birds the blood was infective by the eighth hour but not by the fourth. In intramuscular inoculated birds the blood was infective by the forty-eighth hour but not by the thirty-second hour. The agent was present in the blood until the fifteenth day. The duration of the viremia is not known but it was not present at 52 days after inoculation (Benton and Cover, 1959). Passage in eggs prolongs the incubation period and reduces the pathogenicity of the agent. Direct contact is necessary for infection. When a wire partition separates pens of chicks, spread does not occur. Vertical transmission is suspected. Chicks from hens that survived a natural outbreak and chicks from hens that were experimentally inoculated were brooded until 5 to 10 weeks of age. One of the 543 chicks developed synovitis at 3 weeks of age (Wills and Delaplane, 1955). The disease has been seen in chicks 6 days old (Thayer *et al.*, 1958), further indicating fertile egg transmission. Isolation of the agent was reported from 2 dead embryos one of which was laid as early as 48 hours and the other 11 to 29 days after inoculation of the dams (Snoeyenbos and Basch, 1958). Carnaghan (1961) found infection in 6 per cent of the embryos and in one chick hatched from eggs produced by clinically normal survivors of the disease. He also experimentally produced the disease in adult birds. The agent was isolated from embryos dying during incubation and from chicks hatched from eggs produced by survivors of the experimental disease. In view of these observations and the PPLO etiology of infectious synovitis there is little doubt that egg transmission is the most likely means of transmission. *M. synoviae* occurs in the respiratory tract of birds without producing clinical signs or gross lesions (Olson *et al.*, 1964a).

Diagnosis. The presence of pale comb, droopiness, emaciation, leg weakness, along with breast blister and enlarged foot pads, or hock joints which contain a viscous, creamy or caseous exudate, with splenomegaly and enlarged liver or kidneys, is sufficient to make a presumptive diagnosis. A positive diagnosis may be made by isolation and identification of the mycoplasma involved. The serum plate agglutination test using *M. synoviae* antigen and the procedure as for CRD may be used to make a positive diagnosis. However, it takes approximately two weeks for agglutinins to develop in chickens (Olson *et al.*, 1965). Cross reactions will occur between *M. synoviae* and *M. gallisepticum*; therefore, it is usually necessary to find the end point of reactivity of the serum (Olson *et al.*, 1965). Bacteria as a cause of synovitis or arthritis must be eliminated by bacteriological procedures. Embryonating chicken eggs or chickens or both should be inoculated as a further check since primary isolation of mycoplasma is frequently difficult.

Immunity. Cassidy and Grumbles (1959) were not able to demonstrate immunity to IS, however, Wichmann *et al.* (1960) found that after 9 passages in tissue culture the pathogenicity was reduced but not its antigenicity. On the other hand, hyperimmune rabbit serum prepared against ISD-PPLO inhibits their growth (Chalquest and Hallfhill, 1962). The immunity to IS needs further clarification. Birds exposed intranasally were resistant to subsequent footpad challenge. (Olson *et al.*, 1964a).

FIG. 28.4 — An isolated control turkey (right) and two experimental turkeys with infectious synovitis (left).

Shelton (1958b) found 200 grams per ton of feed of CTC effective in preventing signs and recurrence of the disease if given at time of inoculation of day-old chicks. If the disease was allowed to progress for 8 days and CTC fed for 3 weeks, 200 grams per ton of feed prevented signs of IS as long as it was given but even 1000 grams per ton did not prevent signs from developing after withdrawal of medication.

An agent recovered from the joints of chickens was not susceptible to antibiotics in ova (Cover et al., 1956) and in vivo (Olson et al., 1957b). Also Snoeyenbos et al. (1958) reported strain differences in their susceptibility to antibiotics.

The reported efficacy of NF-180 (Cosgrove, 1957) has not been confirmed by other published work.

Dihydrostreptomycin injections (25 mg. per lb. body weight) satisfactorily controlled infectious synovitis if given at the time of experimental inoculation (Munro et al., 1956). If given 4 or more days after inoculation, only slight benefit was noted. Increasing the dose to 200 mg. per lb. of body weight increased its effectiveness slightly (Shelton and Olson, 1957–58; Snoeyenbos et al., 1958).

Infectious synovitis in turkeys. The disease in turkeys has not been studied to the same extent as it has in chickens. A staphylococcus arthritis is more frequently encountered in turkeys than is infectious synovitis. However Chalquest and Fabricant (1960) isolated PPLO and a staphylococcus from the same turkey.

Infectious synovitis generally causes the same signs and lesions in turkeys as in chickens (Snoeyenbos and Olesiuk, 1955). However, in turkeys the disease appears to be less acute, and the marked enlargement of the joints is not so common. Infected flocks (Snoeyenbos, 1956) usually have low morbidity (1 to 20 per cent) but mortality resulting from cannibalism is significant. Lameness is the most prominent symptom. Warm fluctuating swellings of one or more joints of lame birds are usually found. Occasionally there is an enlargement of the sternal bursa. Severely affected birds lose weight, but many birds less severely affected make satisfactory weight gains when separated from the flock. In experimentally infected turkeys (Olson et al., 1956), the first noticeable sign is failure of the bird to grow (Fig. 28.4). Noticeable swellings in joints are not always present; however, when the hock joints are opened, a small amount of purulent exudate is present. The agent is recovered from this exudate after injection into embryonating eggs, and inoculation of the exudate into chickens produces signs and lesions of synovitis. Further work is needed to determine the incidence of the disease in turkeys.

Treatment in turkeys. Protection is af-

forded by CTC at 200 gm. per ton of feed during prophylactic medication of turkeys. Partial protection is produced by levels as low as 50 gm. per ton. The comparative efficacy in turkeys of the tetra-

cycline antibiotics has not been determined. Treatment of affected birds with streptomycin or CTC has given discouraging results. Prophylactic medication of turkeys has not been economically feasible.

Rabies, Infectious Equine Anemia and Foot-and-Mouth Disease in Fowl

Rabies in Fowl

Rabies is an acute infectious disease caused by a filterable virus and characterized by symptoms of a central nervous disturbance, progressive paralysis, and followed by death in most animals Gibier (1884) one of the first to carry on experimental studies on rabies infection in fowl, was successful in transmitting the disease to chickens and reinfecting mammals with virus recovered from diseased birds. Spontaneous recovery in experimentally infected birds was recorded.

Kraus and Clairmont (1900) studied the susceptibility of various species of birds to rabies, variations in the course of the disease, and the clinical symptoms observed. The raven, falcon, and old pigeons were refractory to rabies infection. Old pigeons could be infected after a period of starvation. Young pigeons were susceptible to rabies. Considerable variation in the incubation period — from 2 weeks in owls and geese to 40 days or more in chickens — was recorded. Gradual recovery in some birds was reported. Vaccines made from avian tissues were ineffective for immunization. Rabies was transmitted from birds to rabbits, and the incubation period was found to be progressively extended until the virus was rendered inactive. Incoordination and paresis, followed by paralysis and death, were the clinical manifestations observed. Lesions in the brain and spinal cord were similar to those found in man and animals.

V. Löte (1904) found that some birds of prey were susceptible to rabies. He infected a mouse hawk (*Buteo vulgaris*) subdurally with virus secured from the brain of a rabbit. Symptoms of a central nervous disturbance and loss of appetite were recorded 11 days following inoculation. Convulsions of short duration were also observed. The bird could no longer stand, and it lay on its right side pros-

trated 3 days after the first appearance of clinical manifestations. The bird was dead the following day. V. Löte transmitted rabies to two eagle owls which died 2½ and 9 months, respectively, after inoculation without developing any appreciable clinical symptoms. He transmitted rabies to guinea pigs with brain tissue from these birds. Chickens and pigeons were considered to be more resistant to artificial infection than birds of prey. Only one of three cocks experimentally infected with rabies virus contracted the disease. The course of the disease was unusual. The first symptoms developed after a 43-day incubation period and included evidence of incoordination and refusal of food. Definite improvement was noted 3 days after the first appearance of clinical symptoms. The subject appeared to be normal for 14 days but then developed severe paralytic symptoms. One week later the bird had made a complete recovery. This disease ran a similar course in an experimentally infected hen which recovered completely.

Marie (1904) reported a great variation in the incubation period and course of rabies in birds. He attempted to increase the neutralizing power of the sera of mature pigeons immune to rabies by hyperimmunization; this was unsuccessful. Rabies "street" virus, passed through birds repeatedly, gradually decreased in virulence to an inactivated state in which it was no longer capable of producing any reaction in mammals. Active virus, after seven or more serial passages through birds, was so altered that suitable quantities of brain emulsion from these infected birds, injected intraperitoneally or subcutaneously, protected mammals against intraocular inoculation of "street" virus.

Remlinger and Bailly (1936) transmitted rabies to the stork (Ciconia ciconia) by intracerebral inoculation of "street" virus. The symptoms manifested were exclusively of the paralytic type. The experimental transmission of rabies to the pheasant (Diardigallus diardi B.P.) was reported by Jacotot (1938).

The occurrence of rabies in the chicken under natural conditions was considered comparatively rare by Remlinger and Bailly (1929a, b). They successfully transmitted the disease to the bird by bites inflicted on the comb by a rabid dog. Manifestations of the furious type or the paralytic form may develop after a long or short incubation period. The diseased bird may attack its mates or other animals in the furious form of the disease and can be considered a potential source of danger in transmitting the disease to animals and man.

Very little definite proof of the occurrence of spontaneous rabies in fowl can be found in published reports. Experimental studies have provided practically all of our information regarding the avian form of this disease. Schweinburg (1928) reported a case in which a patient had been injured by a rabid hen. The hen showed symptoms of the furious form of rabies for a period of 3 days.

Infectious Equine Anemia in Fowl

Infectious equine anemia, or swamp fever, is caused by a filterable virus. The transmissibility of this disease to birds is a controversial question, and the evidence in support of this assumption is not adequate and lacks confirmation. Reports found in the literature are of interest and should be reviewed. Oppermann and Lauterbach (1928) claimed that chickens may be infected with the virus of infectious anemia of horses. The histopathologic changes in the liver of birds were considered to be similar to those found in diseased horses. Round cell infiltration and hemosiderin deposits in the liver were thought to be significant. They further claimed that the disease could be diagnosed in horses on farms where significant liver changes associated with infectious equine anemia were found in chickens. Chickens were reported to have been infected with manure of horses suffering from infectious anemia, producing typical liver changes. No specific clinical symptoms could be produced in birds, but Oppermann and Lauterbach concluded that the disease assumed a very mild form and resulted in a significant reduction in the number of red blood cells. They thought it probable that the hemosiderin deposition in the liver resulted from the destruction of the erythrocytes. Certain death losses in chickens were attributed to this type of infection. The liver changes in the chicken which Oppermann and Lauterbach considered characteristic of

infectious equine anemia were found most consistently in chickens killed 5 to 7 days after infection. They also believed that since man is also susceptible to this virus infection, spontaneous infections of birds are factors in the control of the disease.

Balozet (1937) could not transmit infectious equine anemia to chickens nor was he able to recover the virus from inoculated birds. He reported birds to be completely refractory to the disease. Gochenour et al. (1938) concluded, after years of experimental investigations, that this disease was confined largely to horses, mules, and asses. A few cases had been reported in man. Stein (1940) found no alterations in the appearance, condition, or development of chicken embryos following inoculation of the chorio-allantoic sac of 5- to 12-day-old embryos. Furthermore, there was no evidence of unfavorable reactions on the development of any of the embryos, following the intravenous inoculation of virulent blood taken from horses during a febrile attack, when 11-day-old chicken embryos were used.

No conclusive evidence has been found, in spite of the extensive investigations conducted in recent years, to indicate that this disease may be transmitted to birds. The failure to transmit the disease from inoculated birds to the horse, mule, or ass and the inability to produce clinical manifestations in inoculated birds seem to indicate that birds are completely refractory to the disease.

Foot-and-Mouth Disease in Fowl*

The early literature includes references to observations made by Wildner, Spinola,

and Becker on the clinical occurrence of foot-and-mouth disease in fowl. References to these reports can be found in Hutyra and Marek (1905), Ehrhardt (1914), and van Heelsbergen (1929). The con-

ditions described indicated both local and general reactions. Small vesicular lesions on the comb, the conjunctiva, in the region of the nostrils, wattles, mouth, throat, and toes were observed. Eroded areas, which developed several days after the rupturing of the vesicles, healed over in a week or two. Following significant temperature reactions, a weakness and depression occurred due in part to the inability of the birds to eat because of the developing lesions in the mouth and throat. The course of the disease was 1 or 2 weeks, followed by complete recovery. Uncomplicated cases were not considered fatal. The early clinical diagnoses which were not confirmed by experimental investigations cannot be considered as definite proof that these conditions were foot-and-mouth disease. According to van Heelsbergen (1929), the lesions described by the early investigators resembled those of fowl pox. He also referred to a vesicular "eczema" on the comb and wattles of chickens similar in appearance to the lesions of fowl pox. Furthermore, these conditions were reported in areas which were definitely free from foot-and-mouth disease. The relationship between these various vesicular manifestations in fowl and foot-and-mouth disease still has to be determined, according to Reis and Nobrega (1936).

The transmission of foot-and-mouth disease to fowl by experimental feeding or inoculation was unsuccessful as reported by van Heelsbergen (1929). Three of twelve fowl fed large amounts of guinea pig virus passed active virus in their feces between 10 and 24 hours but not later than 26 hours, as detected by experimental calf inoculation tests reported by Minett (1927). Further reports indicate the inability to transmit the disease to sea gulls, ducks, sparrows, and martins. Galloway (1937) reported that thirteen out of sixteen adult wild ducks inoculated intradermally into the pads at the base of the feet and digits showed vesicles on the upper surfaces of the web 2 or 3 days after inoculation. The disease was transmitted through eight consecutive duck

passages by the inoculation of virus secured from the vesicles on the feet.

There has been considerable speculation for a number of years on the possible spread of foot-and-mouth disease by birds. Extensive research by British scientists indicates that some degree of susceptibility of birds to infection may exist, but there is little evidence to support such a hypothesis. There is a remote possibility that sea gulls and other fowl which feed on farm land at times and travel great distances might act as mechanical carriers of the virus of foot-and-mouth disease. The experiences and observations of various authorities in this country have never indicated that fowl ever become reservoirs or vectors of the foot-and-mouth virus. Man has been considered as one of the more important factors in the mechanical spread of this virus disease by such authorities as Kling and Höjer (1926), Waßmann and Hirschfelder (1938), and Kling et al. (1939).

The propagation of foot-and-mouth disease virus in the chorio-allantoic membrane of the embryonated eggs of the hen and duck were unsuccessful as reported by Galloway in 1937. Only occasional passage of the virus from one embryonated duck egg to another was experienced, but further passages were unsuccessful. This could possibly have been due to virus dilution, as no evidence of the multiplication of the virus could be detected. Twenty serial passages of virus in chicken embryos were reported by Peragallo (1937), but Richter (1939) was unable to confirm this work. Traub and Schneider (1948) were able to cultivate a strain of foot-and-mouth disease virus of the Vallée O type in chicken embryos. Hecke (1932) propagated foot-and-mouth disease virus in tissue cultures containing epithelial tissues of embryo guinea pigs. This virus may be grown in tissue cultures containing embryonic tissues from species which are susceptible to the disease.

Skinner (1954) infected baby chicks a few hours old with Vallée O type of foot-and-mouth disease virus of cattle origin after the 85th mouse passage. The virus

from infected chicks was obtained from the muscles and hearts 4 days after inoculation and injected into mice 1 week of age. During 12 alternate passages of the virus in chicks and mice, virus from the blood of chicks was recovered over a period of 3 to 5 days after inoculation. Other chicken tissues were tested for virus after macroscopic tongue lesions were observed subsequent to the 8th alternate passage. Virus was found in tongue tissue. Later, using the original cattle strain for intramuscular inoculation into newly hatched chicks, well developed tongue lesions were observed 1 or 2 days later. The lesions often involved the dorsal epithelial surface and were similar to characteristic lesions usually observed in other susceptible species. Histological examinations confirmed the clinical observations. Local lesions developed following direct inoculation of preparations made from tongue epithelium into older birds. Six serial passages of a cattle strain were made following direct inoculation of preparations in birds 2 to 4 months old.

Intramuscular inoculation of large doses of Vallée O type virus of cattle origin and three stock guinea pig strains O, A, and C types, in newly hatched chicks, subsequently produced tongue lesions. The guinea pig strains were successfully passaged four to six times by intradermal inoculation of the tongue of older birds. Two of these strains produced small areas of separation of the lower epithelial structures on the under surface of the feet of newly hatched chicks when inoculated intramuscularly or by direct inoculation in the region of the central foot pad. The development of light local lesions was followed by definite secondary lesions on the tongue. There was no severe systemic reaction during the course of infection in the experimental chickens of all ages. Epithelial lesions completely exfoliated in 1 or 2 days, and no scars or blemishes were left on the tongue.

Virus from selected material was successfully transmitted to 14-day-old chicken embryos. The myocardium seemed to be the main area of virus multiplication in this type of embryo. The highest concentration of virus was secured after 5 or 6 days' incubation at 35° C. The susceptibility of the embryos to infection was reduced considerably by incubation at higher temperatures. Infection was usually followed by the death of the inoculated embryo in 3 to 6 days using inoculum conditioned by eight serial passages or more. Distinct cardiac lesions could be found upon examination.

Failure of the earlier workers to propagate foot-and-mouth disease virus in chicken embryos using the chorio-allantoic method of inoculation has been generally accepted. Success has been reported only in a few instances. The more recent technique, using the intravenous method of inoculation and the subsequent incubation at 35° C. for at least 3 hours, may be the vital factors concerned in successful propagation of foot-and-mouth disease virus in the embryonated chicken egg.

The following diagnostic procedure, as formulated by Olitsky and Schoening in a previous edition of *Diseases of Poultry*, is still valid. "The diagnosis of a virus recovered from fowl, such as that of foot-and-mouth disease, is made by the cutaneous injection of vesicular fluid in the scarified foot pads of healthy, adult guinea pigs or on tongues of normal, previously unexposed cattle. Twelve hours to 5 days later characteristic vesicles appear which are transmissible in series to normal guinea pigs. There are at present three distinct types of virus; according to German (Waldmann) classification they are A, B, and C; according to the French (Vallée) terminology, the A is called O and the B is called A, the type C being designated in the same way as in the German classification. A number of immunologic variants have been identified in both type O and A viruses. The type of virus as well as the character of variants is determined by cross-immunity tests in guinea pigs or cattle, as well as by complement-fixation and neutralization tests. Type specific antisera for these tests are ordi-

narily derived from hyperimmunized guinea pigs."[1]

[1] It should be stressed at this point that the importation of foot-and-mouth disease virus into the United States is prohibited by national statute (Public Law 496, 80th Congress, approved April 24, 1948).

The only research program on foot-and-mouth disease in this country is being carried on by the federal government under strict supervision at Plum Island.

Duck Virus Hepatitis

A new and highly fatal disease of young White Pekin ducklings broke out during the spring of 1949 in the duck-raising section of Long Island, New York (Levine and Fabricant, 1950). The disease spread rapidly, and before the summer was over practically all of the seventy-odd duck farms in the area had suffered losses. At first, ducks 2 to 3 weeks of age were affected. Gradually the disease attacked younger birds until ducklings less than a week old were succumbing. On severely affected farms, mortalities up to 95 per cent were not uncommon in some broods. Successive lots of ducks almost invariably became infected. Later, occasional broods would escape with little mortality. It was estimated that 15 per cent of the total number of ducklings started for that year died from the disease, a total of 750,000 birds. In the United States the disease has been diagnosed in Massachusetts, Illinois (Hanson and Alberts, 1956), and Michigan. It has also been reported from Canada

(Macpherson and Avery, 1957), England (Asplin and McLauchlan, 1954; Asplin, 1956), Germany and Egypt (Shehata and Reuss, 1957), the Netherlands (Smits, 1957), Belgium (Schyns, 1957), Italy (Rossi and Pina, 1957; Agrimi, 1958), Russia (Prokofiva and Doroshko, 1960), and Hungary (Derzsy cited by Reuss 1959a).

Signs. The onset and spread of the disease was very rapid, with practically all the mortality occurring within 3 or 4 days. Affected ducklings at first failed to keep up with the brood. Within a short time the birds stopped moving, and squatted down with eyes partially closed. The ducklings fell on their sides, kicked spasmodically with both legs, and died with heads drawn back (Fig. 30.1). Death occurred within an hour or so after signs were noted. During the height of severe outbreaks, the rapidity with which ducklings died was astonishing.

Gross lesions. The principal damage was found in the liver. It was enlarged and
FIG. 30.1 – Ducklings dead from infection with virus hepatitis. Note typical opisthotonus.
FIG. 30.2 – Livers with hemorrhagic lesions caused by duck virus hepatitis infection.

contained punctate or ecchymotic hemorrhages (Fig. 30.2). Frequent reddish discoloration or mottling of the liver surface was seen. The spleen was sometimes enlarged and mottled. In numerous cases the kidneys were swollen and the renal blood vessels injected. These lesions were reproduced in young ducks by inoculation and feeding of egg-propagated virus.

The older ducks examined at the first appearance of the disease had a marked pericarditis and air sac infection characterized by a whitish-yellow, fibrinous deposit. It is now believed that these lesions probably were produced by another condition and were not related to the virus hepatitis infection even though that virus could be isolated. As the younger ducklings became affected, the typical liver lesions made their appearance.

The microscopic changes in uncomplicated, experimentally induced infections have been studied (Fabricant et al., 1957). The primary changes consisted of necrosis of the hepatic cells and proliferation of the bile duct epithelium. Varying degrees of inflammatory cell response and hemorrhage occurred. Regeneration of the liver parenchyma was observed in ducklings that did not die.

Host specificity. In the field, the disease only occurred in young ducklings. Adult breeders on infected premises did not become infected. These birds continued in full production, and their eggs were highly fertile with excellent hatchability. One attempt to infect breeders with egg-propagated virus failed. No experiments were made to attempt transmission of this disease to other species of birds. Field observations indicated that chickens were not susceptible, since broiler chicks being brooded in the same pens where ducklings were dying failed to become infected. On one farm, turkeys being reared on a slatted platform attached to the side of a duck brooder house where the disease was present were not affected.

Schoop et al., (1959) and Reuss (1959a) failed to infect chickens experimentally. The latter worker could not transmit the disease to rabbits, guinea pigs, white mice, or dogs.

Etiology. No bacterial agent could be isolated from the sick ducklings. Infected material treated with penicillin and streptomycin and inoculated into the allantoic sac of 9 day-old chicken embryos yielded a virus. On subsequent study the virus proved to be one that hitherto had been undescribed. Practically all tissues, including the blood, yielded this infective agent. Embryos that either died on the fifth or sixth day or were destroyed on the sixth day were stunted and edematous (Fig. 30.3). The edema was noted especially around the thigh and abdomen. The amnionic sac contained an excess of fluid. The yolk sac was reduced in size and the contents were more viscous than usual. A greenish discoloration of the embryonic fluid and yolk sac was often found and could be detected on candling of the eggs. The livers of the embryos often were greenish in color and frequently had whitish-yellow, necrotic foci, varying from pinhead in size to larger areas involving considerable portions of the parenchyma. Allantoic fluids from these embryos and from infected duck tissues contained the virus and killed from 10 to 60 per cent of the embryos by the sixth day.

The virus could be passed through both the Seitz and Berkefeld W filters, as evidenced by the production of typical embryo lesions with filtrates. The hepatitis virus did not agglutinate chicken red cells nor was it neutralized by Newcastle disease antiserum. Through the courtesy of Dr. Osteen of the United States Bureau of Animal Industry, antiserum from the duck plague infection in Holland (Jansen and Kunst, 1949) was obtained. Neutralization of the hepatitis virus with duck plague antiserum did not occur (Fabricant, 1950). Virus neutralization tests with convalescent sera from human and canine virus hepatitis failed to demonstrate any serological relationship of these diseases to duck virus hepatitis (Fabricant et al., 1957).

Reuss (1959a) determined by electron
FIG. 30.3 — (Left) A normal 15-day-old chick embryo. (Right) A 15-day-old chick embryo inoculated with duck virus 6 days previously. Note the small size and the edema, especially around the thigh and abdomen. (Courtesy of the Cornell Veterinarian.)

microscopy that the virus was a rounded or spherical particle that measured 20–40 mμ. He was unable to find elementary bodies in tissues nor could he agglutinate chicken red cells with the virus.

The virus survived 8 months at −30° C. (Schyns 1957) and a month at −20° C. but was dead in 6 days at refrigerator temperature and in 4 days at room temperature (Reuss 1959a).

It is interesting to note that early in the investigation Newcastle disease virus was isolated twice from ducks on a farm where losses were occurring. Efforts to incriminate Newcastle disease with the losses failed.

Transmission. Although the high mortality and rapid spread of the disease on farms indicated extreme contagiousness, occasional exceptions were observed. In one pen 65 per cent of the ducks died, while in an adjoining pen separated only by a 14-inch curb, the mortality was negligible.

The first efforts to transmit the disease to small groups of three or four caged ducklings by injection and feeding of egg-propagated virus were not successful. In another experiment, with tissues from a natural outbreak, some of the ducklings became infected. Transmission was most easily accomplished by intramuscular injection and by feeding egg-propagated virus and infected organs to larger groups of ducklings (ten to twenty) kept on litter under a hover. The incubation period was 24 hours in most experiments, and practically all of the deaths took place by the fourth day. Uninoculated ducklings placed in the same pens with the inoculated birds contracted the disease and died somewhat later than the injected ducks.

Egg transmission presumably does not take place. Newly hatched ducklings pro-

duced by breeders on infected premises remained well when taken to premises where no ducks were being kept. Asplin (1958) confirmed this finding.

Diagnosis. The sudden onset, rapid spread, and acute course of this disease is characteristic. Lesions in the livers of young ducklings up to 3 weeks of age are practically pathognomonic. Absence of bacteria and isolation of the virus in chicken embryos, with production of the characteristic lesions previously described, serve further to identify the causative agent. The specific neutralization of the virus by immune duck virus-hepatitis serum is a positive means of identification.

The use of the agar gel diffusion precipitin technique for the identification of the virus was described by Murty and Hanson (1961). There is the possibility of adapting this test for diagnostic purposes.

Prevention and control. The epizootiology of duck virus hepatitis has not been completely worked out. Although numerous possibilities for spread of the disease by visitors, garbage and dead-bird collectors, etc. existed, outbreaks occurred on farms under excellent management and good sanitation.

Unsuccessful attempts were made to immunize ducklings with killed (formalinized) and live virus vaccines made from chicken embryo fluids. It was not until prophylaxis with duck virus-hepatitis antiserum was attempted in controlled experiments that protection from the experimentally transmitted disease was obtained. The subsequent application of serum therapy in the field has proven to be highly successful. Blood from exposed and recovered ducks is collected at the slaughter house and processed. An antiserum bank sufficient to treat four million ducklings is kept on hand at the Duck Disease Laboratory at Eastport, Long Island, under the direction of Dr. William D. Urban (Dougherty, 1953). One-half ml. duck virus-hepatitis antiserum (0.5 per cent phenol added) is injected intramuscularly into all ducklings of a brood when the first

few deaths from the disease occur. The mortality is negligible in the treated ducklings. If, however, a portion of the brood is not treated, the usual heavy mortality occurs. No relapse in treated broods occurred during the summer of 1950. In the past few years, relapses in serum treated broods have necessitated repeated serum injections before losses could be stopped.

Another possible approach to the control problem was described by Asplin (1956), who immunized breeder ducks with hepatitis virus. The parental immunity the dams conferred on their progeny successfully protected the ducklings on challenge with virulent virus. Ducklings produced by nonimmune dams succumbed to challenge. On the other hand, Reuss (1959b) found that ducklings with parental immunity resisted challenge with virulent virus successfully only when their dams had received previously 6 live virus injections. Ducklings from dams injected 3 times were susceptible. Recently, Hwang et al. (1962) have applied the dam immunization procedure for the control of virus hepatitis in ducklings with good success.

Reduction of the pathogenicity of the duck hepatitis virus by serial passage in chick embryos has been reported by Asplin (1958), Schoop et al. (1959), Reuss (1959b), and Hwang and Dougherty (1962). Asplin found that his attenuated virus applied by stabbing the footpad with needles immunized young ducklings. Field application of this vaccine was effective. Reuss (1959b) also reported successful immunization experiments with his attenuated strain.

The virulence and persistence of the field virus, the level of parental immunity in the ducklings, the age and breed susceptibility of the ducklings, the husbandry practices and environmental influences will be some of the factors that will affect the choice of control programs in different localities.

Avian Monocytosis (So-called Pullet Disease), Infectious Nephrosis and Bluecomb Diseases of Turkeys

AVIAN MONOCYTOSIS

Synonyms. Pullet disease, bluecomb, summer disease, housing disease, unknown disease, new disease, X disease (Beaudette, 1929), XX disease, cholera-like disease (Ryff and Stafseth, 1942), contagious indigestion (Waller *et al.*, 1942), battery nephritis, Bright's disease (Weaver, 1941), Tom Barron's disease, acute toxemia or colibacillosis (Weisner, 1941), hepato-nephrosis (Jungherr and Levine, 1941), avian monocytosis (Jungherr and Matterson, 1944), mud fever of turkeys (Peterson and Hymas, 1951), avian infectious diarrhea (Watanabe *et al*, 1951, quoted by Watanabe, 1952), bluecomb disease of turkeys (Pomeroy and Sieburth, 1953), transmissible enteritis of turkeys (Sieburth and Johnson, 1957), uraemia (Hungerford, 1962), infectious nephritis-nephrosis syndrome (Winterfield and Hitchner, 1962), kidney breakdown disease complex (Cumming, 1963a).

While these diseases share clinical, hematologic, and perhaps therapeutic features, recent studies indicate that they include at least 3 separable entities, namely pullet disease of young chicks and an infectious renal disease of chicks caused by a virus related to that of infectious bronchitis, and bluecomb of turkeys recently recognized as a vibriosis. The principal characteristics of these conditions are discussed separately as far as possible.

Under the term "X disease" Beaudette (1929) briefly described a disorder of adult fowl which usually affected heavy birds in high production and was characterized by cyanosis of the comb and wattles and sudden death; flock mortality was comparatively low. At necropsy affected birds showed congestion of the respiratory tract, liver, ovary, kidneys, and intestine, the latter filled with thick catarrhal material. The heart and the abdominal fat surrounding the gizzard showed small hemorrhages; in one case the liver exhibited evidence of necrosis. The disorder revealed an anatomic resemblance

---

* Deceased April 16, 1965.

to fowl cholera, but culture and transmission studies with unfiltered and filtered materials failed to demonstrate an infectious agent.

A similar condition of chickens and occasionally of turkeys had been observed both in the field and in the laboratory, throughout the northeastern states, but no systematic study had been reported until Jungherr and Levine (1940) attempted a pathologic delineation of the syndrome. Although these authors recognized an acute form similar to X disease, and a subacute form primarily characterized by kidney lesions, they found certain microscopic and chemical features to be common to both forms and regarded them as an entity. On purely symptomatic and gross-pathologic grounds, Bullis (1940) believed the acute and subacute forms, termed by him "pullet" and "blue comb" disease, respectively, to represent different entities. This possibility was likewise considered by Beaudette (1940), who differentiated them and applied the names "X disease" and "new wheat poisoning."

These opinions emphasize the common occurrence, in young laying birds, of an important disorder which has the earmarks of an infectious disease but for which a transmissible etiologic agent has not been demonstrated with certainty. Without recognition of "pullet disease" as a definite condition, certain cases of adult morbidity and mortality could not be diagnosed. Watanabe et al. (1951) described a pullet diseaselike condition of chickens under the term "avian infectious diarrhea." They consider the term "avian monocytosis" unsuitable for pullet disease because monocytosis also occurs in Newcastle disease. Similar objections would hold for any pathologic nomenclature of a disease, e.g., coryza. Although these various conditions share certain features in nomenclature, pathology, and therapeutic response, their etiologic interrelationship is not established.

Occurrence. The statistical data on the geographic distribution of pullet disease are limited. Lack of agreement on the morphologic range of the syndrome retards diagnostic classification. Some reports of the disease have been based on symptomatic evidence alone. However, even if one considers only the acute and most easily recognizable form, the occurrence of pullet disease has been reliably reported, aside from New Jersey (Beaudette, 1929), from most of the northeastern states, Michigan (Weisner, 1941), and California (Hurt, 1941), and Ontario (Weaver, 1941). Verbal reports seem to indicate its presence in North Carolina, Utah, and Missouri (reported by Jungherr, 1945).

Gordon and Blaxland (1945) reported the occurrence in England of a disease in poultry resembling the so-called pullet disease in America. Mochizuki (1951), working at the Government Experimental Station for Animal Hygiene in Tokyo, observed an infectious diarrhea in chickens with clinical, pathologic, and hematologic manifestations strikingly similar to the condition under discussion. That this syndrome represents a clinico-pathologic entity of wide geographic distribution and economic importance is indicated by reports from Italy (Caparrini, 1960), Holland (Maas and Voûte, 1961), East Pakistan (Ali, 1961), West Pakistan (Qureshi, 1955), Bombay (Vaishnar and Parnaik, 1961), and Australia (Lindtner, 1960; Ranby, 1958). The literature has been reviewed by Maas (1960) and Chanteclair (1962).

A Connecticut survey for the years 1931–39 (Jungherr and Levine, 1941) showed that pullet diseaselike conditions occurred in 15 per cent of 1,765 survey cases examined; 72 per cent of the positive cases were classified as uncomplicated. These cases were observed in flocks of birds kept on rations prepared according to a standard New England formula, and on 20 different commercial brands. Various poultry breeds were found to be susceptible, the heavy breeds predominating. The majority of the cases occurred between the ages of 5 and 7 months, that is during early production, but pathologically indistinguishable cases were observed in

chicks 4 weeks old and in 2-year-old layers. The available data placed the major seasonal incidence between June and November, with the peak in August. A continuation of the Connecticut survey for the 4 calendar years 1940 to 1943 showed a similar seasonal distribution of the incidence (Jungherr and Matterson, 1944). During 1943 the attack rate was particularly high, namely 34.5 per cent of 269 specimen consignments of chickens 3 months of age or older (Scott et al., 1944). Since that time, the numerical incidence has decreased markedly, a fact for which no ready explanation has become available.

Cole (1950) gave a valuable account of an outbreak in an experimental flock of 2,850 Single Comb White Leghorn chickens, 9 to 17 weeks of age, which had been bred especially for resistance and susceptibility to avian lymphomatosis, and showed a significant nonparallel strain and family difference in mortality from pullet disease. During the 30-day course of the apparently contagious disease, there was a marked intensification of the clinical and pathologic manifestations of the syndrome. Moultrie et al. (1955) obtained additional evidence for genetic variation in resistance to bluecomb disease among families of birds, a factor which was apparently unrelated to mortality from other causes. Strain differences in susceptibility to renal disorders, of which pullet disease is an example, were also reported by Biely and March (1958) and Hicks (1958).

Whereas the incidence of pullet disease in chickens has decreased in the United States during the past years, according to diagnostic reports, a similar condition has been reported in West Pakistan (Qureshi, 1955) and an increase of the acute type in England (Blaxland, 1957).

Symptomatology. In the typical acute form, a large proportion (average 15 to 21 per cent) of an apparently healthy flock shows a sudden affliction which is characterized by depression, lack of appetite, and whitish or watery diarrhea; occasionally there is constipation. Some birds exhibit distension of the crop with sour-smelling contents, darkening of the head (bluecomb or cyanosis), sunken eyes, shriveled legs, and high fever in the terminal stages. Laying flocks undergo a severe drop in egg production. Maas (1961) made a careful study of the effect on egg quality 3 months after an outbreak and found the average egg weight to be 1.23 grams less than that of comparable controls. Mortality is usually sudden and ranges from 50 per cent to almost zero, with an average of about 5 per cent of the flock. Subacute cases are distinguished by a comparatively low, often spotty incidence and prolonged course. The clinical signs in the flock are less intense; but individual birds, according to Weaver (1941), may show severe prostration, oliguria, convulsive symptoms, and impaired vision.

The primary signs of pullet disease are nonspecific in themselves, but when considered together with the seasonal incidence during early active production, they are highly suggestive of the disorder, if known infectious diseases can be ruled out. Sporadic cases often go unnoticed and are classed among the culls.

The course of the disease in most cases extends over a period of from 1 to 2 weeks, and terminates in a high percentage of apparent recovery, especially if prompt attention is given to the ailing flock. Egg production, however, tends to lag for several weeks, and a partial moult may ensue. After the acute attack has subsided, relapses may occur (Weaver, 1941), which simulate the picture of the subacute form. An unusually prolonged course is often complicated by other factors, especially neoplastic diseases.

Pathology. Pullet disease is characterized morphologically by dehydration, necrosis of the liver (spottiness) and pancreas (chalkiness), hemorrhages on the serous membranes, increased mucus in the intestine, various renal changes, and degenerations in skeletal muscle (fish flesh-like) and ovary (soft or broken follicles). The acute form exhibits congestive phenomena, or liver and muscle lesions,

while renal predominate in the subacute form. Blaxland (1957) has compared the anamnestic and pathologic features of the acute and subacute forms on the assumption of a possible etiologic difference. Different combinations of such organic alterations in either gross or microscopic intensity produce a highly variable pathologic picture, especially as revealed by ordinary necropsy technique. This variability holds true for initial as well as follow-up specimens from the same outbreak, so that microscopic, hematologic, and chemical studies are necessary for complete diagnosis.

Birds affected with avian monocytosis are usually well developed and in good flesh, with a tendency to obesity. The appendages of the head appear congested, as well as the mucous membrane of the nasal passages. The vent feathers are soiled by urinary material. The *skeletal muscles*, especially the breast muscles, appear dehydrated and show capillary injection. In some cases circumscribed pale, often turgent (fish fleshlike) areas are seen, which microscopically represent patches of muscular degeneration: the myofibers are either in a state of granular disintegration separated by interstitial

edema or, more characteristically, show loss of striation, fragmentation, and hyaline swelling, associated with mild polynuclear infiltration and incipient regeneration. In other words, they show the features of Zenker's degeneration, as seen in human typhoid fever and other toxic conditions (Fig. 31.1).

Although the *liver* may appear fatty or congested, an infrequent but most typical alteration in this organ is an evenly spaced studding with round yellowish areas about 1 mm. in diameter, which often have a minute hemorrhagic center. These foci may be few in number and may be associated with subcapsular petechiae. There is ordinarily no evidence of hepatic tumefaction or fibrinous exudation. Microscopically, the areas vary in size and represent typical focal necrosis of no particular zonal orientation (Fig. 31.2); pathogenetically they seem to develop either on the basis of simple coagulative necrosis of hepatic cells, or the accumulation of hyaline material in the Kupffer cells leading to sinusoidal thrombosis. The necrotic foci often undergo secondary polynuclear infiltration and may later be replaced by regenerating liver cells. The rest of the parenchyma shows

FIG. 31.3 — Avian monocytosis. Section of liver. Severe bile stasis. ×150.

marked biliary stasis, especially in the larger ducts (Fig. 31.3).

The *serous surfaces* often reveal multiple but comparatively few and widely spaced punctiform hemorrhages. These tend to occur on the visceral surface of the sternum, on the gizzard and abdominal fat, and on the pericardium. Microscopically, the peritoneal surface of the visceral organs is frequently seen to be covered by a homogeneous eosinophilic material which is infiltrated with heterophils and spherical eosinophilic globules (Fig. 31.4) which are apparently derived from broken egg cells (Jungherr and Levine, 1941).

The *spleen*, as a rule, presents a normal appearance. The lack of tumefaction is helpful in the differential diagnosis and elimination of bacterial and leukotic diseases. Small necrotic foci are observed at times, together with bile- and hemosiderin-laden phagocytes. The *pancreas*, which normally displays a pinkish-gray homogeneous color, is apt to present a chalky appearance which resolves itself into numerous fine whitish areas on close inspection. This change, according to microscopic observation, seems to be brought about principally by cloudy swelling in the center of the acinar lobules, a process which may go on to karyorrhectic necrosis (Jungherr and Matterson, 1944). In addition, the size of the Langerhans' islets appears sometimes increased; their cells are swollen or show here and there pale eosinophilic intranuclear inclusions, which may represent colloidal degeneration products (Jungherr and Levine, 1941). Similar inclusion bodies have since been observed in chickens and turkeys not known to be affected with avian monocytosis by Lucas (1947) and classified as of the multiple homogeneous type, in distinction from the clustered granular type also found in turkeys (Lucas, 1951).

The external surface of the *intestine* is unaltered. The lumen of the ileum is usually filled with turbid tenacious mucus which is often removable as a perfect cast. Histologically the changes are those of catarrhal enteritis. There may be desquamation of the epithelium with the subepithelial zones showing marked increase in cellularity. The inflammatory cells are composed chiefly of mononuclears, lymphocytes, and histiocytes. It is not uncommon to find many cystic crypts con-

taining inspissated mucus (Jungherr and Matterson, 1914).

The gross lesions of the *kidneys* present a gradient from insignificant changes to marked enlargement, especially of the anterior lobes, and finally the familiar picture of uric nephritis known as visceral gout. Microscopic alterations are frequent in grossly "normal" kidney tissue; they are often of patchy distribution and vary in character. In the most acute cases, one sees extensive cloudy swelling, pyknosis, and desquamation of the epithelium of the proximal convoluted tubuli, a point which can be evaluated only in fresh necropsy material. Other definite renal changes consist of dilatation of tubuli associated with flattening of the epithelium and formation of hyaline casts (Fig. 31.5) and pseudogiant cells (Fig. 31.6) from infolding epithelium. The larger of these foci may show crystalloid radiating centers considered to be pathognomonic for uric nephritis (Siller, 1959). In protracted cases the tubuli show many cellular casts composed of disintegrating heterophils. The glomeruli likewise may exhibit significant alterations in avian monocytosis, such as thickening of the basement membrane, protein precipitate in Bowman's space (Fig. 31.7), adhesions, and dilatation (loculation) or hyaline thrombosis (Weaver, 1941) of the tuft capillaries. Fibrous obliteration of the glomeruli does occur in some instances.

The *ovary*, often being in full production, quite commonly presents irregular soft or broken egg follicles. The yolk material is of normal consistency. Massive fibrinous exudate around the follicles is present, and if present is probably due to secondary bacterial changes.

The similarities in the pathologic concept of avian monocytosis as presented here, and those of Mochizuki et al. (1952), Qureshi (1955), and Blaxland (1957) for the disease of chickens are striking.

Hematology. The blood may show severe hemoconcentration, increased viscosity and coagulability, and low venous pressure. For these reasons it is sometimes difficult to obtain good blood samples by venepuncture. Birds are apt to die in the process. The hemoconcentration is reflected in increased hemoglobin values averaging 15.1 grams per cent in severely affected birds (Jungherr and Matterson, 1944).
FIG. 31.6 – Avian monocytosis. Section of kidney showing pseudogiant cells in tubuli. ×500.
FIG. 31.7 – Avian monocytosis. Section of kidney showing dilated glomerular space containing desquamated cells. ×150.

In hematologic studies by the above authors, there was a consistent but moderate leukocytosis, averaging 40,000 per mm.³ The most significant change in the blood picture was a relative and absolute monocytosis which averaged about 20 per cent or 8,000 per mm.³, respectively, in comparison with the normal of 8.9 per cent for females, or 1,700, according to Olson (1959). The intensity of the blood changes varied with the clinico-pathologic picture and seemed to be particularly marked in cases of kidney involvement. As a rule, the majority of the birds in a specimen consignment showed the monocytic shift which sometimes constituted the only morphologic evidence of the disease. In stained smears the monocytes were ordinarily of the large, mature type but were sometimes characterized by basophilic cytoplasm and rounded nuclei suggestive of immaturity. Mitotic figures were rare. Differential counts by Mochizuki (1951) on 19 birds grouped according to severity of symptoms also showed, in all but one bird, a relative monocytosis ranging from 12 to 52 per cent. Similar results were reported for naturally and artificially infected chickens by Watanabe et al (1951).

The significance of the hematologic findings increased with the certainty with which other diseases such as fowl typhoid and fowl cholera could be ruled out. Since the blood changes seemed to represent the outstanding common denominator in pullet disease cases of varying intensity, the scientific term "avian monocytosis" was proposed (Jungherr and Matterson, 1944).

Chemical pathology. Clinical resemblance of avian monocytosis to uremia and the pathologic evidence of kidney and liver involvement emphasize the importance of the chemico-pathologic aspects. The earlier studies (Jungherr and Levine, 1940) have been extended by Levine and Jungherr (1941). It appears that the blood of birds affected with pullet diseaselike conditions shows high average values for nonprotein nitrogen

(26.8 mgm. per cent), and especially for uric acid (18.9), approximately normal values for phosphorus (5.5), magnesium (2.36), and total ketone bodies (15.5) and usually low values for calcium (13.9 mgm. per cent). The average value for glucose (200) is somewhat high, but wide variations are encountered in both affected and normal birds. In severe cases of avian monocytosis, the values for serum potassium are slightly below normal while those for whole blood potassium are high. Total chlorides may be strikingly low (Jungherr and Matterson, 1944). This chemico-pathologic picture is in keeping with a uremic concept of pullet disease. Very acute cases of avian monocytosis usually fail to show high values for uric acid, but the nonprotein nitrogen may be increased.

Urine analysis of birds with high blood uric acid usually reveals a polycy tosuria; this may be due to hyperglycemia, defective reabsorption on the part of damaged renal tubuli, or both. A reducing substance in birds suffering from experimental nephritis was first observed by Dworin et al. (1941) in this laboratory, and confirmed and identified in field cases of pullet disease by Levine and Jungherr (1941). Albuminuria was frequently observed in laying birds when the urine was obtained by the cloacal technique of Davis (1927) and Coulson and Hughes (1931), while urine obtained by cannulization of exteriorized ureters (Hester et al., 1939–40) was free from albumin. Thus, the albumin seemed to be due to admixture of secretions from the genital tract, and to be of no pathologic significance.

Differential diagnosis. Some phases of the clinical and to a certain extent the pathologic picture of this disorder can be brought about by any of the common infectious diseases such as fowl cholera, pullorum disease, and fowl typhoid. For this reason it is of diagnostic significance to exhaust the possibility of known specific infections. Flock outbreaks can often be suspected from the anamnestic data.

Etiology. The exact factors involved in

the causation of the field syndrome of avian monocytosis are unknown. Etiologic studies have been concerned with the possibility of nephrotoxic substances particularly in wheat, physical factors such as overheating and dehydration, and of infectious agents.

Severe cases of avian monocytosis represent essentially a uremic condition referable to renal damage. Pathologic involvement of the liver in renal diseases is recognized in man under the term "liver death" and/or hepatorenal syndrome (Wilensky, 1939). This would be plausible in birds on account of the close circulatory connection between the two organs and the existence of a special portal circulation in the avian kidney (Spanner, 1925; Gordeuk and Grundy, 1950). Experimental nephrotoxicoses may shed some light on the problem, especially since the demonstration of nephrotoxic antagonists to essential nutrients (ethionine against methionine in rats) by Wachstein and Meisel (1951). In birds, repeated intramuscular injections of potassium dichromate (0.001 per cent of body weight) caused uric nephritis together with occasional necrobiosis of liver, pancreas, and skeletal muscle (Jungherr and Levine, 1941). Feeding chicks certain inorganic acids, particularly sodium citrate and acetate, produced the so-called "salt effect" which was preventable by potassium salts (Correll, 1941). In confirmation of this work, Scott et al. (1944) found the salt effect to be indistinguishable from visceral gout or uric nephritis and to be preventable by potassium-rich molasses and potassium chloride. The latter substance also seemed to have a certain curative effect on spontaneous avian monocytosis. The possible effect of the sodium-potassium balance on the development of "uraemia" was studied by Beilharz and McDonald (1960). In 6 groups of 4-week-old chicks, fed diets varying in protein source and supplementary sodium and potassium chlorides for 8 weeks, an outbreak of uremia was less severe in the potassium supplemented than in the nonsupple-

mented groups. The possibility of a coexisting infectious agent was not ruled out. In man, renal and cardiac lesions associated with chronic diarrhea have been termed "kaliopenic nephropathy," an entity recently studied under the light and electron microscope by Biava et al. (1963). The principal renal lesion was an expansion of normally existing extracellular spaces together with changes in the tubular basement membrane and was considered similar to that in hypernatremia. Selye (1942) produced nephrosclerosis in chicks by repeated subcutaneous injection of desoxycorticosterone acetate, by watering with physiologic salt solutions, or both (Selye and Stone, 1943), and believed the experimental condition to resemble avian monocytosis. Hormonal adrenal deficiency and faulty adaptation have been suggested by Van Ness (1951b) as underlying causes of this disorder; this might find some support from the reported therapeutic response, especially of the subacute form, to antihistamines (0.1 gram Anthisan per os) (Thompson, 1951). High protein diets alone, although producing articular gout in turkeys (Bollman and Schlotthauer, 1936a, b) and in chickens (Oppenheimer, 1941; Oppenheimer and Kunkel, 1943), apparently had no such damaging effect on the kidneys. Fisher et al. (1961) observed repeated outbreaks in both male and female yearlings when transferring them from floor pens to individual cages. These authors considered water deprivation and change in environment as a possible sole or major cause.

Investigating the popular claim that avian monocytosis represented a form of wheat poisoning, Quigley (1943) subjected it to experimental inquiry and obtained some epizootiologic as well as experimental support for this belief (1944a). He failed to find chemical differences between pullet disease-inducing and non-inducing wheat samples, but found the former to have lowered germination ability (1944b) and to be associated with a high bacterial and low fungal flora (Petty and Quigley, 1947). In further

studies Quigley (1948) again found different loss of wheat to vary in their ability to cause pullet disease. Fortification of the mash with calcium carbonate and sodium bicarbonate improved egg production but had no preventive effect on the disease.

This subject of possible causes of visceral gout in birds has been reviewed by Stonebrink (1947).

High atmospheric temperatures have long been considered as a possible factor, as indicated by the synonym "summer disease." Yeates et al. (1941), in their studies of the reactions of domestic fowl to hot atmospheres, failed to observe pullet disease. Jungherr, in cooperation with Scott and Matterson (1946), examined chickens which had been kept at constant high atmospheric temperatures with or without adequate water supply, but failed to find a condition which would fit the diagnostic criteria of avian monocytosis. Fox (1951) reviewed the problem of heat tolerance of domestic fowl and found the survival time to depend on breed differences and persistency in water consumption. Van Ness (1953) collected nationwide incidence data which suggested bluecomb in chickens to resemble early shock and to occur primarily 3 to 4 days following temperature waves of 85° F. or over.

Maas and Voûte (1961) made detailed epizootiologic observations in an intensive breeding area of southwestern Holland during the summer of 1959. In a pullet population at risk of 800,000, 4 to 8 months old, with flocks averaging 5,000 birds on 10 acres of land, they observed 215 cases of bluecomb, 124 of them uncompli cated. The attack rate was 3 to 4 per cent of young hens but was not uniform since broad strips were apparently spared. Clinical signs corresponded to those in the world literature. Outbreaks were frequently preceded by sudden changes in temperature. Egg production receded by 30 per cent and returned to normal within 3 to 6 weeks after treatment. The latter consisted of reduction of grain feeding and 1:10,000 oxytetracycline in the drinking water. This recent report is of interest in view of the diminishing incidence in the U.S.A.

No bacterial organism has been found to be constantly associated with avian monocytosis, except for the unconfirmed claim of Weisner (1941) that the disease is caused by certain strains of Escherichia coli.

Waller (1942, 1944a) reported the isolation of a filterable agent from the blood, liver, feces, and eggs of birds affected with the acute form. The virus (1944b, 1945) could be cultivated on the chorio-allantoic membrane of 8- to 9-day-old chicken embryos where it produced a compact or circular lesion with radiating processes, stunting of the embryo, and death in about 12 per cent. Turkey and duck embryos usually succumbed to the inoculation. Injection or feeding of the freshly isolated virus caused a nonfatal sickness (in about 50 per cent) characterized by subcutaneous edema, widespread petechiation, tumefaction of the parenchymatous organs, and catarrhal enteritis. The experimental disease in chickens and turkeys was accompanied by marked heterophile leukocytosis which reached its peak about 96 hours post inoculation.

Blood sera from birds that had recovered from the experimental or spontaneous diseases were capable of agglutinating washed killed Salmonella pullorum organisms which had been allowed to adsorb virus from infected allantoic fluid.

Based on the refractivity of birds to reinoculation, a live vaccine was prepared from infected chorio-allantoic membranes dried in vacuo over anhydrous calcium chloride and used on about 44,000 birds with encouraging results.

Isolation of a virus in embryonated chicken eggs was reported by Watanabe and associates (1952a, b). The authors succeeded in the isolation of two strains from Chamberland L_3-filtered intestinal content of acutely affected birds. The virus was cultivated in the allantoic cavity of 8- to 10-day-old chicken embryos for 14 passages and caused embryonic deaths within 1½ to 3 days, accompanied by hyperemia and petechiation of eyelids,

legs, and lung, or severe stunting within 7 days. Later studies found the yolk sac route preferable. The egg-propagated virus was nonhemagglutinating and neutralizable, and was capable of inducing the field syndrome in healthy birds on oral or intravenous administration within 5 to 6 days. Tanaka and Kawashina (1961) further characterized the virus of infectious diarrhea of pullets. Blaxland (1957) confirmed the embryo-pathogenicity of the Japanese agent when inoculated into the yolk sac of 6-day-old embryos. But intravenous inoculation of the virus into British fowl caused only a transient monocytosis. Neutralization tests on the principal birds prior to, and post, inoculation were not reported.

Although the viral etiology has not been confirmed definitely, failure to do so may be entirely technical in nature but demonstrates the difficulties involved, particularly for diagnostic purposes. Waller (1944b) rightly pointed out the unlikeliness of many birds being attacked simultaneously by uremia of noninfectious origin. On the other hand, to explain the often explosive outbreaks of avian monocytosis on an infectious basis, one would have to assume that the viral agent is already widely seeded in the susceptible population, and that its pathogenic action is set into motion by secondary nonspecific factors (Jungherr and Matterson, 1941).

Treatment and control. Certain therapeutic measures have been used in the field, apparently with favorable response if applied in the early stages of the acute form of the disease. For individual treatment Van Ness (1951a, b) suggested instillation into the crop of 10 to 20 ml. of 4 per cent acetic acid or of vinegar, followed by gentle massage.

In general, the measures consist in providing an abundance of clean, readily available water, and cool, well-ventilated quarters, and in reducing consumption of grain. If possible, birds should be allowed access to runways or shaded range. Flushes are contraindicated in view of the severe dehydration.

Some observers claim to have obtained good results from the use of 1:2,000 copper sulfate or 1:1,000 potassium dichromate in the drinking water (Weisner, 1941). Molasses has been used widely and has some justification because in high doses it prevents experimental nephrotoxicoses probably on account of its potassium content (Scott et al., 1944). Blaxland (1957) thinks of molasses merely as a source of readily assimilated carbohydrate. Molasses may be used either in the drinking water (2 per cent) or administered in a mash composed of equal parts of bran and rolled oats, mixed with 10 to 30 per cent of molasses and water in amounts sufficient to obtain a crumbly consistency. The treated mash is given on alternate days for a period of 3 hours, after withholding food for about 2 hours.

Instead of molasses, potassium chloride or good fertilizer grade of muriate of potash (containing at least 60 per cent K_2O) may be used at the rate of 0.5 per cent in the water for the first 7 days and, if necessary, at the rate of 1¼ per cent in the feed for an additional 7 days. According to Van Ness (1917a, b), under experimental conditions, prolonged or excessive use of potassium chloride may have untoward effects. The general role of potassium in human medicine is finding new emphasis (Darrow, 1950; Martin et al., 1951) and militates against a concept of pullet disease as being a primary potassium deficiency.

Antibiotics, namely penicillin, chlortetracycline, and oxytetracycline, were first shown to be effective in individual oral treatments of turkey cases by Peterson and Hymas (1951), who also obtained good results in the field with 100 and 5 parts per million of oxytetracycline in mash and water, respectively. Since then, treatment of the disease in chickens with high level oxytetracycline has been reported as both successful (Cromley, 1953) and unsuccessful (Adler et al., 1952). Pullet disease responded promptly to treatment with high levels of chlortetracycline in the experience of McKay and

Pelly (1956). On the theory that the acute form is a metabolic disorder and the sub-acute form is due to an infectious agent, Blaxland (1957) recommended treatment only for the subacute form. He stated, however, that this was based upon field experience, not upon controlled experiments.

If the virus etiology of avian monocytosis is confirmed, specific vaccination may be contemplated. At the present time, a specific vaccine is not available.

Control measures should be attempted along the lines of good management. Direct and indirect contact with affected birds should be avoided. Routine prophylactic vaccinations (fowl pox, etc.) are best carried out during the early growing period, preferably at the age of 2 months. At the time of housing, the birds should be well fleshed but not fat; transfer from the range to confinement must be made gradually with a minimum of disturbance to the birds. Shade, ventilation, and water supply are important factors, and mash feeding should be intermittent during the critical period.

INFECTIOUS NEPHROSIS OF BROILERS

An apparently new disease of chickens was observed in the Delmarva broiler area since 1956 and reported by Cosgrove (1962) under the term avian nephrosis, popularly known as "Gumboro disease" according to the locale. Referring to it as "nephritis-nephrosis syndrome of chickens" Winterfield and Hitchner (1962) determined its viral etiology but found two agents which produced mild respiratory signs associated with renal alterations. Winterfield et al. (1962) recognized distinct pathogenetic differences between these agents and suggested naming the respiratory agent "infectious bronchitis variant virus" and the Gumboro disease agent which causes enlargement of the bursa of Fabricius and renal lesions, "infectious bursal agent."

The immunologic relationship of the bronchitis variant virus to other known serotypes of this virus has been detailed by Hitchner et al. (1964) and Winterfield et al. (1964).

The pathologic aspects of the infectious bursal agent have been studied by Helmboldt and Garner (1964). After intraocular inoculation of 21-day-old susceptible chicks, there was gross enlargement of the bursa of Fabricius within 3 days and microscopically general necrosis of the lymphoid elements, especially in the spleen, cecal tonsils, and thymus followed by partial regeneration. Nephritis occurred irregularly in the terminal phases of the experimental disease.

In Australia, Newton and Simmons (1963) likewise observed an acute disease of broilers with initial respiratory and late nephritic signs and believed it to be the most prevalent form of avian nephritis in Queensland. The authors obtained a chicken embryo lethal agent via the yolk sac route. Suspensions of kidneys from affected birds or of infected yolk sac reproduced the disease either by intra-abdominal inoculation or exposure to aerosols. By the latter techniques two-day-old chicks developed a nephritic, older chicks a respiratory, syndrome. In the over-all, the disease was similar to that described by Hungerford (1962) as fulminating "uraemia" in brooder plants.

Cumming (1963a) objected to the term uremia and stated that the "kidney breakdown disease complex" has been a problem in Australian poultry flocks since 1948 and now represents a major poultry disease. In six-week-old chicks the disease started with respiratory signs for 24 hours, followed in 3 to 4 days by high losses (up to 15 per cent) which were principally characterized by dehydration and renal enlargement. Inoculation of pathologic material into the allantoic cavity of developing hen's eggs yielded a virus which caused changes in the embryos ordinarily ascribed to those of infectious bronchitis virus, and which was capable of reproducing the disease in 15-day-old chickens. Since Australia was believed to be free from avian viral bronchitis the isolant was con-

sidered an aberrant strain of infectious bronchitis virus.

In follow-up studies on infectious avian nephrosis in Australia, Cumming (1963b) reported isolation of the virus from various localities around Sydney and elsewhere. The virus could be isolated from lung, trachea, and kidney, even from dead birds. The experimental disease, produced by intraocular instillation of infected allantoic fluid, caused respiratory signs without discharge in 24 hours. After a 3- to 4-day period of normalcy, the birds became hunched, ate little, and drank much. The vents were soiled, the droppings white, and the combs cyanotic. The natural disease was also observed in young layers where respiratory signs were followed within 4 days by drop in egg production, embryonic mortality in their progeny for about 2 weeks, and decrease in egg quality for a longer period, by and large typical of infectious bronchitis. An attack was followed by immunity in about 6 weeks. The disease was considered self-limiting and probably caused by interaction of nutritional and viral factors. Except for the enlargement of the bursa of Fabricius, the Australian nephrosis syndrome resembled the American form; preliminary results have shown no serologic cross-neutralization of the respective viruses.

While the interrelationships of avian nephrosis in broilers in various parts of the world to pullet disease in older birds have not been worked out, the recent findings strengthen the infectious theory and promise etiologic clarification. They also demand careful re-examination of bronchitis-like viral strains, especially vaccine strains, for purity and pathogenetic spectra.

BLUECOMB DISEASE OF TURKEYS

Occurrence. Bluecomb disease of turkeys has been recognized in various turkey raising areas of the United States and Canada. Peterson and Hymas (1951) described an unfamiliar disease of turkeys, observed in the state of Washington for the past seven years and locally known as "Mud Fever," which had the general characteristics of pullet disease. Pomeroy and Sieburth (1953) reported on an extensive outbreak of the disease that occurred in Minnesota in 1951. A similar condition had been recognized as occurring sporadically in growing turkeys for several years. It had been designated as trichomoniasis of the lower intestinal tract because of the presence of increased numbers of trichomonads in the cecum and rectum. Boyer (1953) reported on the disease in New York as having a similar pattern to what was described in Minnesota. The disease was recognized in Virginia as a serious disease problem in young turkeys (Sieburth and Johnson, 1957). Ferguson (1961) reported the disease had occurred in Ontario for several years and in 1959 had become a serious disease problem.

Economic importance. Surveys of turkey growers conducted by the State-Federal Crop and Livestock Reporting Service in Minnesota in 1951, 1956, and 1961 indicated that bluecomb disease was the most costly disease encountered by the turkey industry in that state. In 1961, 31 per cent of the flock owners reported losses from the disease, in 1956, 22 per cent, and in 1951, 14 per cent. The estimated value of the turkeys lost in 1961 was $189,000 and morbidity losses would greatly increase that figure. The average age of the birds at the time of most frequent loss in 1951 was 21 weeks, in 1956 it was 13 weeks, and in 1961 it was 9 weeks. Because of the change in turkey production to a year-round program on many farms today, the disease is encountered frequently in young birds before they are placed on range, as compared to previous years when the production was more seasonal and the disease was seen in mature birds (Erlandson and Mesick, 1962).

Etiology. The exact cause of bluecomb disease in turkeys has not been fully characterized. Pomeroy and Sieburth (1953) demonstrated the infectious nature of the disease and were able to reproduce the disease with unfiltered intestinal contents. Tissues, other than the intestinal

tract, did not harbor the transmissible agent. Sieburth (1954) studied various bacterial isolates from the intestinal tract of bluecomb disease-infected poults but was unable to reproduce the disease with various types of microorganisms. The agent failed to pass Seitz EK, Berkefeld N, and sintered glass UF filters. Sieburth and Pomeroy (1955) reported additional studies on the etiology but were unsuccessful in isolating a specific agent. Tumlin et al. (1957) established that the agent readily passed Berkefeld and Selas filters of the smallest pore size but would not pass through a Seitz EK filter. Sieburth and Johnson (1957) reported similar findings. A similar agent has been obtained from bluecomb-affected chickens which is transmissible to chicks and poults. However, infective material from poults did not cause the disease in chicks (Sieburth and Pomeroy, 1956b). Tumlin and Pomeroy (1958) found that 1:2 dilutions of serum from recovered field cases completely neutralized Selas 02 filtrates of agent-bearing intestinal contents, but no evidence of measurable passive immunity was found in their progeny. Truscott et al. (1960) isolated a small Gram-negative anaerobic pleomorphic rod from the intestinal tract, which they considered as the etiological agent. Truscott and Morin (1964) further characterized the agent as a member of the genus Vibrio, and reproduced the disease with vibrio cultures. Vibrio isolations were made from the liver and bile, as well as intestinal tract. Serological studies suggested that at least three serological types were isolated. The relationship of these vibrios to the vibrio associated with hepatitis in chickens has not been established.

Larsen (1964) has consistently isolated an enterovirus from intestinal tracts of bluecomb-infected turkeys and recently has verified the presence of vibrio organisms in experimental and natural infections. He has not been able to reproduce the disease with the enterovirus or vibrio organisms alone or in combination.

Symptomatology. The disease affects turkeys of all ages. In young poults the disease appears suddenly. There is depression, subnormal body temperature, anorexia, dehydration, and frothy or watery diarrhea. There is constant chirping and poults seek heat. The incubation period is 48 to 72 hours. In growing turkeys the appearance of the disease in a flock is sudden with a concurrent drop in water and feed consumption. The affected turkeys have a diarrhea, some depression and show darkening of the head and skin. There is a rapid loss of weight and a sunken crop. The droppings may contain mucous threads and casts and may be greenish to brownish in color. As the disease progresses in a flock, the droppings contain primarily urates. There is a subnormal body temperature. In turkeys in production a similar pattern as seen in growing turkeys is encountered and, in addition, a rapid drop in egg production with chalky eggshells.

The mortality varies depending on the age of the turkeys and environmental factors. In young poults under experimental conditions the loss may vary from 50 to 100 per cent, whereas under field conditions, the losses may vary from 5 to 50 per cent with higher losses occasionally encountered. In young turkeys four to eight weeks of age the death loss may be kept to a minimum if supplemental heat is provided. In range turkeys the loss may be low but is dependent on environmental conditions. If adverse weather conditions prevail, the loss may be as high as 25 per cent. The course of the disease may extend over a period of ten days to two weeks and it may require several weeks for the birds to regain lost weight. In mature birds, particularly males, some never regain satisfactory weight and there is a general unevenness in the flock. The morbidity loss may be high because of the loss of weight and inability of the flock to mature at a normal rate (Pomeroy and Sieburth, 1953; Sieburth, 1954; Sieburth and Pomeroy, 1955).

Pathology. In poults the gross changes

are confined to the intestinal tract. Contents of the duodenum and free portion of the small intestine and cecums are watery and gaseous. Bulbous areas are noted along the intestinal tract. There are no gross lesions in the lungs, heart, liver, spleen, pancreas, and kidneys. The muscles are dehydrated with a generalized emaciated condition of the carcass.

In growing and mature turkeys the gross changes are confined primarily to the intestinal tract, although changes are noted in some of the other organs. The liver is normal in size and appearance. The spleen is usually smaller than normal. The pancreas may appear normal or have a chalky appearance with numerous small whitish areas. The kidneys usually present a normal appearance. Urate deposits are rarely found. The crop is empty. The lumen of the intestinal tract contains watery, gelatinous mucus and occasionally casts. The cecums are distended and filled with watery yellowish-brown feces having a fetid odor. Small petechial hemorrhages may be noted on the surface of the intestinal mucosa (Pomeroy and Sieburth, 1953; Sieburth, 1954; Sieburth and Pomeroy, 1955). Hilton (1954) found similar histopathological changes in tissues from experimentally and spontaneously infected turkeys. Histologically changes were primarily of a catarrhal enteritis. He found a marked round cell infiltration of the adrenals.

Hematology. Hilton's (1954) hematologic findings in experimentally infected turkeys were similar to those reported in chickens (Jungherr and Matterson, 1944).

Chemical pathology. Hilton (1954) conducted some blood chemistry studies on experimentally infected turkeys but the results were inconclusive.

Differential diagnosis. In young poults the disease may be easily confused with hexamitiasis. Salmonellosis may be a complicating factor in natural outbreaks. Moniliasis is a very common secondary infection particularly following antibiotic therapy. In growing and mature birds increased numbers of trichomonads are found in the contents of cecums and rectums. Their role in natural outbreaks is not known. The possibility of known specific infections, such as erysipelas, fowl cholera, and entero-hepatitis, must be eliminated by laboratory studies.

Treatment and control. Because of the highly infectious nature of the disease every management precaution must be taken to prevent the introduction of the disease onto a turkey farm. Since there is evidence of a carrier status in recovered turkeys, complete depopulation of a turkey farm is the only way to break the cycle of infection.

Various antibiotics and other chemotherapeutic agents have been evaluated in the treatment of the disease. No regime has been found that will completely prevent the disease. Peterson and Hymas (1951) reported success in individual oral treatment of turkeys with penicillin, chlortetracycline, and oxytetracycline. Various antibiotics have been used under controlled conditions at high levels. Penicillin, chlortetracycline, oxytetracycline, and streptomycin were effective in reducing the death loss at 500 grams per ton in the feed and 1.0 gram per gallon of drinking water (Pomeroy and Sieburth, 1953; Sieburth and Pomeroy, 1956; Pomeroy, 1956a, b). Tumlin and Pomeroy (1958) reported on the prophylactic value of three nitrofurans in experimental infections that resulted in reduced mortality but had no effect on morbidity.

Truscott *et al.* (1960) found the bacterium they considered the causative agent of bluecomb disease resistant to penicillin, streptomycin, tetracycline, erythromycin, chloromycetin, and spotin, but sensitive to neomycin. They recommended 0.7 gm. of neomycin per gallon of drinking water as a treatment.

In turkeys sick with this disease, increasing the environmental temperature until the birds seem comfortable is also of considerable value in keeping losses to a minimum.

Neoplastic Diseases of the Chicken

An attempt is made in the following presentation to describe briefly the various forms of neoplastic disease that occur in the chicken and to discuss their salient characteristics. This contribution is intended to supply the information necessary for a pathologist to make a differential diagnosis of neoplasia in the chicken, provided the case in question is one of the commoner forms of tumor. Key references to the literature are provided for those who wish to seek more detailed information.

Scientific interest was aroused about 55 years ago in two types of neoplasia of the chicken which were found to be transmissible by means of an ultramicroscopic agent separable from tumor cells. These tumors were fowl leukosis and certain tumors of connective tissue. Because of considerable research on the transmissible tumors of chickens, evidence is accumulating to indicate contact exposure of the very young bird is the mode of transmission of these diseases under natural conditions.

INCIDENCE

Although neoplastic disease is generally recognized as one of the more common diseases of the domestic chicken, its incidence can be estimated in only a general manner. Reports referred to in Table 32.1 indicate an incidence of from 3 to 19 per cent.

Ask-Upmark (1938) reported what he believed to be an epidemic of tumors in a flock of chickens in Sweden. Between 20 and 25 birds from a flock of 100 died within a year. Only 5 of the birds were actually examined, yet all 5 were affected with carcinoma of the ovary with extension to the viscera. Olson (1912) studied the tumors that occurred in a small poultry flock in which the incidence of disease

TABLE 32.1

Frequency of Neoplasia Observed in Chickens
(Excluding Neurolymphomatosis and Osteopetrosis)

Author	Locality	Number of Birds Examined	Period of Observation	Per Cent With Tumor
Curtis (1915)	Maine	880	8 years	8.98
Schneider (1926)	England	11,000	. . . .	2 to 3
Hoogland (1929) . . .	Holland	1,707	32 years	10
Babic (1931) .	Yugoslavia	647	8 years	6.6
Eber and Malke (1932)	Germany	11,903	32 years	3.12
Goss (1940), .	New York	7,408	. . . . .	19.5
Olson and Bullis (1942) . . .	Massachusetts	2,304	2 years	12 9
Campbell (1945) .	Scotland	2,063	5 years	18.7
Reis and Nobrega (1955). .	Brazil	15,549	23 years	6.6

was unusually high. The flock numbered 48 birds, and when the last bird was slaughtered, 3 years later, 13 birds (27 per cent) had died with neoplastic disease. In another flock of 478 birds, 42, or 11.4 per cent, became affected with lymphocytoma in a 2-month period (Olson, 1948).

Various factors obviously will affect the result of any survey on the incidence of neoplasia. Some of the more important factors are age of the group under survey, length of period covered by the survey, the *genetic composition or inheritable tendencies* of the group under survey, and certain other factors, as yet unknown, which may cause a high incidence of certain *types of tumors.*

Some forms of neoplasia are much more common than others. Lymphocytoma is recognized generally as the most common tumor found in chickens. Collectively the other varieties cause much loss, and other types of tumors may be a serious problem in some flocks of poultry.

CLASSIFICATION OF NEOPLASMS OF CHICKENS

Many schemes or systems have been proposed for the systematic grouping of true tumors. *A fairly satisfactory system of classifying tumors is that which depends on the type cell from which the tumor originates* (Table 32.2). Such a classification is based on the embryogenesis and histologic identity of the respective cells that make up normal tissues and takes cognizance of the fact that tumors may arise from any of the distinct varieties of cells that are concerned normally in the structural or functional welfare of the body. One practical difficulty with this system of classification is that although cells of normal or mature tissues usually possess characteristics by which they can be recognized readily, unripe or immature cells such as make up rapidly growing tumors, or those cells representing primitive tissues, may exhibit so little differentiation that recognition of the type cell may be difficult or impossible.

TUMORS OF CONNECTIVE TISSUE

The widespread distribution of the different connective tissues throughout the body provides potential sources for a variety of connective tissue tumors. Another potential source of connective tissue tumors *is the free histiocyte which exists in* all loose connective tissues.

Tumors derived from the various con-

	IX. Mixed tumors
	    Thymoma
	    Carcinosarcoma
	    Teratoma
	    Dermoid cysts
	    Embryonal nephroma

nective tissues may be extremely simple in their constituents and easily recognized, or they may be more or less complex in structure and difficult to classify with certainty. Many variations of structure occur. Single benign fibroblastic tumors may be associated with edema or mucinous substances, and it may be difficult in the latter instance to determine whether or not one is dealing with a simple fibroblastic entity associated with mucinous degeneration or with a tumor that is primarily myxomatous. The connective tissue tumors composed of cartilage, fat, or bone are ordinarily not difficult to recognize if sufficient differentiation has occurred.

Frequency of occurrence. Generally speaking, the benign connective tissue tumors are among the rarer neoplasms of chickens. In a series of 113 chicken tumors (exclusive of leukotic tumors) reported by Goss (1940a), only 1 benign connec-

tive tissue tumor – a fibroma – was listed. Among 237 tumors of chickens examined histologically by Eber and Malke (1932), 11 benign connective tissue tumors were found. These included 1 myxoma, 5 fibromas, and 5 lipomas. Hoogland (1929), of Utrecht, reported 12 fibromas among 176 chicken neoplasms. No other forms of benign connective tissue tumors were listed by Hoogland. Eight of Goss's series of 113 tumors were fibrosarcomas. In Jackson's (1936a) series of 205 neoplasms (including lymphocytoma and leukosis) of chickens, 21 malignant connective tissue tumors are listed. The different varieties were as follows: 7 fibrosarcomas, 1 myxosarcoma, 1 osteochondrosarcoma, and 15 histiocytic sarcomas. In the series of 585 neoplasms of chickens, inclusive of leukosis, presented by Olson and Bullis (1942), there were 16 fibrosarcomas, 5 histiocytic sarcomas, 5 neurogenic sar-

comas, 1 osteochondrosarcoma, and 1 fibrochondrosarcoma.

As in most other forms of neoplasia of the chicken, adequate, precise statistical data on the incidence of connective tissue tumors are not available. In the older literature the term "sarcoma" was used in a rather nonspecific sense, and no attempt was made to separate the various types of sarcomas on the basis of the type cell. Our observations and the impressions obtained from the reports of others suggest that the benign connective tissue tumors occur infrequently and that the malignant varieties are at least of moderate frequency.

Sites of occurrence. As may be inferred, tumors of connective tissue origin may arise from any situation where the prerequisite parent cells occur. Fibromas, myxomas, and lipomas are most likely to arise from the integument, while simple tumors composed of cartilage or bone or a mixture of these two tissues may be expected to arise from situations where cartilage or bone normally occurs. Certain multipotent mesenchimal cells may and sometimes do give rise to cartilage and bone in situations where these tissues ordinarily are not expected. Of the connective tissue tumors, the group designated

histiocytic sarcoma is capable of the widest anatomic distribution. Situations in which this tumor has occurred include the wattle, esophagus, subcutis, liver, spleen, and ovary.

Osteogenic sarcomas may arise wherever periosteal tissue occurs.

Effects on the host. The malignant varieties of connective tissue tumors are potentially lethal, and the effect on the host depends on whether metastasis has occurred and what organs are affected. One gets the impression that these tumors, especially the fibrosarcomas and the histiocytic varieties, grow rapidly, and death or extreme debility may ensue relatively soon after the disease has become disseminated. Most of these tumors produce a progressive destructive disease that invariably results in death.

Gross and microscopic description. Like many other tumors, those derived from connective tissue elements seldom have sufficient distinguishing gross characteristics to make their identification certain. Fibromas are usually circumscribed, fleshy, nodular or oval masses that may be soft or firm (Fig. 32.1). A capsular covering usually can be recognized. Myxomas are likewise more or less circumscribed and of soft consistency, and the slimy mucinous

FIG. 32.1 — (1) Fibroma encircling the intestine. (2) Fibroma in the ventricular wall of the heart.

or gelatinous character of most specimens is evident. A lipoma, being composed largely of fat, offers little difficulty in recognition. The identifying features of benign tumors of cartilage or bone should be obvious.

Gross features that might enable one to distinguish malignant connective tissue tumors from other malignant growths are not to be relied on when an accurate diagnosis is desired. Although signs suggestive of malignancy, such as lack of encapsulation, multiplicity of lesions within the same general region, or the presence of contiguous implantations or distant metastatic growths, usually will permit no doubt as to the malignancy of the process, specific features that might enable one to recognize the specific character of such a neoplasm are missing. The diagnosis of these tumors, as of most others, must depend on microscopic examination.

Special features. One of the most interesting features of connective tissue tumors of the chicken is the transmissibility of some forms by filter-passing agents. The transmissibility of a considerable number has been studied, and a huge literature has accumulated which deals with these investigations (Claude and Murphy, 1933; Foulds, 1934). A variety of such agents has been studied. They differ from each other both in the specific form of tumor they produce and in certain serologic characteristics. The existence of ultramicroscopic tumor-producing agents suggests the possibility of epidemics of neoplasms. Carr (1944) reported no neoplastic disease in chicks hatched from hens that had recovered from the Rous No. 1 sarcoma. Yolk of eggs laid by the hens contained a substance which neutralized the action of the sarcoma agent. Previously Carr (1943) had demonstrated persistence of the neutralizing substances, in blood serum of fowls recovered for 1 to 2 years, which were believed due to latent virus still in the tissues of the hens. Duran-Reynals (1940) reported similar neutralizing substances believed to exist as natural antibodies in the blood of adult normal chickens. Kenzy and Neuzil (1953) found such neutralizing antibodies in 60 per cent of serums from flocks with a high incidence of lymphomatosis, but such antibodies could not be produced by artificial with transmissible or nontransmissible lymphoid tumor material (Kenzy, 1953). In another series, Kenzy et al. (1961) found a rather marked variation in the occurrence of tumors and prevalence of Rous virus neutralizing antibodies in different flocks. Usually a low level of tumors was related to a low level of antibodies. Duran-Reynals et al. (1953) found that chickens recovered from and subsequently resistant to a lymphoid tumor were susceptible to implants of Rous No. 1 tumor. A good review of the antibody against tumor virus and other inhibiting factors is given by Bryan (1958) and should be consulted by one interested in these aspects. The RIF factor of Rubin (1960) is regarded by him as a naturally occurring avian leukosis virus which will produce resistance against Rous sarcoma virus in cultures of chicken embryo tissue. Rubin et al. (1962) studied a flock with high incidence of lymphomatosis and found that one of every six hens had persistent RIF viremia and regularly infected their embryos. These congenitally infected birds had no detectable antibodies to RIF. Birds not infected through the egg became infected by contact with those having a viremia and in turn developed a transient viremia followed by formation of antibodies to RIF. An etiologic relation between certain fibrosarcomas and fowl leukosis is discussed in the section describing fowl leukosis. The situation described by Kenzy (1953), of a myxosarcoma giving rise to a transmissible lymphoid tumor with a long incubation period, is unique. The diminishing titer of Rous tumor-neutralizing substances with the serial passage of the lymphoid tumor in chickens suggests only a partial association of the lymphoid tumor and the factor causing such neutralization. Some of the transmissible connective tissue tumors of chickens have been reproduced experimentally in other species of fowl. Harris (1955) has shown that the

natural resistance of older turkeys to *Rous* sarcoma can be overcome if the turkeys are given normal chicken blood intravenously when they are hatched. This induces a state of immunological tolerance. Perhaps most spontaneous connective tissue tumors of the chicken might prove transmissible if all the conditions conducive to success could be supplied. Duran-Reynals (1946a) was more successful with transplantation and demonstration of cell-free agents of sarcomas occurring in chickens 5 to 10 months of age. Carcinogenic chemicals have produced connective tissue tumors in birds under proper experimental conditions. However, such tumors do not appear transmissible by cell-free agents (Murphy and Sturm, 1941a, b, Peacock, 1946). Peacock (1946) studied the histology of 15 transplantable, chemically induced sarcomas and 3 sarcomas that could be transmitted by cell-free agents. He states that slight but definitely recognizable differences exist between tumors induced by chemicals and those by cell-free agents.

The intensive research on agents of chicken tumors will continue to provide new facts. The vascular lesions produced in ducks by a variant of the Rous sarcoma agent (Duran-Reynals, 1950), the leukemic form of an endotheliona induced by X-ray (Oberling *et al.*, 1953), and the hepatitis observed in chicken embryos with a strain of the erythroblastosis agent (Atanasiu, 1956) indicate that they are not rigidly specific as to their action. The visualization of the agents with electron microscopy allows study of their relation to structures within cells (Epstein, 1957) and the observation of agglutination of viral particles by immune serum (Beard *et al.*, 1957).

Fibroma and fibrosarcoma. A fibroma in its simplest form consists of rather adult fibroblasts and narrow to wide strands of collagen disposed parallel to the longitudinal axis of the fibroblasts. The fibroblasts vary in size and number according to the rate of growth. Fibromas that progress slowly show the greatest degree of differentiation in that more collagen is produced, and the resultant structure contains relatively few cells in proportion to the collagen present. The less differentiated forms are more cellular and less firm owing to a relatively small amount of collagen. In some instances markedly edematous regions occur in which the fluid causes separation and retrogression of the collagen fibrils. The edema in these instances should not be confused with the mucinous product of myxomatous tumors. If infection has occurred because of erosions at the surface, various phases of inflammation and necrosis may be recognized.

The essential features of fibrosarcomas are the immaturity of the type cells and the aggressive and destructive behavior of the neoplastic process (Fig. 32.2). Large, irregularly arranged, hyperchromatic fibroblasts are abundant, and mitosis is common. Collagen is present in variable amounts but is less abundant than in fibroma. Stromal elements, frequently disposed as irregular septa, may occur, and small blood channels usually can be recognized. In rapidly growing specimens, small to extensive regions of necrosis are likely to occur. Occasionally, widespread edema is present, causing considerable separation of the fibroblastic components.

Myxoma and myxosarcoma. Myxomas consist of stellate or spindle-shaped cells surrounded by a homogeneous, slightly basophilic, mucinous matrix. Long cytoplasmic processes may extend from the stellate cells and become fused with the matrix and collagen fibrils. In the malignant form of myxoma the mucinous matrix is less abundant than in the benign form, and the type cells are proportionately more numerous and more immature. The histogenesis and structure of primary myxomatous tumors are closely related to those of the fibroblastic tumors, the essential difference being that in myxomatous tumors the fibroblastic cells are more specialized and are capable of producing
FIG. 32.2 — Fibrosarcoma in the musculature of the breast. The neoplastic process was bilateral and had metastasized to the lungs. ×120.

mucin in addition to the usual products such as fibroglia, collagen, and elastic fibrils.

Lipoma. Like other tumors of connective tissues, those derived from the lipoblast may be composed of adult cells and present the physical appearance of ordinary fat tissue, or the immature forms of the lipoblast may predominate, in which case the tumor presents a sarcomatous appearance. The microscopic appearance of lipoma is extremely simple. The process consists of compactly arranged, moderately large to extremely large polyhedral cells filled to capacity with a large fat globule or several small ones. The nucleus may be crowded to the periphery of the cell and be entirely obscure. The stroma consists of narrow strands of connective tissue which provide support for the blood vessels. A thin capsular covering is usually evident. Grossly the yellowish, fatty consistency of lipomas of the chicken strongly suggests their true nature. Frozen sections stained with scarlet red provide convincing evidence of their lipomatous character.

Osteoma and osteogenic sarcoma. The rarity of these forms of connective tissue tumors among chickens has precluded our obtaining examples for study. Heim (1931) cited the report of one case of osteoma in the chicken. The brief descriptions which follow represent a study of tumors of bone from animals other than fowls. The structure of an osteoma simulates bone with the exception that much of the finer histologic detail is lacking. The process consists of a diffusely disposed acidophilic matrix of osseomucin separated at irregular intervals by collections of osteoblasts. Lamellae may be recognized, and the mimicry may include structures comparable to or suggestive of haversian canals. Osteogenic sarcomas are usually very cellular, infiltrative growths which destroy the surrounding tissues and readily metastasize. The immaturity of the cells is usually evident, and mitotic figures are commonly numerous. The cells may be spindle-shaped, ovoid, or polyhedral, and foreign body giant cells occasionally occur. Although an osteogenic tumor is usually a highly cellular and frequently a rapidly growing tumor in which immature or undifferentiated cells may constitute the bulk of the structure, a few to many cells usually can be found in which

sufficient differentiation has occurred to produce osseomucin. The finding of this substance, which has a homogeneous acidophilic appearance, is usually sufficient to reveal the true character of these tumors.

Cbondroma and chondrosarcoma. Only a few cases of simple chondrogenic tumors in chickens have been reported (Heim, 1931). It should be kept in mind that cartilage cells are the product of specialized fibroblasts of mesodermal origin, and in the early phases of their functional differentiation these cells have the appearance of ordinary mesenchymal cells. By a gradual process of transition, adult cartilage cells finally are evolved which produce chondromucin in addition to collagen and elastic fibrils. The adult cartilage cell is the end phase of the transition process and is not capable of the production of other cartilage cells. These must arise from certain fibroblasts that have the latent capacity to produce chondromucin. Chondroma, the benign form of these tumors, is characterized microscopically by a typical and unique structure. It consists of groups of two or more cartilage cells lying in a homogenous matrix of chondromucin. The tumor may be separated into lobular compartments by strands of fibrous connective tissue. The appearance of the rapidly growing or sarcomatous variety of cartilaginous tumor is more subject to variation than is that of the benign form. In the former all gradations in the development of the type cell from the most immature phase to the fully adult cartilage cell may be seen in a single microscopic field. The undifferentiated cells are spindle-shaped, while those in the zone nearer the adult or fully differentiated cartilage cells are polymorphic.

Although, as we have mentioned previously, simple chondrogenic or osteogenic tumors occur rarely in chickens, connective tissue tumors, usually of the malignant type, occasionally occur in which cartilage or bone or both may be present. In these instances tumors that are primarily and predominantly fibrosarcomas in structure have within them areas of chondrogenic or osteogenic tissue. Tumors may be found composed of immature fibroblastic connective tissue, cartilage, and bone. Such specimens may be designated fibrochondroosteosarcoma. Tumors composed of immature chondrogenic and osteogenic tissues also have been noted in chickens. The multipotency of the primitive fibroblast accounts for these unusual neoplastic combinations.

Histiocytic sarcoma. This type of connective tissue tumor was first described adequately and established as a definite neoplastic entity by Jackson (1936a). Those interested in the histogenesis of histiocytic sarcoma as exemplified by the so called Rous sarcoma should consult McGowan (1928), whose views are, in general, in agreement with those of Jackson (1936a). Jackson reported having encountered 14 cases among 203 cases of neoplasia of poultry.

Perek (1960) reported an outbreak of histiocytic sarcomas in a flock of 600 one-year-old hens. During a four-month period, 200 died and about 200 had to be slaughtered. Tumors of the liver were found in 90 per cent though the exact number examined was not stated. Five of six birds carefully examined in the laboratory had tumors of the liver and in some the spleen, kidney, and skin were affected. The tumor was transplanted through 59 passages and the agent was filterable. This was suspected of being an infectious granuloma but bacteriological examinations were negative.

In our series of 11 cases the ages of the birds varied from 35 days to 16 months, with 7 of them aged 1 year or less. While it would appear that histiocytic sarcoma may arise from almost any situation in the body, the ovary seems to be one of the sites of predilection. Other sites in which histiocytic sarcoma has occurred include esophagus, wattle, breast, pectoral muscle, subcutis, liver, and spleen. Campbell (1943) described a case primary in the kidney. Other organs, such as the lungs, gizzard, and heart, also have been involved.

but involvement of these organs and of the serous tissues of the abdomen probably represents secondary rather than primary manifestations of the neoplasm.

The gross appearance of histiocytic sarcomas is not diagnostically characteristic. Encapsulation does not occur. These tumors are invasive and extend into the surrounding tissues in a rather diffuse manner. Those that arise in the ovary may be expected to extend to the contiguous tissues, especially the serosa, and to fuse the intestines, mesentery, and pancreas into a single unit. One should keep in mind, however, that similar spread by implantation is rather characteristic of other types of malignant ovarian neoplasia. Distant metastasis of histiocytic sarcoma to the lungs may occur, and occasionally microscopic foci may be found in the kidneys. The metastatic growths in the lungs are often severe, and both lungs may appear as solid masses of neoplastic tissue. All histiocytic sarcomas are potentially malignant.

Microscopically, to the inexperienced, histiocytic sarcomas are likely to present a structure of confusing complexity. These tumors usually appear as a mixture of two or more types of cells that, while morphologically dissimilar, are in fact closely related histogenetically (Fig. 32.3). The cells that may be recognized are (1) spindle-shaped cells that usually appear in groups or bundles somewhat like the structure of simple fibrosarcoma; (2) stellate reticulum-producing cells (fixed histiocytes); and (3) large phagocytic cells or macrophages (free histiocytes), the latter usually showing evidence of their functional specificity. In addition, one usually can observe numerous transitional forms, of which many are polymorphic.

Foreign body giant cells are quite often present in regions where macrophages are numerous. In those instances in which the tumor has metastasized, there is usually present in the primary situation a greater number of spindle-shaped cells than there are macrophages or histiocytic forms. In metastatic foci the reverse is usually true, and macrophages and the primitive histiocytic forms predominate.

The microscopic diagnosis of histiocytic sarcoma is facilitated if the varied character of the type cell is kept in mind. The cellular constituents vary from spindle-shaped elements resembling fibroblasts to
FIG. 32.3 — Histiocytic sarcoma of the spleen. The varied character of the cellular constituents is shown. ×285.

FIG. 32.4 — Neurogenic sarcoma apparently arising from the dorsal root ganglion of the first thoracic spinal nerve.
stellate and polygonal elements of bizarre form. A mixed type of structure is often the most striking feature of the microscopic picture. The recognition of the various constituents comprising these so-called mixed tumors is sufficient to distinguish their true character.

Neurogenic sarcoma. Neoplasia of connective tissue elements of peripheral nerve trunks has been reported by Jackson (1936a), Olson and Bullis, (1942), and Duran-Reynals (1946a). Jackson observed such tumors as multiple nodules usually associated with the cutaneous nerves. Olson and Bullis described five cases. In two cases the tumor was single, and involved the ganglia of the dorsal root of the brachial nerve plexus (Fig. 32.4); in one case the tumor was found in two widely separated nerve trunks; and in the remaining two cases the lesions were not localized within the nerve but infiltrated the tissues adjacent to the affected nerves.

The minute structure of the tumors was quite similar and consisted of fibroblastic elements of low malignancy which showed a distinct tendency to assume a whorl-like arrangement, sometimes with fissures The histogenesis of these tumors is rather obscure, but it seems probable that they may originate from the fibrous sheath of the nerves.

Proper classification of these tumors is difficult. The whorl-like formations are similar to multiple neurofibromatosis of man, but, except for Jackson's case, the localization and invasiveness of these tumors are dissimilar from the characteristics of neurofibromatosis in human beings. A palisading of nuclei often noted in neurogenic sarcoma of human beings was not observed in any of the cases in chickens.

Metastasis and malignancy. Since the type cell of the benign and malignant forms of the connective tissue tumors is fundamentally the same, all of these tumors are potentially malignant. However, it is recognized that many grow slowly, never invade the surrounding tissues, and continue indefinitely as strictly localized processes. It is our impression that in chickens the benign forms of connective tissue neoplasms occur much less frequently than those that are malignant. The malignant forms are capable of widespread metastasis with secondary foci occurring in the visceral organs. The most striking metastatic manifestations are those of the lungs and of the intestinal serosa. In the histiocytic sarcoma there is some evidence that what may appear to be secondary foci of metastatic origin are in fact independent tumors arising as a result of a process that is systemic rather than local.

Diagnostic characteristics. The features that aid in the diagnosis of the connective tissue tumors are those associated with derivatives of the mesenchyme. The recognition of intercellular fibrils, reticulum, collagen, mucin, cartilage, or bone will suggest the connective tissue origin of these tumors.

TUMORS OF MUSCLE TISSUE

Two general classes of tumors of muscle tissue are recognized. Tumors of one class, known as rhabdomyoblastomas, are composed of muscle cells that have the inherent ability to produce within the cytoplasm both longitudinal and cross striations. Tumors of the other class, designated leiomyoblastomas, are composed of smooth muscle cells and their associated elements. Tumors of either class may be benign or malignant. The benign form of rhabdomyoblastoma is known as rhabdomyoma, the malignant form as rhabdomyosarcoma. Benign leiomyoblastomas are designated leiomyomas, while those that are malignant are known as leiomyosarcomas.

A review of the literature indicates definitely that rhabdomyoblastoma is among the rarer forms of neoplasms of chickens. So far as we know, only a few cases have been reported. Meyer (Feldman, 1932) reported a rhabdomyoma that arose in the skeletal musculature of the sternum of a chicken. The tumor was multiple and consisted of six separate masses measuring from 1 to 2 cm. in diameter. They were composed largely of striated muscle fibers, partially separated by strands of connective tissue. On account of the mixed character of the growth, Meyer designated the tumor "fibromyoma striocellulare." Another case of rhabdomyoblastoma was that reported by Peyron and Blier (1927). The tumor arose in the region of the hip joint of a rooster, grew slowly, and proved transplantable. Babic (1931) described rhabdomyomas of the pectoral muscle and submental region in a chicken. Olson and Bullis (1942) found two cases of neoplasia

which were diagnosed rhabdomyoma. In one bird the tumors were multiple with a peculiar bilateral symmetry of occurrence. In the other case a small tumor was found in the semitendinosus muscle with a secondary nodule on the intestine. In the remarks that follow, tumors of smooth muscle only are considered.

Frequency of occurrence. Tumors composed of the elements of smooth muscle are among the commoner neoplasms of chickens. In Jackson's (1936a, p. 432) series of 43 primary tumors of the female reproductive system, 15 were leiomyomas. Among 384 neoplasms of chickens encountered by Olson and Bullis (1942), 84 were leiomyomas. Nelson (1946) found 59 cases in a breeding flock of 1,108 hens, all of which were subjected to necropsy.

Sites of occurrence. Although leiomyoblastomas may arise from smooth muscle wherever the tissue occurs, the vast majority of the tumors occur in the ligament of the oviduct or in the oviduct proper. Other situations in which tumors of smooth muscle have occurred include the muscular walls of the large and small intestines, the mesentery, the gizzard, and the crop.

An unusual case was described by Jackson (1936a, p. 532) in which a mass weighing approximately 1 kg. and designated leiomyoma fibrosum involved the ovary. Multiple tumors of similar character affected also the ovarian bursa and the proctodeum. In another case mentioned by Jackson, a leiomyoma involved the ovary and the oviductal ligament.

Effects on the host. Most tumors composed of smooth muscle apparently grow slowly and require considerable time to attain sufficient size to interfere seriously with the normal functioning of the involved or adjacent tissues. Since these tumors are seldom invasive or destructive locally, the ultimate effect, if any, that they may exert on the host will depend largely on the amount of mechanical interference their presence may have on proper functioning of the involved parts. Those of the oviduct and of the broad

FIG. 32.5 — A relatively small leiomyoma in the mesosalpinx.
ligament could conceivably reduce or preclude egg production. Actually, Olson and Bullis found that 18 birds that had leiomyoma of the oviduct or the mesosalpinx were more than average in egg-laying ability. The interval between the last egg laid and necropsy varied from 1 to 75 days and averaged only 12 days. A causal relation between a long period of heavy egg production and development of leiomyoma of the mesosalpinx was suspected by Olson and Bullis. Nelson's (1946) data do not indicate a strong familial tendency for the disease. Leiomyomas of the intestines or other hollow organs might provide obstruction to the free passage of ingesta. If the tumor is malignant and secondary subserous implantations have occurred, ascites may develop.

Gross and microscopic description. Most leiomyoblastomas are smooth, elongated, ovoid, or irregularly spherical tumors. The benign forms usually are covered with a capsular structure that can be removed with difficulty. These tumors are resilient and of firm consistency. The size varies from 1 cm. or less to large masses several centimeters in diameter. They are flesh pink to grayish-white, and when they are cut across, the structure frequently appears distinctly fibrous. Although some specimens have a pedunculated form of attachment to the tissues from which they arise, in most instances these tumors are attached firmly by a rather broad base or over a considerable portion of their structures to the adjacent tissues (Fig. 32.5).

Microscopically, a typical leiomyoma presents a compactly knit structure composed of neoplastic smooth muscle cells. The degree of cellularity varies somewhat with the rate of growth, the cells being most numerous in those tumors in which the rate of growth is accelerated. Groups of cells usually are arranged in units of bundles which are disposed in every conceivable direction. The nuclei are ovoid or often elongated and contain a considerable amount of granular chromatin. The amount of connective tissue present between the respective bundles of muscle cells is subject to considerable variation. In some regions it is unrecognizable, while infrequently the fibrous elements may equal in amount the muscular tissue. Vascular channels are usually numerous.

In leiomyosarcoma the cells have the appearance of immaturity and are more numerous than in the slowly growing benign form. Cells undergoing mitosis are
FIG. 32.6 — Malignant leiomyoblastoma (leiomyosarcoma) of the oviduct of a 2-year-old hen. ×660.

seen frequently, and the invasive tendencies of the process usually can be distinguished (Fig. 32.6).

Metastasis. As mentioned previously, tumors composed of smooth muscle cells are seldom malignant, and consequently metastasis is observed infrequently. Should metastasis take place, the liver and the lungs are the most likely sites of secondary foci.

Diagnostic characteristics. Tumors that arise in intimate association with tissues or organs containing smooth muscle are likely to be leiomyoblastomas. This is especially true of tumors of the wall of the oviduct or of the ventral ligament. The presence of smooth muscle cells arranged in interlacing strands or bundles disposed in a divergent manner is fairly characteristic. In differentiating tumors of smooth muscle from certain connective tissue tumors, the van Gieson stain may be helpful.

TUMORS OF BLOOD AND LYMPH CHANNELS

General considerations. Neoplasia may arise from the elements of the blood and the lymph vessels. Tumors developing from neoplastic growth of blood vascular channels are called hemangiomas, and those from lymph channels, lymphangiomas. Different types of growth may occur. In some instances the newly formed vessels are small and capillarylike, and the terms "capillary hemangioma" and "capillary lymphangioma" are applicable. In other tumors the blood or lymph spaces are large, and "cavernous hemangioma" or "cavernous lymphangioma" is the appropriate term. The tumors may be benign or malignant. In some hemangioblastomas, particularly those which are malignant, parts of the cellular mass may not show any evidence of differentiation and may appear similar to a fibroblastic sarcoma. The general character of such tumors is revealed, however, by the more differentiated regions in which distinct vascular channels are formed. Such tumors require careful study for correct identification.

Jackson (1936a, pp. 17–18) pointed out the difficulties in connection with the term "endothelioma," which sometimes is used in connection with tumors of vascular channels. The lumen of both normal and neoplastic vascular channels is lined with specialized cells called endothelial cells. Whether these are derived from the same

source as the angioblast forming the vessel wall or have an independent origin is a moot question. While some tumors have been designated simply as endotheliomas, their exact character, except in certain cases, is extremely vague. Such a diagnosis might refer to a tumor of the lining cells of blood channels. It might refer to a tumor of the meninges of the brain or spinal cord. It might also refer to a tumor arising from the reticulo-endothelium which is disseminated so widely in all organs of the body that the existence of such a specialized tissue is not often recognized. In actual practice, the term "endothelioma" usually can be avoided by careful study of the material, which enables one to arrive at a proper classification. Thus, meningeal tumors of this type are properly a form of fibroblastic neoplasia. Those of the reticulo-endothelial system are more properly associated with neoplasia of the hemopoietic organs. A tumor of the endothelium of vessels would be extremely difficult to recognize unless there was sufficient differentiation to form capillaries, in which case the origin of the cells would be in question and, furthermore, the tumor probably would be recognized as a capillary hemangioma.

Blood vascular tumors. *Frequency of occurrence.* Tumors of blood vascular tissue appear to be relatively infrequent in the chicken as judged by reports in the literature. Heim (1931) found 5 cases in the literature he reviewed. These included 4 cases of multiple hemangioma reported by Schurman and Pauly. The tumors affected the skin, musculature, mesentery, serosa of the duodenum, kidney, lungs, and subcutis of the throat. Darcel and Franks (1953) suggest that the disease of the skin may be more common than generally realized since it is not often the cause of death and it may occur as a familial angiomatoid lesion. Babic (1931) described 4 cases of hemangioma in chickens. These involved the liver in 2 birds and the skin and subcutis of the head and the eyelid in another chicken. In the fourth case the tumor was a cavernous hemangioma on

the peritoneum. Babic also described an angiomatous nevus of the wing in a canary. Olson and Bullis (1942) found 5 instances of hemangioma in a collection of 384 tumors of chickens. Three were of the cavernous type, and 2 were capillary hemangiomas. Only 2 of the tumors were considered malignant. The liver was affected in 4 of the 5 cases, suggesting a predilection of the liver of the chicken for the development of hemangiomas. In 2 cases the tumor in the liver was so small that it easily might have been overlooked. Ball (1915) reported a hemangio-endothelioma of the iris in a 21-week-old pullet.

Gross and microscopic description. Hemangioblastomas are variable in appearance according to the type of tumor. The large cavernous form is characterized by greatly distended blood spaces whose lining is a thin wall of endothelial cells (Fig. 32.7). The distended blood spaces often protrude from the affected organ or tissue. Such tumors are typical in macroscopic appearance. Capillary hemangiomas may appear as solid masses of neoplastic tissue varying from gray-pink to red. Histologically, their character is apparent. Small capillaries containing blood are the essential features. All gradations between the cavernous and capillary forms may occur. Hemangiomas of the skin are often multiple and may involve the underlying musculature (Monlux and Delaplane, 1952), and Rigdon (1954) has reported spontaneous regression of such tumors.

Lymph vascular tumors. Tumors of the lymph vascular elements may possess the same histologic features as those of the blood vascular system, except that lymph instead of blood is contained within the spaces formed by the tumor cells. A few blood cells may be found occasionally in the lymph. Macroscopically, milky fluid (lymph) may be recognized in the cyst-like structures of cavernous lymphangioma.

Very few cases of lymphangioma have been described in the chicken. Heim (1931) mentioned one case of lymphangioma of the eyelid in a bird which was found by Teutschlaender. Babic (1931)

FIG. 32.7 — Cavernous hemangio-endothelioma of the mesentery. ×70.

described a lymphangiolipoma of the mesenteric serosa in a chicken. Olson and Bullis (1942) encountered one case of lymphangioma in which the tumor was a pedunculated mass attached to the ovary.

Telangiectasis. Telangiectasis may be considered as a benign form of hemangioblastoma in which a group of blood or lymph vessels becomes dilated with blood or lymph. The pathogenesis of telangiectasis is not known, and different authors have suggested that it is either a congenital or a hereditary disease or that it follows injury and repair to an organ in which the circulation has been disturbed (Ewing, 1928; Feldman, 1932). Telangiectasis may be multiple and capillary or cavernous.

TUMORS OF HEMOBLASTIC ORIGIN

Lymphocytoma. Definition and terminology. The neoplastic lymphocyte is the type cell of a common tumor of chickens to which the simple descriptive term of lymphocytoma may be applied. Many other terms have been given to this tumor. These include round-cell sarcoma, lymphadenoma, lymphocytomatosis, lymphomatosis, lymphatic leukosis, leukoblastic leukosis, leukemia, and others. The question of terminology is made somewhat

difficult because of the frequent association of lymphocytoma with fowl paralysis and fowl leukosis. This has come about as a result of experiments intended to demonstrate the transmissibility of these diseases. The relationship between lymphocytoma and fowl paralysis is an unsettled question since research has yielded conflicting results. The report by Davis and Doyle (1947a) provides a concise review of the literature on this question and shows the diverse conclusions reached from attempts at experimental transmission experiments. Sevoian et al. (1962) reported an isolate from a naturally affected chicken that caused neural, ocular, and visceral diseases. This isolate produced lymphomatosis in 90 to 100 per cent of inoculated chickens within two to three weeks. For the present, etiologic considerations should not be allowed any part in the nomenclature of these diseases. We have adopted the precept of dealing only with the pathologic anatomy in assigning names to these conditions.

Histogenesis. The lymphocyte is a most important cell in the animal organism and has many diverse physiologic functions. Our knowledge of these functions is far from complete. The lymphocyte is an integral part of the widespread reticuloendothelial system. It is normally an un-

stable cell and may assume many different forms. Jordan (1936) expressed the belief that the lymphocyte is a hemoblast capable of developing into any type of blood cell. According to him the large lymphocyte, as found in the circulating blood, represents a young cell with the foregoing potentialities. The small lymphocyte is a more mature adult cell which has lost or outgrown the ability to become transformed into other types. The factor or factors which govern and direct the transformation of lymphocytes into other cells are not well understood.

The histogenesis of lymphocytoma is likewise obscure. The orthodox concept of neoplasia that a tumor begins as a result of a cell or a localized focus of cells assuming a state of neoplasia does not seem applicable in the case of lymphocytoma. Lymphocytoma appears to be more of a systemic disease in which the lymphocytes in widely scattered regions become transformed simultaneously into neoplastic cells. This feature of lymphocytoma suggests the existence of a specific stimulus which, when applied to lymphocytes in a susceptible stage, causes them to become capable of the unrestricted growth characteristic of autonomous proliferation. Lymphocytoma is found more often in certain organs rich in lymphoid tissue than in others. Although it commonly affects the liver, gonad, kidney, and spleen, other organs likewise rich in lymphoid tissue, such as the marrow, bursa of Fabricius, and thymus, are affected less commonly. This fact suggests that the lymphoid tissue in the latter group of organs is in a functional state different from that in the organs first mentioned, rendering it less susceptible to the hypothetical stimulus for neoplasia.

Lucas and Oakburg (1950), upon studying the lymphoid tissue of the pancreas, suggested that 1 per cent lymphoid tissue in the pancreas be considered evidence for lymphomatosis. They calculated that birds of their experimental material required 33 days to develop grossly visible tumors and that 90 per cent of the time

was involved in developing the 1 per cent area of lymphoid tissue, after which the process developed rapidly. More recently, Lucas et al. (1954) extended this work to include the liver and spleen of chickens which received a presumed lymphomatosis agent. A similar reaction was found in the liver and spleen but was less sustained in the liver. These workers have developed an intriguing hypothesis in which they suggest that lymphoid foci develop in response to an agent and that the infective stage be considered "lymphomatosis"; when the lymphoid foci become neoplastic and grossly visible the condition is in the neoplastic stage and should be called lymphocytoma. The results of future research should confirm or deny this interesting hypothesis.

Structurally, three forms of lymphocytoma may be recognized. These are the diffuse, the nodular, and the combined diffuse and nodular forms. In the diffuse form the affected tissues are infiltrated diffusely with neoplastic lymphocytes which crowd and replace the parenchymatous tissues of the involved organs. The nodular form is characterized by a follicular arrangement of the tumor cells, which are confined by a more or less well-developed retaining wall of connective tissue, rich in reticulum. The third form of lymphocytoma is a combination of the diffuse and the nodular forms. In such cases a single organ may show both forms, or one organ may be affected with one form and other organs with the other form.

A possible explanation has been suggested for the existence of these diverse forms of lymphocytoma (Olson and Bullis, 1942) based on the hypothesis that they develop because of the inherent resistance on the part of the individual host to the growth of the tumor. Thus diffuse lymphocytoma develops in birds that have little resistance to the growth of the tumor, and nodular lymphocytoma develops in birds which are able to muster considerable resistance. The third form of combined diffuse and nodular lymphocytoma develops in birds that have only a moder-

ate degree of resistance to growth of the tumor. Evidence in support of this hypothesis is provided by several facts. Involvement of fewer organs and less extensive damage usually are noted in the nodular form of disease than in the diffuse form. Birds affected with the nodular form are often emaciated, suggesting a prolonged course, whereas the carcass in cases of the diffuse form is usually well nourished. The response of connective tissue in the nodular form suggests an attempt to limit the growth of the tumor.

Solution of the problem of the causation of lymphocytoma is an almost essential requirement for developing a sound conception of the histogenesis of the disease. For the present it may be said that lymphocytoma develops from lymphoid cells which are scattered widely throughout the body, but the stimulus or mechanism by which the cells become malignant is yet unknown.

Frequency. Lymphocytoma is without question the most common form of neoplasia affecting the domestic chicken. Olson and Bullis (1942) found 213 cases of lymphocytoma in a collection of 384 tumors, an incidence of 55.5 per cent. It has been recognized by poultry pathologists that lymphocytomas may be much more common in some flocks than in others. They may be as common as to constitute a serious economic problem in some flocks. Experimental results such as were reported by Hutt et al. (1941) suggest that the incidence of neoplasia can be controlled by selective breeding. Since they stated that "approximately 95 per cent of the deaths attributed to neoplasms were caused by lymphomatosis of one kind or another," it is inferred that by selective breeding lymphocytoma would be affected significantly. The exact effect of such a breeding program on the incidence of lymphocytoma alone is unfortunately not available, since suitable data on which to draw conclusions are not given.

A summary report of Hutt and Cole (1947) indicates a marked difference of incidence in the pathological manifestations classified by these workers as "neoplasms" in two lines of chickens selected for resistance and the susceptible line of chickens developed by them. While their classification of neoplasms includes all varieties of neoplasia and the so-called neural and ocular forms of lymphomatosis, the condition designated lymphocytoma is probably affected by such a breeding program since it is so commonly encountered in chickens. Another factor has been woven into the fabric of the thesis on "resistant" and "susceptible" strains. This is the question of exposure to the as yet undefined "agent of lymphomatosis" which was given impetus by the reports of Barber (1942, 1943) and considered as a factor in the work reported by Waters (1947). Waters (1945, 1954) believed transmission through the egg was indicated by data which he studied. Cole and Hutt (1951) came to the opposite conclusion. Burmester and Waters (1955, 1956) believe that hens which shed the agent in their eggs are important in creating a few "carrier" chicks which spread the disease to other chicks during the brooding period. There is also some evidence to suggest that parental immunity may also play a part in this process (Burmester et al., 1957).

The disease usually affects chickens less than a year old. Birds that had lymphocytoma in the series of cases studied by Olson and Bullis had an average age of about 8½ months. The youngest bird affected was 6 weeks old and the oldest was 2 years of age. It was formerly believed that males were affected about as often as females when one considered the disproportionate numbers of male and of female chickens in the general poultry population. The data of Olson and Bullis tend to suggest that the male is affected with lymphocytoma less commonly than is the female. Burmester (1915) reported that the incidence of lymphomatosis (presumed to include lymphocytoma, neurolymphomatosis, and the iritis commonly associated with neurolymphomatosis) was twice as great in female as compared to male

uninoculated chickens. Marine and Rosen (1910, 1941) noted a rather high incidence of lymphomatosis (which in most of their cases appears to be similar to lymphocytoma) in castrated male chickens. They suggested that an imbalance of hormones may have activated a latent tumor-producing agent in these birds. A higher incidence of lymphomatosis in castrated male chickens was also observed by Burmester and Nelson (1915) whose studies showed a similar effect on castrated females. They further reported that administration of a female sex hormone (diethylstilbestrol) lowered the incidence in capons but had no effect on intact males. Administration of a male sex hormone (testosterone propionate) seemed to lower the incidence of lymphomatosis in both males and females. Burmester and Nelson (1915) suggest that these hormones increase the resistance of the bird to lymphomatosis. Davis and Doyle (1947a) also reported a higher incidence of visceral lymphomatosis in females and capons than in intact male chickens.

Anatomic situation. Lymphocytoma may affect nearly every organ or tissue in the chicken, and in a given case usually more than one organ or tissue is affected.

In a series of 213 cases of lymphorytoma (Olson and Bullis, 1942) there were only 31 instances in which the disease was confined to a single organ or tissue. The liver, spleen, kidney, and gonad were the organs most commonly found to be affected. Nineteen different organs or tissues, exclusive of nerves and the circulating blood, were found to be involved with the disease. In this series the different combinations of organs or tissues that might be affected with lymphocytoma were studied. The great variation of the manner in which lymphocytoma may express itself is indicated by the fact that 152 different combinations were found. The more frequent of these combinations were as follows: ovary alone (10 cases); liver, spleen, kidney, gonad, and marrow (7 cases); liver, spleen, and kidney (7 cases); liver and spleen (5 cases); peritoneum alone (5

cases). The histologic form of the disease appears to be a determining factor with respect to the number of organs or tissues involved. The diffuse and the combined nodular and diffuse forms tend to be more widespread and affect more organs than does the nodular form.

In view of the tendency of lymphorytoma to become widely disseminated, it is logical to assume that nerve tissue may be affected with the disease. In 83 of the 213 cases of lymphocytoma studied by Olson and Bullis (1942), deposits of neoplastic lymphoid tissue were found in the peripheral nerves. The amount of tumor tissue varied from a localized, lightly infiltrated region to complete replacement of the nerve tissue and marked enlargement of the affected nerve. The presence of such deposits of lymphoid tissue associated with peripheral nerves raises the question whether they represent foci of lymphocytoma or are an expression of the disease known as fowl paralysis. The lesions of the nerves in fowl paralysis have been described as either inflammatory or neoplastic. When inflammatory, the lesions consist of polyblastic infiltration (lymphocytes, histiocytes, and plasma cells) often associated with the proliferation of the cells of the sheath of Schwann and degeneration of neurons in the ganglia. The neoplastic lesions differ from the inflammatory lesions in that the infiltrating lymphoid cells have a definitely neoplastic character, are multiplying actively, and may be so aggressive as to replace almost entirely the nerve elements within the sheath. The neoplastic process may penetrate the nerve sheath and infiltrate the adjacent surrounding tissue. Separation of the lesions into two such groups is complicated by those cases in which both types of lesions are found. Wight (1962) classified three histological types of lesions in 100 cases of fowl paralysis. Marked neoplastic changes were present in only 11 cases. Edema was the predominant change in affected nerves of an inbred stock of Brown Leghorns and infiltration with lymphocyte and plasma cells

the principal change in cases from several other sources.

Involvement of the nerves in some cases of lymphocytoma is obviously due to the penetration of the nerve sheath from without by neoplastic lymphoid tissue. However, those instances of lymphocytoma in which neoplastic lymphoid tissue is found in nerves at a site removed from other tissues affected with lymphocytoma constitute a difficult problem in interpretation. They may represent metastasis of the tumor from a primary focus situated elsewhere. The tumors may have developed in the nerve in response to a hypothetical causative agent of lymphocytoma. They may be lesions of fowl paralysis existing coincidentally with lymphocytoma. On the other hand, one may assume that a single agent is responsible for both fowl paralysis and lymphocytoma and that the type of response to the agent depends on factors as yet unknown. A final solution of this question must await the solution of the problem of causation.

Effects on the host. Lymphocytoma is usually considered to be a fatal disease. While this may be generally true, an affected bird may recover. In our material two such cases have been noted in which the birds had multiple tumors of the skin. Diagnosis of the disease was made by biopsy and histologic examination of representative cutaneous lesions. The birds were held under observation for several weeks, and the remaining tumors of the skin disappeared. A similar regression of a tumor in a visceral organ can occur. Davis and Doyle (1947b) have reported a study of monthly liver biopsies on 96 chickens done over a 10-month period. Some of the birds had been inoculated with material from a case of spontaneous visceral lymphomatosis, and others were uninoculated controls. These interesting data showed that fatal cases of the disease developed very rapidly. For example, biopsy material was normal in birds that died with lymphomatosis 3 to 4 weeks after biopsy. In some instances, lesions of the liver characteristic of lymphomatosis

were observed in biopsy material, and the lesions later disappeared, indicating recovery from the disease. St. Louis encephalitis virus has an oncolytic action on a transplantable lymphoid tumor in which the agent can multiply in the tumor but does not destroy cells. Changes do occur which are believed either to render the cells more susceptible to phagocytosis or to increase their ability to stimulate the defense mechanism of the host (Love and Sharpless, 1954).

There are no specific or pathognomonic symptoms displayed by birds affected with lymphocytoma. In many instances birds under relatively close observation may die from the disease without indication of ill health. In most cases, signs of a general disturbance of physical health are evident for a variable period preceding death. These signs are listlessness, inappetence, ruffling of the feathers, and general depression. An affected bird is often first noted to be standing in droopy attitude with its eyes closed and with an intermittent shaking of the head as though the sensorium were befogged. The location of the lesions may provoke distinctive signs referable to their situation. For example, tumors of the skin or musculature cause localized swelling. Involvement of the digestive tract may cause either diarrhea or obstipation, and involvement of a nerve may cause paralysis of the part supplied by the nerve. Palpation of the abdomen may reveal displacement of the viscera due to an enlarged liver. Emaciation will develop in cases of long standing, which are usually due to the nodular form of lymphocytoma.

Olson and Bullis (1942) obtained data on the egg production of 15 birds that died of lymphocytoma. These birds were considered average to slightly better than average producers of eggs. The rather rapid course of lymphocytoma is suggested by the finding of a relatively short interval between cessation of egg production and the death of the birds. This period averaged 38 days and varied from 4 to 73 days.

Olson and Dukes (1938) found that

the basal metabolic rates of two chickens affected with lymphocytoma were greatly increased over the normal level. In this respect these cases of lymphocytoma of the chicken were similar to neoplastic diseases of the lymphoid cell system as encountered in human beings. The rate of basal metabolism should be studied in more cases of the disease, and if it is found that an increase is a constant feature, the result might possibly explain the rapid wasting and emaciation associated with the more chronic form of lymphocytoma.

Gross and microscopic description. Organs or tissues affected with lymphocytoma have a gross appearance which varies with the extent of infiltration and the character of the process. Organs, which on gross examination appear normal, may contain neoplastic foci when examined microscopically. The characteristic color of neoplastic lymphoid tissue is gray-white, and the tissue may have a red tint in the more highly vascular areas. Necrosis of the tumor substance is not observed commonly but may develop in regions of the tumor in which the blood supply has been reduced by occlusion of the vessels either from pressure or from the infiltrative growth of the neoplasm.

As mentioned previously, the growth may be diffuse or nodular or a combination of the two. In diffuse lymphocytoma the affected organs are enlarged uniformly, and the color of the organs may change until it resembles the gray-white of the tumor. The extent of enlargement and the degree of change of color depend on the amount of tumor tissue present. Organs severely affected and in which there is much replacement of the parenchyma are quite soft. In nodular lymphocytoma the neoplastic tissue has a well-developed supporting framework of connective tissue which adds much to the firmness of the tumor. Affected organs contain nodular gray-white masses whose margins are discrete and sharply defined. The nodules may almost completely replace the parenchyma of an organ, reducing the latter to narrow bands compressed between the masses of tumor (Fig. 32.8). In some cases of nodular lymphocytoma, the tumor may be distributed throughout the affected organ and resemble the diffuse form of the disease. Such cases can be recognized by the firmer consistency of the tumor and its histologic appearance. Fairly frequently the tumor may erode the walls of the blood vessels and cause hemorrhage. Fatal hemorrhage into the peritoneal cavity may occur from

FIG. 32.8 — Lymphocytoma; nodular type, showing multiple lesions in the liver.
FIG. 32.9 — Nodular type of lymphocytoma, liver of a chicken. The multiple aggregates of neoplastic cells have characteristically replaced most of the parenchyma, leaving thin strands of hepatic cells and vascular channels. ×25.

rupture of the taut capsule of organs greatly enlarged from growth of the neoplasms. Such hemorrhages are noted most often from the liver and spleen.

Microscopically, the tumor consists of masses of proliferating neoplastic lymphoid cells situated extravascularly (Fig. 32.9). The foci of cells tend to develop most rapidly in the immediate vicinity of blood vessels. The cells of the tumor are quite uniform and comparable in size to the large lymphocyte or monocyte of the circulating blood. They tend to be spherical, although in the denser parts of the tumor they are so compact that the shape either cannot be distinguished or is distorted. The cytoplasm is relatively scant, is without specific granulation, and stains faintly blue with hematoxylin and eosin. The nucleus is relatively large and has a vesicular appearance. The chromatin is arranged as an irregular band at the nuclear margin and in small clumps in the nucleoplasm. One or two distinct nucleoli are usually present. Mitotic figures are commonly found. A fine meshwork of reticulum enclosing small groups of tumor cells can be demonstrated by appropriate histologic procedures.

In the diffuse form of lymphocytoma, the infiltration of the tumor between the parenchymatous cells of an affected organ appears to proceed without the slightest restraint. As the disease progresses, the tumor cells destroy and replace the normal cells of the organ. This process may continue until the affected organ is almost completely converted into a solid mass of tumorous tissue.

In nodular lymphocytoma a marked response of connective tissue accompanies the proliferation of neoplastic lymphoid cells. The connective tissue surrounds and isolates clumps of tumor cells, forming a sort of capsular wall. These foci of tumor cells may be small and isolated, but more often they are contiguous to other such foci. Sometimes several such foci seem to merge with one another, forming larger masses surrounded by a thicker wall of connective tissue. The fibroblastic components of the connective tissue wall are not anaplastic and would seem to be the response of the host attempting to delimit the growth of the tumor rather than a part of the tumor itself. Cases of lymphocytoma occur in which both the nodular and the diffuse form of the disease may be found in either the same organ or different organs of the same animal.

Occasionally, the cells of lymphocytoma

may either erode or infiltrate into the lumina of blood vessels and thereby enter the circulation in numbers sufficient to be mistaken for a leukemic state, but this process is distinctly different from that leading to true leukemia. It should be regarded rather as an embolic phenomenon.

In addition to such emboli of tumor cells, changes of the blood picture may be found occasionally in lymphocytoma. These are of a secondary nature. Foci of lymphocytoma are found fairly frequently in the bone marrow where they may disrupt normal hemopoiesis by mechanical means. For example, they may replace sufficient myeloid tissue to lead to a state of insufficiency, causing anemia and leukopenia. They may also mechanically dislodge unripe cells from the marrow, forcing them into the circulation.

The cellular changes of the circulating blood in birds suffering from lymphocytoma have not received adequate attention. Part of this neglect is due to the difficulty of detecting cases sufficiently early so that the changes might be studied during the development of the disease. Several authors have made blood smear examinations of such cases at varying intervals preceding death, but their main objective was a search for pathologic cells in the blood rather than a study of variations of the cells normally present.

A fairly complete study was made of the blood in one of our cases, a lymphoid tumor which later was demonstrated to be transplantable (Olson, 1941). Although in this case the tumor has not been designated as lymphocytoma because of its transplantable nature, other features are such as would cause it to be considered as a lymphocytoma. These changes in the blood were observed during the 25-day period preceding death of the bird and may be summarized briefly as follows: Erythrocytes, hemoglobin, thrombocytes, eosinophils, and basophils were only slightly affected. The number of heterophils, lymphocytes, and monocytes fluctuated widely and approached normal levels only near the terminal stage of the dis-

ease. The severity of the involvement of the bone marrow did not seem sufficient to explain the variations observed. It seems probable that the disease in this instance was associated with the production of noxious materials which were responsible for the increase of the numbers of heterophils, lymphocytes, and monocytes.

Extension. The aggressive nature of lymphocytoma is revealed in many cases by the extensive lesions in markedly enlarged organs. As stated previously in the section on histogenesis, lymphocytoma is probably a systemic disease in which the process is initiated in several sites at the same time. Extension of the disease by direct spread from one tissue to another is illustrated by those cases in which the peritoneum is involved. The peritoneum may become affected by extension of the disease from the ovary, and the intestine may be involved in turn from the previously affected peritoneum. Further examples of such extension of the disease require only examination and study of material that comes to necropsy. Although emboli of tumor cells may be demonstrable in the blood vessels, acceptable evidence of true metastasis is difficult to obtain.

In this connection it is pertinent to mention a few unsuccessful attempts at autoplastic transplantation of lymphocytoma. In these experiments (Olson and Dukes, 1938) bits of skin tumor were transplanted into the subcutis and musculature of the birds from which the tissue was obtained for biopsy. Although only a few trials were made, in each case the implants failed to develop despite continued growth of the original skin tumors. Failure of such autotransplants may be due to concomitant immunity such as displayed by a transplantable lymphoid tumor in which the immunity developed 10 to 15 days after the initial graft protected the bird against subsequent grafts even though the original graft continued to grow (Olson, 1915). These experiments bear on the question of metastasis for they suggest that metastasis may be of rare occurrence in lymphocytoma. This would

lead to the conception that extension of the disease is largely a matter of direct spread from one organ or tissue to another rather than of circulatory metastasis.

Diagnostic characteristics. With an adequate knowledge of the fundamental pathologic changes, it is usually a relatively simple task to differentiate lymphocytoma from other diseases. Myelocytoma, leukosis, fibrosarcoma, epithelioblastoma, and some types of granulomatous processes are conditions which should be considered in arriving at a differential diagnosis of lymphocytoma. General features which may serve as a guide in distinguishing between these diseases are set forth in Table 32.3. Other less common tumors may cause confusion in the differential diagnosis of lymphocytoma; histiocytic sarcoma is a good example.

Special features. In the older literature, one will encounter the term "round cell sarcoma" with surprising regularity. While such a term is descriptive of the shape of cells found in such cases, it does not give any information on the histogenesis of the tumor. Heim (1931) made a thorough review of the literature on neoplasia of the chicken and, in addition to discussing "round cell sarcoma" of the connective tissue, devoted another section of his report to "round cell tumors of unknown genesis." This latter group was subdivided further into a "large celled" form and a "small celled" form. No doubt examples of what we today call lymphocytoma were included in both categories, as well as histiocytic sarcoma and perhaps other types of tumor.

The relation between spontaneous lymphocytoma and experimentally transmissible neoplasms of lymphoid cells is not well understood. Furth (1935) expressed the belief that the disease produced by the "Strain 2" tumor-producing agent studied by him is rare in a spontaneous disease of chickens and dissimilar from the commonly occurring lymphocytoma. Both Pentimalli (1941) and Olson (1941) have found a spontaneous lymphoid tumor that was transplantable to experimen-

tal chickens. The original cases of both possessed features which would permit them to be classified as lymphocytoma, and the principal reason for not doing so was that transplantability had not been demonstrated as a characteristic feature of lymphocytoma (Olson, 1940, 1942, 1947; Engelbreth-Holm, 1942; Duran-Reynals, 1946b).

Burmester and Prickett (1945) described strains of transplantable lymphoid tumors similar and apparently immunologically related (Burmester and Belding, 1947) to the lymphoid tumor reported by Olson (1941). Burmester (1947) reports variation in the reaction of chickens to cell-free material from birds bearing different transplantable strains of lymphoid tumor. Brewer and Brownstein (1946) state that "lymphomatous" liver and spleen material from several birds produced visceral lymphomatosis in young chicks. Details are given on only one strain which was infective with fresh affected tissues by feeding and simultaneous instillation in the eye and nose as well as subcutaneous inoculation. This tumor does not appear to be characterized by a definite rate of growth. Davis and Doyle (1947a) describe transmission of visceral lymphomatosis with a slower rate of growth than that observed with the lymphoid tumor by Olson. These transplantable lymphoid tumors and cases of visceral lymphomatosis had no predilection for growth in nerve tissue.

Burmester et al. (1947, 1957) reported that visceral lymphomatosis and osteopetrosis could be induced in chickens by filtered material from a lymphoid tumor (RPL 12) which, when maintained by tissue transplantation, caused only lymphoid tumors (Olson, 1941). Similar results were obtained with filtrates from some, but not all, of the transmissible lymphomatous tumors originating in chickens of the laboratory flock (Burmester, 1947). In addition, visceral lymphomatosis occurred in chickens which received cell-free inoculums prepared from normal-appearing liver of embryonating

TABLE 32.3

COMPARISON OF LYMPHOCYTOMA WITH OTHER DISEASES

	Lymphocytoma	Myelomatoma	Leukemia	Fibrosarcoma	Epithelioblastoma	Granuloma
Age (average)	9 months	9 months	11 months	10 months	12 months or more	Any age
Frequency	Common	Uncommon	Uncommon	Uncommon	Rare	Common
Course	Acute	Acute	Protracted	Variable	Variable	Variable
Location	Liver, gonad, kidney, and other tissues	Peritoneum, liver, spleen, gonad, marrow, and other tissues	Bone marrow, liver, spleen, kidney. Recent hemorrhages may be present in fascia and intestinal mucosa	Any organ	Any epithelial tissue	Any tissue
Extent	Widespread or limited	Widespread or limited	Limited	Limited	Limited	Limited
Character	Nodular or diffuse	Diffuse	Diffuse	Localized	Localized	Localized
Texture	Soft or firm	Soft	Soft	Quite firm	Quite firm	Soft or firm
Color	Gray-white	Dull white	Organs pale	Gray-yellow	Not consistent	Yellow (necrosis common)
Blood	Usually normal, may show anemia, sometimes embolism of tumor cells	Anemia, myelocytes in circulation	Severe anemia, immature blood cells	Essentially normal	Normal	Sometimes leukocytosis
Histologic characteristics	Extravascular infiltration with neoplastic lymphocytes	Extravascular infiltration of neoplastic myelocytes. Tumor cells may appear in blood stream	Intravascular collections of neoplastic unripe blood cells	Infiltration with neoplastic fibroblasts	Masses of neoplastic cells of epithelial origin	Inflammatory reaction
Causative factors	Probably filterable agents	Unknown	Filterable agent	Unknown and filterable agents	Unknown	Trauma, pathogenic bacteria, fungi, parasites, degenerative processes

eggs, incubator debris, washings from the oral cavity and respiratory tract, and extracts of feces obtained from chickens of the laboratory flock (Burmester *et al.*, 1955; Burmester and Waters, 1955; Burmester, 1956). The disease also developed in chickens reared in direct contact with penmates that had been inoculated with the filtered material from Strain RPL 12. Burmester (1952) recognized several pathologic entities in the inoculated chickens. One response was death from visceral lymphomatosis, after a latent period of more than 3 to 4 months, characterized by an extravascular accumulation of neoplastic lymphoid elements in one or more visceral organs. Another response was the *occurrence of an intravascular process* with features resembling erythroblastic leukosis, and a few chickens had in addition fibrosarcomas and hemangioendotheliomas (Burmester, 1952). The intravascular process became more common after the causative agent or agents had been propagated in chickens for several generations as cell-free material, and now Burmester *et al.* (1959) recognize the process as erythroblastic leukosis. Olson and Rountree (1957) inoculated chickens with filtrate of Strain RPL 12 (obtained from Burmester) and only erythroblastic leukosis developed in the 15 weeks of the experiment. In addition, osteopetrosis occurred in chickens designated Line 15, obtained from Burmester, but not in an unrelated stock also in the experiment. The erythroblastic leukosis was characterized by neoplasia of the more immature red cells in the sinusoids of the marrow with leukostasis in the liver and spleen. Anemia was not marked, and death was probably the result of hepatic insufficiency. Burmester and Gentry (1956) reported that large doses of cell-free lymphomatosis material resulted in a high proportion of the intravascular syndrome (erythroblastic leukosis) which caused death early; whereas, low doses resulted in a high proportion of the extravascular lymphomatosis with death generally occurring after 4 months. It was suggested (Burmester,

1952) that the former may be the acute and the latter the chronic expression of the same disease, although the possibility that they were caused by different viruses was also pointed out. Burmester and Walter (1961) obtained some cases of visceral lymphomatosis in their Line 15 I chickens inoculated with Rous sarcoma virus indicating its relation to the disease. Rubin and Vogt (1962) obtained an avian leukosis virus from stocks of Rous sarcoma virus which interferes with infection and clone formation of Rous virus in tissue cultures.

The association of spontaneous lymphocytoma with fowl paralysis is a feature still deserving of special attention. Some comments concerning this question have been made in this section, and other comments may be found in the chapter entitled "The Avian Leukosis Complex."

Myelocytoma. The term "myelocytoma" was first applied to this disease by Pentimalli (1915) who described two cases. Ellermann (1920) recognized the condition in the course of his work with leukosis and called the disease aleukemic myelosis. Mathews (1929b) gave an excellent description of the disease under the term "leukochloroma." Since the myelocyte is *the type cell of the tumor, the term* "myelocytoma" seems fitting. Myelocytoma is a neoplastic disease of myelocytes and *may affect almost any tissue in the body.*

Histogenesis. The myelocyte may be recognized readily as the type cell of myelocytoma, but the source of the tumor cells is an unsettled question. Cells which are morphologically similar to those of myelocytoma *may be found in the bone marrow* and in foci of extramedullary myelopoiesis of normal chickens. These represent normal metamyelocytes and myelocytes, which are immature acidophilic granulocytes. Two types of acidophilic granulocytes are found in the blood and the hemopoietic organs of the chicken. The more numerous are called heterophilic leukocytes and fulfill a function similar to that of heterophilic or neutrophilic leukocytes of mammals. The other type is the true eosinophilic leukocyte of

mammals. Although ordinarily the adult heterophilic leukocyte of the chicken contains in its cytoplasm spindle-shaped acidophilic granules, the same granules are spherical at certain stages of their development. The granules of the eosinophilic leukocyte are likewise spherical in the early stages of their development and remain so in the adult cell. Thus it is obvious that while the two types of leukocytes may be differentiated readily by the shape of the granules when adult in form, there are no reliable criteria for distinguishing between these cells in their immature stages of development. Although there are other features by which the two forms of adult cells may be separated, these features do not become apparent except in the later stages of development and are lacking in the type cell of myelocytoma.

During embryonal life, the mesenchyme in parts of the body other than the bone marrow acts as a hemopoietic tissue. This function subsides and at the time of hatching and afterward is almost entirely taken over by the bone marrow. The ability of tissue other than bone marrow to produce myelocytes is not entirely lost in postnatal existence. Foci of such cells developing in the periportal regions of the liver and in the thymus are encountered fairly frequently. The cells of a myelocytoma may arise from any or all of these potential sources.

The tendency for myelocytoma to involve many tissues or organs makes it difficult to determine whether the disease arises from a single primary focus or is an expression of a systemic disturbance. Mathews expressed the opinion that the disease was primary in the bone marrow and metastasized from there to the other sites in which the tumor was found. This opinion is hardly tenable in view of the possibility for the origin of myelocytoma in other tissues where a potential source of myelocytes exists.

Frequency. Mathews (1929b) mentioned two flocks of chickens in which myelocytoma appeared as an enzootic. In one flock the losses from the disease were estimated to be 20 per cent and in the other flock 10 per cent. Although the flocks were small and not all birds that died were examined, this tendency of myelocytoma was well illustrated. Usually, however, myelocytoma is a sporadic disease in a flock. Thirty-six of the cases collected by Mathews were found during necropsy of 3,938 birds, an incidence of 0.91 per cent. Olson and Bullis (1942) found 17 cases of the disease during the examination of 2,304 birds, an incidence of 0.74 per cent.

The age of birds affected with myelocytoma is usually less than 1 year. Mathews (1929b) found most of his cases during the winter months of November, December, and January but expressed the belief that the factor of age was responsible for this apparent seasonal effect. Olson and Bullis (1942) found the incidence of myelocytoma in each of the 4 quarters of the year to be the same when the factor of age was considered.

Mathews noted the disease to be common in chickens of the Barred Plymouth Rock breed. The data of Olson and Bullis suggest a greater frequency of myelocytoma in Barred Plymouth Rock chickens than in Rhode Island Red birds.

Anatomic situations. Study of the distribution of lesions of myelocytoma indicates that nearly any tissue or organ of the body may be affected with the tumor. A notable feature is the tendency for myelocytomas to develop on the surface of bones in intimate association with the periosteum. These may be sheetlike or nodular masses and frequently assume a peculiar, bilaterally symmetrical aspect. Such bilaterally symmetrical deposits often are found affecting the periosteum of the ventral portion of the keel bone and of the ribs. There seems to be a predisposition for the tumor to collect near cartilage at the costochondral junctions of the ribs and about the annular cartilaginous rings of the trachea. In some cases the tumor is disposed irregularly about the bodies of the vertebrae, especially in the lumbo-sacral region. Oberling and Guérin

(1934b) described four such cases. Mathews found similar cases in which the tumor had infiltrated the bone, caused pressure on the spinal cord, and led to paralytic symptoms of transverse myelitis. Although myelocytoma tends to develop on the surface of the keel bones, ribs, vertebrae, and sometimes the flat bones of the skull, a similar involvement of the long bones of the legs and wings is infrequent.

The liver, spleen, ovary, and bone marrow, in addition to subperiosteal tissues, are affected with the neoplasm in most cases. Other organs and tissues are involved less frequently, although there is perhaps no tissue or organ which may be regarded as resistant to invasion by the tumor.

Effects on the host. Chickens coming to necropsy with myelocytoma are usually in a fair state of nutrition, suggesting either that the course of the disease is relatively rapid or that the disease has but little effect on the host. The former would appear more logical since the tumor itself has a distinctly malignant character and appears capable of rapid growth. In a few cases in which data on egg production were available, the period between cessation of egg production and death was short (average of 21 days in three cases). Mathews mentioned that the clinical symptoms of a slight indisposition observed in most cases did not exist for more than a week preceding death and that sudden death without noticeable symptoms sometimes occurred. Mathews also observed symptoms of transverse myelitis in two cases.

Relatively rare cases occur in which the tumor masses can be detected on examination of the exterior of the bird either about the head or about the sternum.

Gross and microscopic description. Myelocytoma has a characteristic appearance which is not likely to be confused with that of any other neoplastic tissue. The color is dull white. The tissue is soft and tends to be somewhat friable. In some instances the vascular bed of the tumor masses may be congested, contributing a distinct pink cast to the color. An irregular infiltrative growth is typical of myelocytoma, and while localized masses may be found near bones, the growth in organs, as the liver, spleen, kidney, and lung, is usually diffuse. The liver, spleen, and kidneys, when affected with myelocytoma, become enlarged. However, the hypertrophy of these organs is not as marked as is commonly true in lymphocytoma.

The lesions of myelocytoma consist of infiltration with monotonously unvarying myelocytes. These cells, as previously mentioned, are similar to normal myelocytes found in the bone marrow and ectopic foci of myelopoiesis. Their nuclei are large, vesicular, and usually eccentric in position and tend to be round or oval in outline, although often their shape is distorted by compression. A distinct nucleolus is commonly present. The cytoplasm is filled with acidophilic granules so tightly packed that their shape cannot often be distinguished, and although the granules are usually spherical, spindle-shaped granules may be noted in some cells. Imprint preparations made by touching a glass slide to the cut surface of fresh tumor material can be stained with a polychrome blood stain after drying in the air. Such a preparation may be compared with similar ones made of the blood or bone marrow. With such a stain the large nuclei have a very fine arrangement of the chromatin and parachromatin, and the cytoplasmic granules, while predominantly acidophilic, are occasionally basic in reaction. These basic-staining granules represent a pre-acidophilic stage and later become acidophilic.

The myeloid tissue of the bone marrow becomes converted into a mass of tissue indistinguishable from foci of the tumor situated elsewhere. From the structure, it must be considered as a neoplastic process in the marrow. The involvement of the bone marrow appears to be a constant feature and may occur in every case of myelocytoma. Mathews (1929b) and Olson and Bullis (1942) found the condition

to exist in every case examined. In this respect, marked similarity exists between myelocytoma and granuloblastic leukosis. What appears to be a fundamental difference is that the neoplastic cells of myelocytoma are of a relatively later stage of development than those of granuloblastic leukosis. A careful comparative study of the minute structure of the bone marrow in myelocytoma and in leukosis will reveal this difference.

Fairly frequently, abnormal myelocytes gain access to the blood stream. The morphologic characteristics of these cells are similar to those of the cells in the extravascular foci of tumor. A distinct increase of the number of heterophils in the blood may be noted also. Probably the extent of involvement of the blood will vary during the course of the disease, although this aspect has not been studied carefully.

Metastasis and spread. Although Mathews expressed the belief that myelocytoma is a primary tumor of the myeloid elements in the bone marrow, there are other reasons, as mentioned previously, to suggest that myelocytoma may develop simultaneously in several widely scattered regions. The possibilities for such development have been mentioned under the heading of histogenesis. When the process is once initiated, further development is infiltrative. Nerves, muscle, and bone may be invaded by the infiltrative growth of the tumor. Cartilage alone seems to be capable of resisting growth of the tumor, and this phenomenon may be studied readily when the trachea is involved. The presence of tumor cells in the general circulation provides a means of dissemination of the tumor; however, the importance of metastasis in the disease cannot be estimated.

Special feature. Mathews made unsuccessful attempts to transmit spontaneous myelocytoma. The Strain 2 agent developed by Furth (1933) has caused a neoplasticlike process, which he refers to as myelocytomatosis, in addition to lymphomatosis and endothelioma. The relation between this experimentally produced

disease and spontaneous myelocytoma is not known. Nyfeldt (1934) reported development of a strain of leukosis in which leukemic myeloblastosis (granuloblastic leukosis) was the predominant type, although a few cases of aleukemic myeloblastosis (myelocytoma?) were also found in experimentally inoculated chickens. The occasional finding of myelocytoma as an enzootic in a given flock suggests the possibility of a common factor or factors as responsible for such an outbreak. For the present very little information is available on this point.

Diagnostic characteristics. Only brief comment is necessary to re-emphasize the comparative ease of recognizing myelocytoma. The color of the tumor and the distribution of lesions are features so characteristic of the disease that most cases of myelocytoma can be identified on macroscopic examination (Table 32.5).

Fowl leukosis. The term "leukosis" has been used with a wide variety of interpretations in connection with avian diseases. It is used in this section in a restricted sense to indicate the single entity briefly characterized in the following paragraph. Other applications of the terms "leukosis" and "leukoses" are noted in Chapter 19.

Fowl leukosis is a disease of the myeloid tissues in which the precursors of erythrocytes and granulocytes are stimulated to unrestricted multiplication. The apparently functionless autonomous growth of myeloid tissues serves to characterize fowl leukosis as a neoplastic disease. The neoplastic character of the immature blood cells is also illustrated by their tendency to become immobilized within the vascular bed of certain organs such as the liver, spleen, and kidney. In these situations they display proliferative growth outside the confines of the bone marrow where under normal conditions they would ripen into mature blood cells before being released into the circulation. The tendency for immobilization has been called leukostasis.

A thorough review of the extensive literature on fowl leukosis is beyond the scope of this section. Such a review was

made in 1940 by Olson and brought up to date by Darcel (1957). The morbid anatomy of naturally acquired fowl leukosis is not different from that produced experimentally. In fact, much of our knowledge of this hemoblastic neoplasm has been gained from study of the experimentally produced forms of the disease.

Histogenesis. A consideration of the histogenesis of fowl leukosis must be based largely on evidence obtained from various experiments dealing with the transmissible forms of the disease. The stimulus responsible for the development of this condition is an ultramicroscopic agent present in the tissues of affected birds. Such an agent was demonstrated first by Ellermann and Bang in 1908. The agent of fowl leukosis can be demonstrated in a spontaneous case of the disease only by reproduction of fowl leukosis in other birds following the experimental introduction of the causative agent.

Although much work has been done with fowl leukosis, the site of inception and the mode of action of the causative agent remain unsettled. A review of the literature has revealed many facts and opinions with regard to the pathogenesis of this malady. Not all strains of the agent are similar. Some appear restricted in action and cause only one form of disease (such as erythroblastic leukosis); some may cause both erythroblastic and granuloblastic leukosis; and some may cause leukosis and fibrosarcoma. The production of either erythroblastic or granuloblastic leukosis by a single agent is not difficult to harmonize with the hypothesis that the agent may attack a stem cell (hemocytoblast) common to both cell lineages. The form of disease which develops apparently depends on either the reactivity potential of the affected stem cell or the ability of the agent to influence the line of differentiation of the stem cell. Extensive studies on leukosis agents producing myeloblastosis and erythroblastosis have led Beard and his co-workers (1956, 1957) to conclude that these agents are distinct though closely related biological entities.

The complexity of the situation is illustrated by a report of Atanasiu (1952) working with the presumed pure strain SK of Engelbreth-Holm in chicken embryos. Most of 556 intravenously inoculated embryos developed erythroblastic leukosis. In addition there were 6 cases of myeloblastic leukosis which on subsequent passage reverted to the erythroblastic form.

The problem introduced by those agents of leukosis capable of also producing fibrosarcoma is more difficult to understand. The hemocytoblast and the fibroblast are related; yet this relation is somewhat distant, and it is rather difficult to believe that fibrosarcomas develop from hemocytoblasts stimulated by the agent of leukosis. The histogenesis of tumors produced by other agents such as the agent of the Rous sarcoma is not settled conclusively, although it is believed that the fixed or free histiocyte plays an important role in the process. Perhaps the agent responsible for leukosis may act in a similar way in the production of fibrosarcoma. Jármai (1935) explained the sarcoma-producing action of the agent of leukosis by suggesting that it had histotropic tendencies in addition to hemotropic tendencies, the latter being the more pronounced. Engelbreth-Holm and Rothe Meyer (1935) have advanced the conception that the different types of disease are caused by a selective action of the different agents of leukosis. For example, leukosis and fibrosarcoma are caused by an agent which attacks a mesenchymal cell capable of forming either blood cells or fibroblasts; those agents causing either erythroblastic or granuloblastic leukosis attack a cell common to both; and those agents causing only erythroblastic leukosis attack a cell already committed to that cell lineage. Carr (1956) has reported multiple nodules of renal adenocarcinoma in some chickens inoculated when less than 2 weeks of age with the ES-4 leukosis strain of Engelbreth-Holm. The size of the infective dose was also a critical factor.

Frequency. Fowl leukosis is usually a

sporadic disease among chickens and ordinarily affects birds more than 6 months of age. The average age of fowls suffering from leukosis studied by us has been approximately 1 year. Hamilton and Sawyer (1939) observed an unusual situation in which 53 of 231 chicks aged 30 and 39 days became affected with the disease within a period of 2 weeks. Olson and Bullis (1912) found 17 cases among 2,304 chickens more than 6 weeks of age, an incidence of 0.74 per cent.

Some evidence seems to suggest that in certain breeds (for example, Barred Plymouth Rock) of chickens, fowl leukosis is more likely to develop than in other breeds. Whether this is due to inherent characteristics of certain families within a breed or is a characteristic of all families of the breed is not known. Most if not all breeds are susceptible to transmissible strains of the agent of leukosis, and the spontaneous disease has been found in many different breeds.

There appears to be some relationship between the season of the year and the occurrence of the disease. Such relationship often has been suggested in the literature and is worthy of study. However, a number of factors serve to complicate such a study. In Denmark the disease appeared most often in the first quarter of the year; in Germany during the autumn, winter, and spring; in Japan in the late spring; and in Hungary in the autumn and winter months. In Massachusetts it appeared most often in birds examined during the second quarter of the year. Engelbreth-Holm and Rothe Meyer (1932) noted a seasonal effect on the results following inoculation of chickens with the agent of leukosis. A more severe form of the disease was noted in the summer months, and the disease developed in a higher percentage of adult birds during April and May than during October and November. Jármai (1938) observed a longer interval between inoculation and death of experimentally inoculated birds in the first half of the year than in the last half.

Gross and microscopic description. Fowl leukosis is fundamentally a disease involving the myeloid tissue of the bone marrow. Pathologic changes in other organs or tissues are secondary to the basic process in the bone marrow. With this simple conception in mind, the varied aspects of fowl leukosis as noted in other parts of the body may be understood readily.

The disease begins as a neoplastic proliferation of unripe erythrocytes or granulocytes. At first the process may resemble marked hyperplasia of myeloid tissue, but soon the normal boundary lines between intravascular erythropoiesis and extravascular granulopoiesis are so disturbed that they can no longer be distinguished. The neoplastic blood cells gain access to the circulation and are released from the diseased marrow in ever-increasing numbers. The tendency for these cells to become lodged in the capillary bed of certain organs has been mentioned previously. In such regions of leukostasis, the neoplastic cells continue to multiply and may rupture the vessel wall and infiltrate the parenchyma of the organ or tissue. Sometimes the lumen of the vessel may be filled with leukotic cells to such an extent that they constitute a thrombus and lead to infarction of the region supplied by the blood vessel.

In fowl leukosis the bone marrow is grayish-red and fills the marrow cavity. Johnson (1934) has called attention to the fact that in a normal bird the bone marrow space of the humerus contains fat and air spaces, whereas in most cases of leukosis the fat and air spaces are replaced by active myeloid tissue. A lining membrane of osteoid tissue may develop immediately inside the dense shaft of the long bones in cases with a protracted course. The intense hyperactivity of myeloid tissue can be studied best in histologic sections prepared from marrow of the long bones. The shaft may be split on its longitudinal axis to allow direct action of the fixative on the marrow. After fixation is complete, a segment of marrow may be embedded in the usual manner. The mar-

FIG. 32.10 — Erythroleukosis showing marked engorgement of the capillaries of the liver by immature erythroblasts. ×195.

row sinusoids are distended with unripe cells, and, likewise, the intersinusoidal tissue consists of unripe granulocytes. The relative amount of each determines the type of leukosis. That is, in the erythroblastic form, erythropoiesis is more marked; and in the granuloblastic form, the intersinusoidal tissue is the more severely affected.

The liver, spleen, and kidneys are the visceral organs of predilection in which the leukotic blood cells tend to lodge and proliferate (Fig. 32.10). The proliferation leads to generalized enlargement of the affected organ. In general this enlargement is not as marked as usually is seen in diffuse lymphocytoma. Microscopically the leukotic cells are confined largely to the vascular bed. The parenchyma of the organ may be reduced by compression from distention of the vascular bed with masses of neoplastic cells. The color of the involved visceral organs is usually pale because of the anemia. Sometimes small white foci may be present and represent localized accumulations of leukotic cells.

Fowl leukosis is associated with a tendency to hemorrhage, probably the result of an early and marked reduction of number of circulating thrombocytes. Hemor-

rhages may be noted in the loose areolar tissues and in the mucosa of the intestine.

The circulating blood is affected in nearly all cases of fowl leukosis. In experimental leukosis, cases may be observed in which the process is well developed in the bone marrow, and death occurs before the leukotic cells gain access to the circulation. Such cases are called incipient leukosis and represent a rapid acute form of the disease. All forms of leukosis may be found in the blood in varying numbers (Fig. 32.11). Usually the first change to be observed is a decrease of the number of thrombocytes. A decrease of the number of erythrocytes and of the amount of hemoglobin is followed closely or sometimes preceded by the appearance of immature cells. The blood picture is subjected to marked variations during the course of fowl leukosis. The microscopic picture of granuloblastic leukosis may sometimes change to that of erythroblastic leukosis. In some instances the blood picture may become apparently normal and remain so, suggesting recovery. Actual recovery of a spontaneous case has not been observed, although such a possibility may exist. In other cases periods of remission may be followed by

FIG. 32.11 — Blood films of chickens affected with leukosis showing marked differences between the myeloid and the erythroblastic form of the disease. (left) Myeloid leukosis. (Right) Erythroleukosis.
the reappearance of pathologic cells in the blood, and the disease eventually proves fatal. Although the foregoing impressions were obtained from experimental data, comparable changes occur in the naturally acquired disease.

Many bizarre and unusual forms of blood cells may be seen in leukosis. Furth (1931) and Oberling and Guérin (1934a) have published excellent colored plates illustrating the various types of blood cells seen in the blood of chickens suffering from fowl leukosis.

Special features. The relative ease with which fowl leukosis may be transmitted by means of the agent of leukosis suggests that spontaneous cases may develop as a result of natural exposure to the causative agent. Wickware (1946) found no evidence of transfer of leukosis to chicks hatched from pullets that had recovered from experimentally produced leukosis. Various experiments had indicated that not only fowl leukosis, but also the transmissible connective tissue tumors of chickens, are not contagious. However, Burmester, Fontes, and Walter (1960) found that contact transmission of Rous sarcoma could occur. Various ectoparasites have been shown capable of obtaining the agent from diseased birds and retaining it in an active form, but spread of the disease by such means can explain the development of few if any cases of leukosis. The spontaneous,

endogenous origin within the host has been suggested for the agents of leukosis and transmissible connective tissue tumors. In this respect these agents would be entirely different from the filterable viruses of contagious diseases such as fowl pox and laryngotracheitis. The concept of endogenous origin receives support in the different behavior of the many strains of the agent of leukosis, suggesting a lack of similarity. Tumors have been induced in chickens by carcinogenic chemicals, and if a tumor-producing agent separable from living cells could be demonstrated in these chemically induced growths, the evidence would support the hypothesis of endogenous origin of such agents. Only contradictory evidence is now available, and the latest report tends to deny the existence of such an agent in artificially induced tumors (Murphy and Sturm, 1941a).

Fowl leukosis is a disease peculiar to chickens. Only one spontaneous case of the disease has been reported in another species of fowl. This case occurred in a small parakeet (*Melopsittacus undulans*) and was described by Jármai (1939). The specificity of action of the agent of leukosis is probably only relative since the disease has been produced experimentally in pheasants, turkeys, and guinea fowl.

Natural resistance to the agent of fowl leukosis may be found in some chickens experimentally inoculated, and those

which recover from the experimental form of the disease also have a relative degree of immunity.

Diagnostic characteristics. The typical case of fowl leukosis is characterized by pale, watery blood which clots slowly, moderate enlargement of the liver and kidneys, marked enlargement of the spleen, and petechial hemorrhages in the loose areolar tissue and in the intestinal mucosa. The myeloid tissue fills the bone marrow space, replacing all fat cells and is grayred to dark red. Examination of smears of the blood will reveal abnormal numbers of immature cells.

In the diagnosis of leukosis, care must be exercised to differentiate it from other entities such as secondary anemias, granulomatous processes, and other neoplastic diseases. Histologic examination of the myeloid tissue should be regarded as the basic requirement for the diagnosis of fowl leukosis, and in some cases this procedure must be supplemented by a microscopic study of other organs as well (Table 32.3).

MELANOMA

Melanoma is a pigmented tumor whose black color is due to the presence of melanin granules in the cytoplasm of the cells. Histologically, the melanin appears as fine, dustlike, yellow-brown particles which may become so concentrated as to obliterate entirely the structure of the cell. The pigment is produced by melanoblasts which produce an enzyme capable of transforming the colorless precursor of melanin into pigment. By means of the "dopa" (dihydroxyphenylalanine) reaction this enzyme can be detected and thus the melanoblasts identified. Melanin granules may be engulfed by phagocytes which become simply carriers (melanophores) of the pigment. The histogenesis of melanoblasts is unsettled, and, according to the present conception, they may have either a mesodermal or a neural derivation (Boyd, 1938).

Excessive pigmentation with melanin without neoplasia may occur and is known as melanosis. Goldberg (1919) described

a case of generalized melanosis in a turkey and cited a similar case observed by Lewin in a chicken. According to Kukleuski (cited by Reinhardt, 1930), pigmentation of the gonads, oviduct, thymus, thyroid, skin, and marrow is often marked in Japanese and Siamese Silky chickens, which normally have a pigmented skin. Reinhardt (1930) commented that pigmentation of one or both testes is fairly common in "singing" birds. Melanosis of the peritoneum occasionally may be noted in the chicken.

Few pigmented tumors of chickens have been described. Reitsma (Hoogland, 1929) and Goldberg (1919) each reported a melanoma, probably primary, in the ovary of a hen, which spread to the serosa of the abdominal viscera. In the case described by Goldberg, the tumor resembled a cavernous angiosarcoma except for the pigmentation. McGowan (1928) described three cases of melanoma in the chicken. Two of the pigmented tumors occurred in Black Leghorn chickens and the other in a Rhode Island Red bird. In all of these cases the tumor was believed to have originated in the ovary. Only one appeared epithelial. The other two were described as similar to the Rous sarcoma. In McGowan's cases numerous implants of pigmented tumors were found on the serosal surfaces of the visceral organs. Olson and Bullis (1942) observed a small pigmented tumor at the base of the tongue which was diagnosed as melanoma. Ball (1945) reported a melanoma of the iris in a 2-year-old hen that died with lymphomatosis.

TUMORS OF NERVE TISSUE

If lymphocytoma is excluded, neoplasia of nerve tissue of the chicken would appear from the literature to be relatively infrequent. Jungherr and Wolf (1939) reviewed the literature on primary neural neoplasms of animals and found only three cases in the common fowl in which the diagnosis of glioma could be accepted. They described two additional cases. All were regarded as astrocytomas. Multiple gliomas have been found in birds with

FIG. 32.12 — Glioblastoma multiforme illustrating irregular cell outlines and glia fibrils. ×480. (Courtesy of Cecil Jackson, Ghana Academy of Sciences, Achimota, Ghana, and of the Director of the Onderstepoort Veterinary Research Institute, South Africa.)
FIG. 32.13 — Showing multiplicity of focal areas of avian gliomatosis. From foci of encephalitis, such as occur in the upper and central left areas, there arise by transition definite gliomatosis neoplasia. An example is the large oval area at the extreme right. ×100. Giemsa stain. (Courtesy of Cecil Jackson, Ghana Academy of Sciences, Achimota, Ghana, and of the Director of the Onderstepoort Veterinary Research Institute, South Africa.)

toxoplasma infection (Erichsen and Harboe, 1953). Jackson (1954) has presented a series of 120 intracranial lesions from chickens with 109 gliomas (Fig. 32.12). He believes that gliomas are more like glioblastoma (spongioblastoma) multiforme rather than astrocytoma and that they represent foci of encephalitis in which glial proliferation becomes exaggerated and assumes a neoplastic character (Fig. 32.13). Jungherr and Wolf also discussed neoplasms reported from other birds and regarded a glioma found in a parakeet and a ganglioneuroma described in a sparrow as of neural origin. They stated that the apparently low rate of incidence of neural tumors in animals is perhaps due to the infrequent complete examination of the central nervous system at necropsy.

Jackson (1936a) has described multiple neurofibromatosis in the chicken, and Olson and Bullis reported five cases of neurogenic sarcoma. These tumors are mentioned in the section dealing with connective tissue tumors. Cole in 1946 reported a case of retinoblastoma.

No attempt will be made to discuss the classification or characteristic features of tumors of the nervous system. Those seeking such information are referred to the chapters on neoplasms in Lichtenstein (1949).

In some instances the brain or spinal cord may be affected by metastatic growth of neoplasms situated elsewhere. The involvement of nerves with lesions of lymphocytoma is fairly frequent in that disease. The significance of these lesions and their association with fowl paralysis are discussed in the section on lymphocytoma.

TUMORS OF EPITHELIAL TISSUES

Papilloma. A papilloma is a benign epithelial tumor composed of fibrous cores or projections which are covered by layers of epithelial cells. These tumors are frequently multiple, and the brushlike or cauliflowerlike structures are often spiny to the touch.

Microscopically, papilloma is a simple structure usually consisting of a few to many separate units or projections, each with a fibrous core that is covered to a variable depth by compactly arranged epithelial cells. The cells nearest the stroma are the least mature, and between the various papillae and on the surface there is frequently present a horny deposit known as keratin. Keratin is the product of the more mature squamous epithelial cells. Characteristically, these tumors grow in an outward rather than an inward direction.

The tumors are sometimes seen on the comb, feet, and wattles of fowls, but they occur much less frequently in fowls than in certain mammals. Olson and Bullis (1942) observed a case of multiple papillomatosis of the esophagus of a chicken. The lesions appeared as small, grayish nodules, some of which were hemorrhagic, in the mucosa. We observed one instance in a pigeon in which there occurred diffuse warty growths in the skin adjacent to the beak and around the eyes. The literature contains but slight mention of papillomas in chickens, and one must conclude that their occurrence is extremely infrequent.

Papilloma of the skin and oral cavity in mammals frequently is contagious and easily transmitted owing to a causative factor that in some instances has been definitely established to be a virus. So far as we know, papillomas of chickens due to agents of a viruslike nature have not been reported.

Adenoma. Adenoma may be defined as a benign epithelial neoplasm in which the structural pattern resembles that of a gland. Any tissue containing glandlike structures normally or aberrantly may give rise to an adenoma. These tumors usually occur singly. Rarely, multiple adenomas may appear.

Adenomas are among the less frequent tumors of chickens, being much less common than the malignant epithelial tumors. Eber and Malke (1932) reported the occurrence of 16 adenomas among 253 tumors of fowls. Of those in chickens, the sites of occurrence were as follows: liver,

6 cases; proventriculus, 1 case; gizzard, 1 case; intestines, 2 cases; ovary, 1 case; and oviduct, 1 case. According to Heim (1931), Joest and Ernesti described a cystic form of adenoma (cystadenoma) in the region of the crop. Although the exact situation of origin was not determined definitely, origin from the thyroid was considered. A few cases of adenoma of the ovary have also been described (Heim). Olson and Bullis observed 1 case of fetal adenoma of the thyroid and 1 case of adenoma of the feather matrix in chickens. The same authors recorded a papillary cystadenoma of the mucosa of the posterior portion of the gizzard in a chicken.

Unless adenoma occurs in a situation where its presence or size may provide a mechanical interference with the proper functioning of contiguous tissues, this variety of neoplasm in chickens is unlikely to have any appreciable effect on the host. Malke, according to Heim (1931), recorded an obstructing adenoma of the cecum. Babic (1931) described multiple adenomatous polyposis of the intestine in a chicken. Such a condition could lead to disturbances of elimination. Should adenoma arise in certain endocrine structures, abnormal physiologic effects may ensue.

Being benign, adenoma never infiltrates the surrounding tissues and does not metastasize. Should an alleged adenoma exhibit these features and especially should metastasis occur, the tumor can no longer be considered benign but should be recognized as malignant. The malignant form of adenoma is designated "adenocarcinoma."

In appearance adenomas may be expected to be encapsulated, nodular, and firm to soft. Opportunity for adenoma to become cystic is provided by the glandlike nature of the parenchyma. Since a duct system for the natural egress of secretory substances is missing, the products of the cells frequently accumulate and produce small to large cysts. Such tumors are often called "cystadenomas."

Microscopically, an adenoma presents the appearance of a gland, a duct, or a tubular structure (Fig. 32.14). Alveolar spaces may be present, or the parenchymal cells may appear as compact masses. In nearly every instance the structure of the tumor bears a resemblance to the normal tissue produced by the parent epithelial cells from which the parenchymal cells of the tumor were derived. The stroma consists of fibrous connective tissue in which are found blood vessels. The stroma may occur in a promiscuous, nondescript fashion, or it may be disposed as septa or ill-defined trabeculae which serve to separate the tumor into irregular lobules.

Adenomas may be identified readily if one keeps in mind certain salient features: 1. Adenomas originate in situations where glandlike structures occur normally. 2. They usually occur as single tumors. 3. They do not infiltrate the adjacent tissues or set up distant metastatic growths. 4. When properly removed they do not recur.

Carcinoma. A carcinoma is a malignant neoplasm composed of epithelial cells and a stroma of connective tissue. The latter provides a supportive structure for the epithelial cells and for the vascular channels inherent to the part. The cells of the carcinoma proliferate in an atypical and lawless manner, have a tendency to infiltrate and destroy the contiguous tissues, and may and often do set up secondary or metastatic foci. Although all malignant tumors of which the type cell is epithelial in origin are properly referred to as carcinomas, certain characteristic structural differences occur that make it desirable to separate carcinoma into several distinct morphologic types. These include adenocarcinoma, in which the parenchymatous cells assume a glandular or ductlike arrangement; squamous cell carcinoma, composed of diffuse masses or compact collections of cells that arise from the epidermis or the mucosa of the esophagus, the mouth, or the pharynx; papillary carcinoma, which has a rough cauliflowerlike surface with the tumor cells arranged in fingerlike sheets; and hepatic cell carcinoma, which arises from the cells of the

FIG. 32.14 — Adenoma arising from the bile ducts of the liver. ×120.

parenchyma of the liver which have undergone autonomous transformation. Tumors of chickens analogous to the so-called basal cell carcinoma of human beings presumably occur infrequently. Olson and Bullis (1942) encountered one case in their material. This is described in the subsequent text. Other special types of carcinoma may arise from the thyroid, the adrenal, the ovary, the kidney, and the pancreas. These constitute only a partial list of the tissues that may give rise to carcinoma. The wide distribution of epithelial tissues throughout the body provides numerous potential situations for the origin of carcinomas.

Frequency. Among 199 neoplasms of chickens mentioned by Hoogland (1929), 33, or 16.6 per cent, were carcinomas. The predominance of sarcoma over carcinoma was illustrated in Hoogland's series, there being 93 tumors of sarcomatous character. Hoogland's list of chicken tumors did not include those of so-called leukotic character (lymphocytoma, myelocytoma, and leukosis). Eber and Malke (1932) observed 29 carcinomas among a total of 239 tumors of chickens. This represents an incidence of approximately 12 per cent. As was true in Hoogland's series, Eber

and Malke probably did not include leukosis in listing the respective neoplastic diseases in their material. However, it is likely that many, if not all, of the so-called round-cell sarcomas mentioned by Eber and Malke were in reality lymphocytomas. As is true with most other reports on neoplasia of chickens, Eber and Malke's material contained many more "sarcomas" than carcinomas. Of the 259 tumors of chickens examined histologically, 167, or approximately 70 per cent, were designated as sarcoma.

Babic (1931) described 16 cases of carcinoma of the chicken, in 10 of which the tumor was primary in the ovary. In 3 the tumor was primary in the skin, in 2 the kidney was the site of origin, and in 1 instance the growth arose in the testes. The tumors occurred in a group of 61 neoplasms collected from several different species of birds.

Goss (1940b), who reported on the types of neoplasia among 7,408 chickens examined at necropsy, found tumors in 1,445. Among 1,104 examined microscopically there were 991 designated "leukotic tumors" and 77 carcinomas. In relation to the total number of tumors listed (1,104), carcinomas represented 7.0

per cent; if the "leukotic tumors" are excluded from the total number, carcinomas represent approximately 68 per cent of the neoplasms examined. Goss's data are of especial interest because of the fact that 70, or approximately 91 per cent, of the total number of carcinomas found were ovarian in origin.

Olson and Bullis (1912) made a study of avian neoplastic material that occurred in 365 chickens. A total of 384 tumors, including those of hemoblastic origin, were found, and 24, or approximately 6.2 per cent, were epithelioblastomas.

From the figures presented, it is evident that dependable information concerning the predictable rate of occurrence of carcinoma in chickens is meager.

Relation to age. There do not exist adequate data to enable one to state definitely the relation of the incidence of carcinoma to the age of the affected bird. Indications are that the majority of carcinomas of chickens occur in adult rather than in young birds. Most birds that have carcinoma are 1 year or more of age. It should be kept in mind, however, that the age at which the neoplastic process began was much earlier. More than 4 years were required for development of epithelial tumors in liver, ovary, and oviduct of chickens which received a carcinogen (2 acetamidofluorene) daily for 3 months beginning when the birds were 6 months old (Campbell, 1955). Methylcholanthrene applied to the wall of the crop produced carcinomas in chickens in 3 to 5 years (Peacock and Peacock, 1956) but, when applied to the skin, epithelial proliferation developed in 2 to 3 months and these regressed (Rigdon and Brashear, 1954).

Sites of occurrence. A fairly complete résumé of the literature on occurrence of carcinoma in chickens is to be found in the treatise by Reis and Nóbrega (1955a). As mentioned previously, carcinomas may arise wherever epithelial tissues occur. Although the epidermis and the mucous membranes constitute the greatest amount of epithelial tissue in the body, in the chicken these tissues do not give rise to the largest number of carcinomas. In chickens most tumors of this character arise from the ovary.

From information obtained from the literature and from data supplied by our own collection, the occurrence of carcinoma in the various anatomic situations in chickens will be described briefly.

1. *Integument.* By far the greatest number of carcinomas of the integument of chickens that have been reported have affected the foot and shank or more specifically the skin overlying the metatarsus. Other situations in which carcinoma of the skin has been reported include the anal region, breast, and the region overlying the femorotibial articulation.

One instance of a tumor that had many of the characteristics of a basal cell carcinoma was reported by Olson and Bullis (1912). The tumor was situated in the skin immediately over the left eye. It was a nodular mass 1 cm. in diameter by 6 mm. thick. The tumor was first observed 1 month before the chicken was killed for necropsy. Microscopically, the mass consisted of several indistinctly lobulated, compactly disposed epithelial cells with moderately basophilic cytoplasm. The tumor was situated largely in the corium but had broken through the epidermis at one point. The structure was richly vascular, and some hemorrhage had occurred. Mitosis was not observed. Metastasis had not occurred. The tumor was diagnosed as carcinoma of the feather matrix. For a review of the different reports of carcinoma of the skin of chickens up to 1930, the paper by Heim (1931) may be consulted. Other cases are mentioned by Pohl (1926), by Babie (1931), and by Jackson (1936a, page 434). An extensive review of the literature pertaining to tumors of the skin of birds will be found in the paper by Abels (1929).

In view of the fact that these tumors of the integument have all the morphologic characteristics of a malignant growth, it is somewhat surprising that they apparently seldom if ever metastasize (Fig. 32.15).
FIG. 32.15—Squamous carcinoma of the skin of the neck of a chicken. Metastasis was not demonstrated, ×120.

Duran-Reynals (1946b) was unable to transplant a localized skin gland adenoma of the wing to other chickens. In the cases we have observed, the neoplasms have remained localized, and in the cases reported previously by others, metastasis has rarely been demonstrated. Structurally, these tumors would appear capable of setting up metastatic foci at a distance from the original lesion. Yet in the many cases reviewed by Abels (1929), metastasis was recorded in only three cases of carcinoma of the skin of chickens.

2. *Alimentary canal.* A few instances have been recorded of the occurrence of carcinoma within the oral cavity of chickens (Heim, 1931, listed several cases). One occurred in our collection. The tumor was a carcinoma of the epidermoid type and occurred in the pharynx of a 2-year-old hen. Although the tumor was locally infiltrative and destructive, metastasis could not be demonstrated.

The literature, according to Heim (1931), yields three cases of squamous cell carcinoma of the esophagus.

Carcinoma of the proventriculus and gizzard appears to be an extremely rare manifestation of the disease. Our material did not contain any specimens from these organs, and the cases reported in the literature are few. Babic (1931) described a medullary carcinoma of the proventriculus. Zannini (Heim, 1931) is said to have observed an adenocarcinoma of both the proventriculus and the gizzard. "Cylindrical cell" carcinomas of the gizzard that had not metastasized were reported by Schöppler (1913) and by Prospero (Heim, 1931). The report of Prospero was not available for review, so that we are unable to comment concerning this case. In Schöppler's case the tumor was considered to have arisen from the glandular elements of the pyloric portion of the gizzard.

3. *Intestine.* The tendency of many primary malignant tumors of the abdomen to spread by direct continuity or by serosal implantation to all of the serous surfaces of the abdomen frequently makes it difficult to ascertain with certainty from what site a given tumor may have arisen. The occurrence of serosal implantations is especially characteristic of ovarian carcinoma, and the resultant widespread distribution of the tumorous tissue may obscure entirely the primary site of origin or lead to false conclusions regarding the primary situation of the tumor. Unless one can demonstrate the primary lesion

in the intestinal mucosa, it would be unwise to claim that a carcinoma of the intestine is present. When the serous covering or even the muscle wall of the intestines is involved with an epithelial glandular type of malignant lesion, discretion should be exercised in concluding that the site of origin was the intestinal mucosa. As a matter of fact the likelihood that such tumors originate in the ovary is much greater than that of their origin in the intestine.

Adenocarcinoma of the duodenum has been reported by Petit and Germain (Pohl, 1926) and by Ehrenreich and Michaelis (1906), and for the "intestine" by Hoogland (1929) and by Jackson (1936a, p. 160). In Jackson's case, metastasis to the liver had occurred. An unusual case was that of Joest and Ernesti (Heim, 1931), in which a medullary carcinoma involving the ileum and ceca was associated with another primary carcinoma of the cloaca. One of the specimens in our collection was of some interest. The tumor, which proved to be an adenocarcinoma, occurred in the mucosa of the ileocecal junction of a 2-year old White Leghorn hen (Fig. 32.16). The tumor was an elongated, roll-like structure about 0.6 cm. in height, and it involved about half of the circumference of the lumen. The tumor had produced some obstruction, but metastasis had not occurred.

According to Heim (1931) two cases of carcinoma of the colon or rectum of chickens have been described. In both instances metastasis had occurred to the liver.

The evidence indicates (1) that malignant epithelial tumors of the intestines of chickens are among the rarer avian neoplasms; (2) that carcinoma of the intestines may metastasize to the liver and lungs; (3) that in female chickens the occurrence of multiple neoplastic foci on the serosa of the abdomen should suggest a malignant lesion of ovarian origin rather than one from the intestinal tract; and (4) that to diagnose with certainty a carcinoma of the intestine, one should

FIG. 32.16—Primary adenocarcinoma of the ileocecal junction of a 2-year-old White Leghorn hen. The advancing neoplastic cells have penetrated the muscolaris mucosae. Distant metastasis was not demonstrated. ×110.

demonstrate the primary lesion in the mucosa of the gut.

4. *Accessory organs of digestion.* Among the accessory organs of digestion that have given rise occasionally to carcinoma are the liver and the pancreas.

Heim listed a few reports of epithelial tumors of the liver, but how many of the alleged cases were actually primary carcinomas of the liver is uncertain. Teutschlaender (Heim, 1931) reported two cases of carcinoma of the bile ducts, and Savage (1926) reported the occurrence of an adenocarcinoma of the gallbladder in a 3½-year-old Rhode Island Red hen.

Primary carcinoma of the liver may arise from two types of cells, the parenchymal liver cells and the epithelium of the bile ducts (Fig. 32.17).

Goss reported one case of carcinoma of the liver cells in a bird more than three
FIG. 32.17 — Hepatocellular carcinoma (hepatoma). The neoplastic liver cells are compressing the normal liver tissue by their expansive growth. In some cases, the neoplastic cells may occur in more orderly rows. ×150.

years old and also an adenoma of liver cells in another chicken. He also recorded 4 carcinomas of bile ducts. Olson and Bullis (1942) described 9 cases of benign hepatoma and 4 of cholangioma. In 3 instances the tumors of the bile duct cells were single isolated masses, and in the fourth case there were multiple tumors scattered throughout the liver, suggesting the malignant character of the neoplasm. An adenocarcinoma primary in the liver of a turkey was described by Babic (1931).

Campbell (1949) studied 22 cases of spontaneous carcinoma of the liver in ducks mostly from 4 flocks. Carcinoma of liver cells was most common (17 cases), while 1 case of bile duct carcinoma and 4 cases of mixed liver carcinoma were encountered. Graft transplants to the livers of other ducks were successful, but attempts to demonstrate a cell-free agent in filtrates or by egg embryo culture were negative. Liver injury with regeneration and metaplasia of bile ducts has been demonstrated in ducks fed a toxic peanut meal or aflatoxin for up to 4 weeks (Newberne, 1964). The same peanut meal or aflatoxin fed for 12 weeks to rats produced hepatomas and cholangiomas. A dietary carcinogen could be suspected in circumstances such as described above by Campbell (1949).

Olson and Bullis (1942) recorded having encountered 3 epithelial malignant lesions of the pancreas. Two of these were designated as carcinomas. Babic (1931) also listed as an adenocarcinoma. Babic (1931) also described an adenocarcinoma of the pancreas.

5. *Adrenal glands.* Mathews and Walkey (1930) described, in adult hens, 6 cases of pedunculated carcinoma which appeared to originate from the region of the adrenal glands. Although the ovary was involved in each instance, the histologic picture of the tumors was suggestive of the adrenal cortex. Mathews and Walkey, however, were not certain that the tumors had originated from this tissue. Metastasis was limited to the mesentery and to the visceral peritoneum and probably occurred as a result of spread by continuity.

Berner (1923) reported an extremely interesting case of hypernephroma or carcinoma of the right adrenal gland with secondary involvement of the serosa of the abdominal viscera and metastatic foci in the lungs. The bird was an 18-month-old female chicken in which the behavior and other characteristics of virilism had been

noted since the bird was 6 months of age. There had developed a male type of comb and spurs, and the gait when walking was particularly vigorous and malelike.

6. *Urogenital tract.* A case of medullary carcinoma of the kidney with metastasis to the liver and lung was found in a pheasant by Babic. He also reported a cystic adeno-carcinoma in the right kidney of a chicken. The latter case might be considered more properly as an embryonal nephroma. A medullary carcinoma of the testis of a chicken with metaplastic keratinization also has been described by Babic.

The ovary is undoubtedly the most frequent site of origin of carcinoma of the chicken. Carcinoma of the ovary of chickens has been described by many observers. Those especially interested may consult the following: Oshima and Roki (1925), Eber and Kriegbaum (1916), and Jackson (1936b). Heim reviewed the literature up to 1930. In Eber and Malke's series of 239 tumors of chickens, 29 were carcinomas. Fifteen, or approximately 52 per cent, of the carcinomas in this series were presumed to have originated in the ovary. Unlike many carcinomas of the ovary of human beings, which affect the ovary secondarily, most carcinomas of the ovary of chickens are primary in this organ. The disease in chickens usually has its inception in the functioning left ovary but may originate in the rudimentary right ovary.

Seifried (1925) described two cases of ovarian tumors in chickens which he designated "oophoroma folliculare." One tumor occurred in the rudimentary right ovary and the other in a left ovary which was otherwise normal. From a careful reading of Seifried's description of the two tumors, we believe that his Case 1 represents a granulosa tumor and not a Brenner tumor as he believed. Case 2 may also be a granulosa tumor, but the evidence is somewhat indefinite.

In the ovary, neoplasia may arise from (1) the germinal epithelium, (2) the Pflüger egg cords, and (3) the immature follicular epithelium. Fischel (1922) stated that most of the ovarian tumors in human beings are derived from primitive mesenchymal tissue which has divergent potentialities, and which in his opinion may give rise to sarcoma or to carcinoma. Babic expressed the belief that most ovarian carcinomas are derived from follicular epithelium. Carcinomas that arise in the oviduct are derived from the epithelium of the mucosa.

Notwithstanding the possibilities for origin of ovarian carcinoma just listed, it should be kept in mind that, with the possible exception to be mentioned, cytologic detail of carcinoma of the ovary does not bear any resemblance to any recognizable ovarian structure. A possible exception to this statement is to be found in the case of granulosa tumor of the ovary. Even with this neoplasm, however, there is little unanimity of opinion concerning its true genesis. Most carcinomas of the ovary are medullary in character.

Attempted transplantation of an adenocarcinoma of the ovary to other chickens by Duran-Reynals (1916b) was not successful.

7. *Other situations.* Information on the occurrence of primary carcinoma of the lung of chickens indicates that this organ is seldom affected. The only reference to primary carcinoma of the lung of the domestic chicken with which we are familiar is a report of a case by Apperly (1935). The right lung and most of the left lung were replaced by a fibrocaseous material, and there was present a small white nodule near the periphery of the liver. Microscopically, the appearance of the lesions in the lung and in the liver was essentially identical. The diagnosis was primary adenocarcinoma of the lung with metastasis to the liver.

Epithelial malignant lesions of the thyroid gland appear to be rare in the chicken. Elsner (Reis and Nóbrega, 1935a) described an adenocarcinoma, and Olson and Bullis (1942), a fetal adenoma in the thyroid of chickens.

Effects on the host. The effects on the welfare of an animal in which carcinoma develops depend on several factors. These

include (1) the inherent malignancy of the process, (2) the anatomic situation involved and the severity of the involvement, (3) the presence or absence of secondary foci, and (4) the duration of the disease.

Carcinomas of the ovary frequently spread by continuity or by implantation to the adjacent structures and especially to the serosa overlying the intestines. When this occurs, moderate to severe ascites eventually follows. As a matter of fact, the presence of ascites in an adult chicken should suggest the possibility of abdominal carcinomatosis or other malignant processes having a multiplicity of lesions.

It is of interest that although carcinoma of the abdominal cavity may be disseminated extensively throughout the viscera, frequently the condition appears not to interfere seriously with the general health of the bird except in the terminal stages. The disease has a protracted course, and in many instances is discovered in apparently healthy chickens at the time the bird is being "dressed" for food. Emaciation may be noted.

Hens that have carcinoma of the ovary eventually become nonproductive, although what degree of involvement of the ovary must occur before egg production ceases is not known.

Although the effect of most carcinomas, like that of many other malignant tumors, depends on the mechanical interference with normal function and on the destruction of normal tissues by the advancing neoplastic process, a few carcinomas occur that affect the host physiologically by producing an excess of hormonal substances. The masculinizing effect of arrhenoblastoma in the human being is well recognized, and if this or certain other specialized tumors occur in chickens, it would seem reasonable to expect an altered behavior on the part of the host. Friedgood and Uotila (1941) described several cases of virilism in chickens apparently due to hormones produced by tissue which they considered neoplastic. They diagnosed these cases as arrhenoblastomas. Virilism in a hen should lead to suspicion of such a condition.

Gross characteristics. The gross appearance of carcinomas varies greatly as to size, shape, and color. With few exceptions these tumors are attached diffusely to the surrounding tissues, and encapsulation, except in rare instances, is not discernible. Contact with the adjacent tissues is usually intimate, this feature being indicative of the characteristic invasive tendencies of these neoplasms. Those on the exterior, being subject to trauma, are readily infected, and as a consequence they may present hemorrhagic, necrotic regions. Their surface is usually irregularly roughened and may have a hard, tough, or cornified superficial covering due to the excessive amount of keratin derived from the squamous epithelial cells.

Carcinomas of the internal organs, especially those of the ovary or oviduct, are single or more frequently multiple, smooth, nodular, pinkish-gray or flesh-colored formations (Fig. 32.18). Multiplicity is frequently a striking feature of intra-abdominal carcinomas, with innumerable nodules of varying sizes and shapes occurring in subserosal situations, especially along the intestines and in the mesentery (Fig. 32.19). Ovarian and oviductal carcinomas may be soft or hard or, more precisely, cystic or solid. Cavities or cysts filled with a shiny mucinous or gelatinous substance are commonly a characteristic feature of these tumors.

Carcinomas of the mucous surfaces are often the site of extensive ulceration. The surface may appear raw and irregular, with evidence of recent bleeding. Signs of secondary infection are present. In situations where metastasis has occurred, as in the lung or liver, the tumorous tissue usually appears as firm, grayish-white foci. In the liver the metastatic foci may be limited to the serosa of the capsule or may occur firmly embedded in the parenchymal tissue.

Microscopic characteristics. Since carci-

nomas arise from many different types of epithelial tissue, the histologic pattern depends to some extent on the character of the parent epithelium from which they originate. However, most carcinomas have one important feature in common. This feature is the infiltrative and destructive character of their growth.

The various types of carcinoma that may be encountered can be described briefly as follows:

1. *Squamous cell carcinoma.* These tumors arise from the cells of the epidermis and consist of diffuse collections or compact masses of squamous epithelial cells. The epithelial cells are usually incompletely separated by a fibrous connective tissue stroma with nestlike groups or packets or fingerlike processes that extend into the surrounding nontumorous tissue. Many if not most of the epithelial cells show signs of immaturity, and mitotic division usually can be seen. Necrosis may be present, and lymphocytes and acidophilic granulocytes commonly infiltrate the tumor. The central portion of many of the compact groups of cells frequently presents a peculiar hyaline appearance due to the accumulation of keratin. Such a tumor may be referred to as a "pearl cell" or an epidermoid carcinoma.

2. *Papillary carcinoma.* Rarely a carcinoma grows away from, rather than into or toward, the body, presenting a rough, cauliflowerlike structure. Such a tumor consists of a central core of connective tissue from which are given off small papillae covered with several irregular layers of neoplastic epithelial cells.

3. *Adenocarcinoma.* This variety of carcinoma arises from tissues normally composed of or containing epithelial glandular structures. The tumor consists of fibrous stroma of variable dimensions which support one or more layers of cuboidal or columnar cells arranged in an alveolar or ductlike fashion (Fig. 32.20). Tortuous ductlike structures frequently are formed, as are cystic spaces containing gelatinous or mucoid material. The cells may assume a papillary type of growth, and, if the process is especially anaplastic, little tendency toward formation of alveoli or ducts may be evident. Instead, the growth appears as diffuse or solid sheets or nests of cells with slight resemblance to the parent structure from which the tumor arose.

4. *Other types of carcinoma.* Another variety of epithelial malignant lesion is that commonly referred to as hypernephroma of the kidney. This is a renal

FIG. 32.20 — Cystadenocarcinoma of the ovary of a chicken. Metastasis to the lungs had occurred. ×150.

carcinoma that arises either from the adult tubules or from foci of nephrogenic tissue that have persisted in the renal cortex. Hypernephroma of the kidney appears to be rare in chickens.

Olson encountered a hypernephroma in the kidney of a hen about 1 year old. The bird died with extensive lymphocytoma of the visceral organs. The hypernephroma was a well-encapsulated, firm, round mass in the posterior pole of the left kidney. The tumor was 4.5 cm in diameter. The cut surface was solid, and thin bands of connective tissue separated islands of yellow-tinged, gray-white tumor tissue which resembled the adrenal gland. The tumor was composed of large cells with a foamy cytoplasm which resembled those of the adrenal cortex. There was no evidence of virilism of the bird, and both adrenals were normal.

Metastasis. Carcinomas, being malignant neoplasms, have the tendency to infiltrate or invade the surrounding tissues, and if the circumstances are propitious, new foci of growth and destruction are likely to be set up in the immediate vicinity of the parent growth or in tissues distant from the primary lesion.

In carcinoma of mammals the usual route of metastasis is by way of the lymphatics, with the blood channels involved infrequently. In chickens the lymphatic route of metastasis is apparently little utilized. As a matter of fact, true metastasis of carcinoma in chickens as a consequence of the conveyance of tumor cells from one situation to another by way of vascular channels seldom occurs. Ovarian and oviducal carcinomas early become disseminated throughout the abdominal tissues, but this results as a consequence of implantation rather than by true vascular metastasis. Distant metastatic growths may be established from these tumors but are of exceptional occurrence (Fig. 32.21). A few instances have been observed in which carcinoma primary in the intestines has metastasized to the liver and to the lungs.

Diagnostic characteristics. Of primary importance in distinguishing carcinoma is the character of the tissue in which the tumor occurs. Being composed of epithelial elements, carcinoma should be thought of when neoplasia occurs in such tissues as the skin or the mucous membrane or in organs in which epithelial tissues are present. These tumors usually exhibit invasive or infiltrative tendencies

FIG. 32.21 — Metastatic cystadenocarcinoma of the lungs. The neoplastic process was primary in the ovary. Same case as Figure 32.20. ×60.

and frequently give rise by implantation, or less often by metastasis, to secondary foci. Microscopically, although the picture is subject to marked variation, carcinoma usually is characterized by the presence of immature epithelial cells growing in an atypical infiltrative manner without the apparent guiding influence that governs normal growth or repair.

MESOTHELIOMA

Neoplasia of the mesothelial cells covering the serous surfaces of the peritoneal cavity appears to be rare in the chicken. Olson and Bullis (1942) described one case of a 9-month-old pullet. In this case two pedunculated masses of tumor having a combined weight of 49 gm. were attached by stalks to the wall of the abdomen and the ovary. There was marked ascites. Eber and Malke (1932) mentioned four cases of what were probably mesotheliomas of the peritoneum. Eber and Malke designated these tumors as "endothelioma." In these cases there were numerous tumorous nodules spread over the serosa of the proventriculus, intestine, oviduct, and mesentery. In all cases microscopic examination revealed masses of neoplastic tissue composed of large cells which had a distinct fibroblastic character. These cells tended to form cylindrical strands, although there were regions in which the cells were loosely arranged.

Mesothelioma may arise from the serosa of the peritoneum or the pericardium. The structure of such tumors may be variable since the mesothelium is of mesodermal origin, and immature mesothelial cells may have the ability to develop into connective tissue cells. In the case of mesothelioma described by Olson and Bullis, the polyhedral cells tended to form sheetlike masses, although in some regions they appeared to be compressed to a spindle shape. The cases described by Eber and Malke as endothelioma might be considered as mesotheliomas in which the elements displayed more of the fibroblastic character than the tendency to form sheetlike masses.

Although mesothelioma appears to be a rare tumor in the chicken, it is important since it might readily become confused grossly with lymphocytoma or carcinoma. Careful study may be required to enable one to distinguish between these conditions.

MIXED TUMORS

For convenience we have classified certain tumors of varying degrees of complexity as mixed tumors. The less complex are those whose cells, although derived from more than one germinal layer, are in a rather advanced state of development and whose potential differentiation is subject to definite restrictions. The tumors of chickens in this category include thymoma and the so-called carcinosarcoma. A more complex group of mixed tumors is that known collectively as teratomas. These are also composed of cells derived from more than one germinal layer but differ from the less complex mixed varieties just mentioned in that the cells giving rise to a teratomatous growth have multipotent potentialities and are capable of unrestricted differentiation. In teratomatous tumors, therefore, one may recognize tissues representing all three germinal layers, some of which may have attained the specialized differentiation characteristic of adult tissues or organs. In chickens the most frequently encountered teratomatous tumors are those of the ovary, the kidney, and the testicle. A third group of complex tumors are those designated embryonal nephroma, which arise from primitive multipotent mesodermal cells that have divergent capacities for differentiation.

Thymoma. In chickens, tumors that arise from the parenchymal tissues of the thymus are among the rarer forms of neoplasia. Feldman (1936) mentioned a case reported by Saupe and described one case of his own. In the latter instance the tumor occurred in a rooster of the Barred Plymouth Rock breed, aged 2 to 3 years, that had been killed for food. The tumor occupied the ventral aspect of the cervical

region, extending from the thoracic aperture forward for a distance of 10 cm. The mass measured $10 \times 5 \times 4$ cm. and weighed approximately 250 gm. Microscopically, the tumor consisted of a richly cellular structure composed largely of intertwining sheets or bundles of polymorphic cells. A moderate number of cells were undergoing mitotic division, and in one region concentric whorls of closely packed cells resembling Hassall's corpuscles were seen. A minimal amount of lymphoid tissue was present. The structure was well supplied with blood vascular channels. Metastasis had not occurred. It was thought that the tumor arose from the reticulum cells of the thymus. Two cases of thymoma similar to the foregoing were found by Olson and Bullis (1912).

Until additional cases provide material for the study of thymic tumors in chickens, their morphologic variations and their effects on the host will remain obscure.

Carcinosarcoma. A tumor somewhat similar to that which we have designated as carcinosarcoma has been described by Jackson (1936a, b) as "carcinoma leiomyotosum." Jackson's term indicates an adenocarcinoma with a stroma of smooth muscle fibers. Jackson expressed the belief that the stroma of muscle fibers is merely a reaction on the part of the host to the growth of the neoplastic epithelial elements. Glietenberg (1927) described a similar process in the oviduct as a "myocystadenoma," implying that both muscular and epithelial elements were neoplastic. Joest and Ernesti (1915) took a similar stand with respect to 2 tumors which they diagnosed as "adenomyoma." A third mixed neoplasm with many peritoneal implants was diagnosed by them as "sarcoma carcinomatodes." Olson and Bullis (1942) found 7 cases of tumors which they termed "carcinosarcoma," all of which were widely implanted on the serosal covering of the viscera (Fig. 32.22). The epithelial elements in these cases appeared to have come from the ovary, pancreas, and adrenal. The supporting stromal tissue was considerable in amount and if

seen alone would have been considered as fibrosarcoma (Fig. 32.23). The presence of acini of epithelial cells constitutes a disquieting feature to an otherwise simple diagnosis in such cases. Bundles of smooth muscle cells also can be demonstrated in the stroma of these tumors in regions remote from where they would normally be expected. An interesting finding was a concomitant smooth muscle tumor of the mesosalpinx in 4 of the 7 cases of carcinosarcoma. However, these leiomyomas were regarded as incidental findings.

Foulds (1937) described "mixed" tumors in the course of transplantation experiments with a carcinoma of the chicken. The original tumor was believed to have arisen from the shell-secreting glands of the oviduct. In one series of transplants, bone tissue was found mixed with the carcinoma cells. Foulds discussed this feature at some length and concluded that the bone was formed either in the hyaline matrix secreted by the carcinoma cells or in the fibroblastic stroma produced by the host.

The tumors we classify as carcinosarcoma can be interpreted in different ways. They may be simple adenocarcinomas in which a highly active stromal reaction occurs and, therefore, may be considered as scirrhous adenocarcinoma. They may have originally been simple carcinomas which stimulated a stroma to the extent that it became neoplastic. On the other hand, they may have begun initially as true mixed tumors. The presence of smooth muscle tissue mixed with fibroblasts and the apparent ability of the connective tissue elements to form peritoneal implants free of the epithelial component suggest the malignant nature of the stroma. Jackson commented that such implants can be explained on the basis of assuming a primary implant of the carcinoma which became destroyed by the more rapidly growing stroma. Carcinosarcoma should not be confused with the process occasionally noted in which a connective tissue tumor infiltrates a glandular structure and causes metaplasia of the epithe-
FIG. 32.22 — Carcinosarcoma showing the extensive, diffuse implantation of the neoplastic tissue over the surface of the mesentery.
FIG. 32.23 — Carcinosarcoma. Tissue from an implant on the serosa of the mesentery. The essential features are the irregular acini of epithelial cells and the abundant stroma of immature connective tissue elements. ×600.

lial elements. Such a process might simulate a carcinosarcoma.

Although there is some confusion surrounding carcinosarcomas at this time, such neoplasms as described do seem to exist as an entity in the chicken and can be distinguished from other neoplasms. Future study should clarify their position as well as determine their histogenesis.

Teratomatous tumors. Our experience agrees with that of Hoogland (1929) that in the chicken, teratoma and teratoid tumors occur most frequently in the ovary and in the testicle. A teratoma of the ovary of a goose was recorded by Babic (1931). Grossly, those of the ovary have resembled carcinoma, and a microscopic examination has been necessary to reveal the true character of the neoplastic process. Usually the ovary has been involved extensively, and secondary foci representing implantation metastatic growths were commonly present. The propensity for ovarian teratoma to produce cysts containing gelatinous or mucoid material was well illustrated in several of our cases. In two of the six cases in our collection, metastatic foci had been established in the lungs.

The microscopic appearance of these tumors is of some interest. A brief summary of the histologic characteristics of the six cases mentioned follows:

Case 1. The growth consisted of a mixture of (1) squamous epithelium; (2) columnar epithelium, with and without mucin; and (3) primitive mesodermal cells, with definite sarcomatous changes. Metastasis to the lung, largely of columnar epithelium, had occurred.

Case 2. Much of the tissue had an embryonic appearance. The tumor consisted of (1) large mucus-forming epithelial cells, which were inclined to form cysts containing mucus; (2) squamous epithelium with central areas of keratin; and (3) large amounts of sarcomatous tissue of the histiocytic variety in which mitosis was common. The pulmonary metastasis was predominantly sarcomatous.

Case 3. The mass was quite cystic, and

the following varieties of epithelium were discernible: (1) squamous, (2) high columnar, (3) low columnar, and (4) epithelium composed of mucus-containing cells.

Case 4. The tumor was epithelial in character and contained squamous cells and tall columnar and low columnar cells.

Case 5. This tumor was a mixture of epithelial and undifferentiated sarcomatous elements. Epithelial cells with and without mucus and with cilia were demonstrated.

Case 6. There were present nests of squamous epithelial cells and regions of papillary adenocarcinoma.

In the six cases mentioned, the occurrence of squamous epithelium with the formation of central regions of keratin was the most characteristic feature (Fig. 32.24). The mesodermal elements frequently exhibited a bizarre picture, with undifferentiation a notable feature. In the ovary as well as in the testicle, cells occur which have the inherent possibility of producing tissues representing all three embryonic layers. From such elements, complex, jumbled, tumorlike conditions may arise that may represent an attempt to produce an embryo. However, in our material none of the ovarian teratomas contained tissue representing the entoderm; all were didermic in character. Apparently in the chicken tridermic teratomas are of rare occurrence.

We have observed one didermic teratoma of the testicle, and Jackson (1956a) mentioned a tridermic teratoma of the testicle of a rooster. Our specimen was apparently similar in many respects to that described by Olson and Bullis except that we did not find any cartilage in ours. A few irregular islands of squamous epithelium were also discernible in the midst of mesodermal elements. Babic described two cases of teratoma of the testis in chickens.

The teratomas of the testicle may attain considerable size. The specimen described by Olson and Bullis measured $13 \times 10 \times 7$ cm. and weighed 606 gm. (Fig. 32.25).

FIG 32.24.—Didermic teratoma of the ovary of a 1-year-old chicken. Note several epithelial "pearls" surrounded by sarcomatous stroma. ×120.

In a teratoma that probably arose in the left testicle of a 21-month-old rooster described by Sheather (1911), the mass measured 15 × 11.5 × 7.5 cm. and weighed 500 gm. These tumors are usually well encapsulated and have an irregular

FIG. 32.25.—Teratoma of the testis. A small nodule of normal testicular tissue extends from the lower aspect of the tumor.

nodulated surface. The color varies from grayish-white to dark livid. Necrosis is common, and cysts of variable sizes are likely to be present. Pohl described what he designated adenocarcinoma of the testicle of a rooster that we believe was probably a teratoma.

Teratoma of the testis has been produced experimentally in chickens by Michalowski (Bagg, 1936), Bagg (1936), and Falin and Gromzewa (1940). This has been accomplished by repeated intratesticular injections of small quantities of zinc salts (chloride, sulfate, and nitrate). An associated seasonal factor is present in that teratomas of the testis can be produced only during early spring. This factor may be affected by administration of *gonadotropic hormone*. Baker (*Fowlds*, 1931) succeeded in making two successful transplants of a spontaneous ovarian teratoma of the chicken.

Embryonal nephroma. This tumor, which we have classified perhaps more or less arbitrarily with the mixed tumors, usually originates in the kidney and is one of the commoner neoplasms of chickens. Among the terms applied to this neoplasm are adenoma, cystadenoma, adenomyosarcoma, sarcocarcinoma, sarco-adenoma,

rhabdomyo-adenosarcoma, adenosarcoma, and Wilms' tumor.

Since it is generally agreed that these tumors arise from primitive nephrogenic tissue, a term that indicates their origin rather than one which may be descriptive in a morphologic sense would seem desirable. For this reason we believe that these tumors, regardless of the variations of their structural pattern, should be designated embryonal nephroma.

Histogenesis. It seems a reasonable presumption that this tumor, which is characterized by more or less unpredictable structural variations, has its origin, regardless of anatomic differences that may occur in different specimens, in a multipotent type of nephrogenic cell. Such a cell possesses all the capacity for differentiation inherent in an immature mesodermal cell

While the vast majority of embryonal nephromas occur in the substance of the kidney, these tumors may arise anteriorly or posteriorly, separate and removed from the nephric tissue (Feldman, 1930). The origin of embryonal nephromas in extranephric situations may be explained on the basis of the failure of certain portions of the mesonephron to be utilized in the development of the permanent kidney. These remains of the Wolffian body, instead of retrogressing, continue to grow but without the guiding influences characteristic of normal tissues, and a neoplastic process results.

Frequency of occurrence. The relative incidence of the occurrence of embryonal nephroma in chickens is uncertain. However, it is generally believed that it occurs more commonly in chickens than in mammals. Reliable statistical data on the incidence of embryonal nephroma are meager. Among a total of 113 chicken tumors exclusive of those designated "leukotic tumors" reported by Goss (1940a), 4 were considered embryonal nephromas. In Jackson's (1936a, p. 418) series of avian neoplasms, the embryonal nephromas accounted for 3.5 per cent of the total. Olson and Bullis (1942) found 21 (5.5 per cent)

embryonal nephromas among 384 tumors.

There is no evidence that one sex is more susceptible to the development of embryonal nephroma than the other. Although the majority of these tumors are discovered in chickens during the young adult or adult stage of life, their histogenesis provides possibilities for their early development. In fact, it is likely that in many if not most instances these tumors are present and of demonstrable proportion when the chick is hatched. Whether or not breed is of significance in the occurrence of embryonal nephroma is problematic. Mathews (1929a) expressed the opinion that the Barred Plymouth Rock breed shows a particular predisposition for the development of this tumor.

Sites of occurrence. Most embryonal nephromas are found embedded in or arising from the substance of the kidney, although occasionally a specimen is encountered that has no direct contact with this organ. The tumors are usually unilateral. In 31 of a series of 41 cases in our collection, one kidney only was affected, and in 10 cases both kidneys were affected. Although there has been an impression that the left kidney is involved most often, in our material of 31 unilateral embryonal nephromas, 15 occurred in the right kidney, 14 occurred in the left kidney, and in 2 instances the specific kidney affected is not known. Jackson (1936a), however, mentioned that in 4 specimens in his collection in which the site of occurrence was known, 3 arose from the left kidney and 1 from the right kidney.

Effects on the host. As with many other neoplasms of chickens, it is difficult to determine what the effect of the presence of an embryonal nephroma may be on the well-being of the animal. Since in the chicken embryonal nephroma seldom if ever gives rise to recognizable objective symptoms, one must conclude that if only one kidney is involved and if metastasis has not occurred, the presence of a tumor of this kind is not likely to be a serious physiologic handicap. Exception must of

course be taken in those instances in which the tumor is unusually large. Specimens of such size as to occupy a considerable portion of the abdominal cavity must provide a source of discomfort to the host. Paralysis may result if the tumor causes pressure on the nerves to the leg. If large hemorrhagic cysts should rupture or if there are extensive regions of necrosis, secondary disturbances may develop. If metastasis should occur, the usual effect of malignant lesions may be expected. If both kidneys are affected and the neoplastic process is extensive and progressive, it is conceivable that sufficient nephric tissue may be destroyed to prevent adequate secretion of urine.

Gross and microscopic description. The gross appearance of embryonal nephroma is subject to considerable variation depending on the size and anatomic situation. The size varies within wide limits from a small focus of grayish-pink tissue embedded in the substance of the kidney to huge lobulated masses that have replaced nearly all of the nephric tissue. One of our specimens had an extranephric origin, weighed approximately 200 gm., and measured 7 × 6 × 6 cm. An exceptionally large keratinizing embryonal nephroma in a 5-month-old Barred Rock cockerel was observed at the Ontario Veterinary College (1945). Two tumors were present—one large and one small. The size of the larger specimen was noteworthy. It meas-

ured 15 × 10.5 × 10 cm., and weighed 802 gm. The color may be yellow, grayish-white, or grayish-pink, and while most specimens have a firm fleshlike consistency, small to large cysts and foci of necrosis may provide regions that are soft and spongelike. Small, hard, pearly nodules may be recognized in some specimens (Fig. 32.26). Such dense material was found in abundance in a large keratinizing embryonal nephroma which we described some years ago (Feldman and Olson, 1933).

Although the contour of these tumors is usually irregular and frequently interrupted by fissures of variable depths, the surface of the nonkeratinizing varieties is smooth and glistening. The large keratinizing specimen previously mentioned was quite roughened, owing to the presence of innumerable closely packed, grayish-yellow, kernel-like units of variable sizes. These gave the surface of the tumor a strikingly pebbled or bosselated appearance.

The tumors are usually well supplied with blood vessels, and in large specimens diffuse regions of hemorrhage may be present. When the interior of moderately large to large specimens is exposed by incision, the distinct lobulations are often apparent. Cysts, if present, may contain a semiclear or hemorrhagic fluid.

The multipotent embryonic character of the elements which give rise to embryonal

FIG. 32.26 — Keratinizing embryonal nephroma of the left kidney. Conglomerate masses of hard "pearly" nodules may be seen.

nephromas provides for the widest possible variation of their microscopic appearance. The structure may be relatively simple or confusingly complex even within the substance of the same tumor. The most consistent feature is the great variability of their histologic appearance. No two are alike. It is difficult, therefore, to compose a written description of the microscopic features of a "typical" embryonal nephroma. In cases in which the disease is represented by the occurrence of a tiny focus just visible grossly, the essential morphologic features consist of a compact, more or less diffuse region of undifferentiated spherical or oval cells situated in the cortical zone of the kidney. Encapsulation is not evident, and the neoplastic cells at the periphery of the lesion are infiltrating into the surrounding substance of the kidney. In large specimens in which it may be presumed that the process has existed for a long period, the microscopic picture is more bizarre. The parenchyma of the tumor is highly cellular, and irregular septa of connective tissue dividing the tumor into indistinct lobules may or may not occur. The parenchyma of the process usually presents tubules or ductlike structures (Fig 32.27)

Frequently, solid nests of cuboidal cells arranged in an acinar fashion may predominate. The ductlike or tubulelike spaces are lined by single or several layers of cuboidal or columnar cells which apparently arise from the surrounding undifferentiated elements.

In some regions the undifferentiated elements, which may be cuboidal or spindle shaped, constitute the predominant feature of the histologic picture. In other regions epithelial elements as represented by the adenomatous character of the structure are the most striking feature. Since the structure of the majority of these tumors represents a mixture of undifferentiated and differentiated cells, no useful purpose is served by attempting to determine in a given specimen which of these elements predominates.

Although the tubular spaces in many of these tumors when examined microscopically are apparently empty, in some a mucinlike substance that is probably the product of the cells lining the tubules occurs. If this substance is produced in excessive amounts, large cysts are formed. Striking evidence of the multipotent potentialities of the cells which give rise to embryonal nephroma may be found in

FIG. 32.27 — Embryonal nephroma, kidney of a chicken. Epithelial elements predominate. ×150.

specimens that contain, in addition to the undifferentiated sarcomatous elements, typical hyaline cartilage and bone. We have not recognized striated muscle in our material, although this tissue could conceivably occur.

Fairly frequently, embryonal nephromas of the chicken are encountered in which epithelial elements reveal a marked epidermoid differentiation. This occurred in varying degrees in 6 of 20 cases we have studied. These changes may consist of small foci of rather typical squamous cells resembling in every respect epithelial "pearls." An occasional embryonal nephroma may occur in which keratinization is a predominant feature.

The vascular supply of the tumors is usually considerable, and hemorrhagic extravasations with organizing or organized blood clots may be present. Edema is present sometimes among the stromal elements, and a few to large numbers of eosinophilic granulocytes may occur promiscuously throughout the tumor.

Metastasis. Although mitosis and other evidences of instability and progression are commonly observed in embryonal nephroma, metastatic dissemination of these tumors appears to be relatively infrequent. Metastasis has been recorded by Jackson (1936a), by Mathews (1929a), and by Duran-Reynals (1946b), but has not been demonstrated in the material at our disposal. In our experience most of the larger specimens have been rather well encapsulated, and while infiltration of the neoplastic elements into the substance of the kidney occasionally occurs, this is infrequent. As a matter of fact, the fibrous zone of connective tissue that is usually present between the neoplastic and the nephric elements must be considered a formidable barrier against the invasive tendencies of the tumor. The destructive effect on the kidney of many embryonal nephromas is due to the pressure atrophy and other retrograde influences that ensue as a consequence of the gradual, progressive expansion of the growth. It should be kept in mind, however, that these are at

least locally malignant tumors, and most if not all of these should be capable of setting up metastatic foci if circumstances are propitious.

Transplantability. Duran-Reynals (1946b) attempted transplants from 10 spontaneous cases, 7 of which proved nontransplantable. One yielded a fibroma type of growth, and grafts from another resembled the original embryonal nephroma with sarcomatous features. Neither of these could be carried in serial passage. The third transplantable embryonal nephroma was carried in regular serial passage as a sarcoma. Duran-Reynals and Shrigley (1946) are inclined to regard this as an independent sarcoma since a cell-free etiological agent was demonstrated.

The renal adenocarcinoma produced by the ES-4 leukosis virus was mentioned in the section on fowl leukosis (Carr, 1956). Ishiguro *et al.* (1962) and Heine *et al.* (1962) have studied the nephroblastomas produced by the BAI myeloblastosis virus in considerable detail and consider it to closely resemble the Wilms' tumor since they contain all the elements of the embryonal nephroma.

Diagnostic characteristics. In chickens, as Jackson (1936a, p. 351) pointed out, embryonal nephroma should always be considered when a tumor occurs in or near the kidney or when a tumor is encountered suspended from the lumbar region although somewhat removed from the kidney. Microscopically, these tumors are usually entirely unlike any other neoplasms. The mixture of undifferentiated cuboidal or spindle cells and of adenomatous epithelial structures, keratin, cartilage, or bone should be sufficient for their correct identification.

CONCOMITANT NEOPLASIA

Concomitant or multiple neoplasia, in which two or more distinct types of neoplastic disease occur in the same bird, appears to have received little attention in the past. Although multiple neoplasia has been noted in other animals, especially old dogs (Feldman, 1932), only a few com-

ments were found in the literature on concomitant neoplasia of the chicken. Perhaps the fact that relatively few chickens are allowed to attain advanced age may be a factor in the apparent infrequency of multiple neoplasia. Another explanation for the relatively few observed cases is that they are not recognized since relatively few diagnoses of spontaneous avian neoplasia are made with the aid of histologic examination. Thorough histologic examination is obviously necessary for the recognition of instances of concomitant neoplasia, for without such an examination, unexamined foci of tumors may be assumed to represent metastasis of a primary growth.

Jackson (1936a) discussed "collision" tumors in which elements of two distinctly different neoplastic processes become intermingled to create the impression of a "mixed" tumor. He described an instance of a histiocytic sarcoma and myelocytoma occurring in the same chicken. Babic (1931) described a chicken which had a fibroma of the intestine in addition to hemangioma of the liver, kidney, and serosa of the proventriculus. Jármai (1939) found both fowl leukosis and fibrosarcoma as concomitant tumors in a parakeet.

Olson and Bullis (1942) observed 19 instances of concomitant neoplasia in a collection of 384 neoplasms found in 365 chickens. Of 6 chickens that had lymphocytoma, 4 also had embryonal nephroma, 1 had neurogenic sarcoma, and 1 had leukosis. Of 5 chickens that had fowl leukosis, 2 also had myelocytoma, and 1 had fibrosarcoma. Of 6 birds that had leiomyoma, 4 were also affected with carcinosarcoma, and 2 with carcinoma. Myelocytoma and embryonal nephroma were found in 1 chicken. Histiocytic sarcoma and hemangioma were concomitant tumors in 1 chicken; adenoma of the thyroid and melanoma of the tongue, in another; and a third chicken had an adenoma of the pancreas and a fibrosarcoma in the pelvic cavity.

The possibility of an etiologic relation between neoplasms occurring simultaneously in the same chicken is suggested in cases of concomitant neoplasia. Experimentally, several strains of the agent responsible for fowl leukosis have been shown to be capable of inducing fibrosarcoma. The spontaneous occurrence of this combination of concomitant neoplasia, therefore, may not be entirely due to chance.

Since certain types of spontaneous tumors are relatively common in the chicken, the occurrence of the more common varieties in birds of a group under experimental observation may be anticipated. This probability necessitates extensive and careful provision for the control of experiments designed to attempt transmission of neoplasia in chickens. Concomitant neoplasia may occur in such experimental birds. Usually such cases should be interpreted as a spontaneous neoplasm which occurred in a bird in which a second type of neoplasia also had developed as the result of experimental inoculation. An example is the association of lymphocytoma and fowl leukosis in a chicken which had received material containing the causative agent of fowl leukosis. Olson (1936) observed two such instances and regarded the lymphocytoma as of spontaneous origin and unrelated to the fowl leukosis.

Concomitant neoplasia may develop in experimental birds treated with carcinogenic agents. Murphy and Sturm (1941a) reported the finding of leukemia and adenocarcinoma in a chicken that had received intramuscular injections of dibenzanthracene in lard. The dibenzanthracene was regarded as responsible for the development of both neoplastic processes.

TUMORS OF BIRDS OTHER THAN CHICKENS

Various types of neoplastic disease have been reported from different species of both wild and domesticated birds. Although adequate data are not available to make absolute comparisons, in no other

single species of bird do tumors appear as likely to develop as in the domestic chicken.

The observations at the University of Leipzig from 1899 to 1931 indicate the relative incidence of neoplasia among *various domesticated species of birds* (Eber and Malke, 1932). During this period 2,353 pigeons were submitted to necropsy, and 14 were affected with neoplastic disease, an incidence of 0.6 per cent. Of 720 geese examined, 1 had "chondrosarcoma myxomatodes." Among 692 ducks, 1 had adenocarcinoma of the liver; among 459 turkeys examined, 2 had neoplasms of the liver (mixed cell type of sarcoma); and among 204 pheasants, 1 had adenoma of the lung, and 1 had myxosarcoma of the liver. In the same interval of time 53 guinea fowl, 52 peacocks, and 25 swans were examined, in none of which was neoplastic disease found. A total of 11,903 chickens were examined, and 3.12 per cent (371) had tumors. Babic (1931) in Yugoslavia reported 16 cases of neoplasia in birds other than chickens. These were encountered during the period between 1925 and 1931. In this interval 59 pigeons were examined, 5 of which had tumors; 27 parakeets, 3 of which had tumors; 45 canaries, 1 of which had a tumor; 40 geese, 2 of which had tumors; 29 turkeys, 2 of which had tumors; 10 pheasants, 1

of which had a tumor; 14 owls, of which 1 had a tumor; 2 storks, of which 1 had a tumor. Of 81 ducks examined, none revealed the presence of neoplasia.

Fox (1923) listed 44 neoplasms found in captive wild birds. Eleven varieties of *tumor were identified.* Species most commonly affected were in the family of Psittacidae and accounted for 23 of the cases, 16 of which were in the undulated grass parakeet *(Melopsittacus undulatus).* It is of interest to note that in a bird of this species Jármai (1939) found a sarcoma and fowl leukosis, and Schlumberger (1954) has reported over 100 spontaneous pituitary tumors in parakeets. Epidermoid carcinomas of the feet of wild birds were reported by Emmel (1930).

Neoplasms in other species of birds are quite similar in general character to those found in chickens. Most reports in the literature concern cases of epithelioblastoma and tumors of connective tissue. Apparently lymphocytoma may occur to a significant extent in turkeys. Simpson *et al.* (1957) report the disease in 60 of a flock of 1,200 8-month-old turkeys. Most of these were nodular in character suggesting partial resistance of the host. Neoplasia of the lymphoid cell system may be encountered occasionally in various species of birds but in none is it as common as in the chicken.

External Parasites of Poultry

Ectoparasites of poultry comprise a relatively large group. Certain species are well known, but it is difficult to evaluate the importance of some because their distribution has not as yet been accurately determined. Furthermore, those parasites believed today to be of relatively minor importance may prove later to need more attention as their number increases or as they become more widely distributed or recorded. Because of the large number of species of external parasites of bird hosts, this discussion will primarily be limited to those of the domesticated chicken, turkey, guinea fowl, duck, goose, and pigeon of the mainland of North America.

Before considering the external parasites individually, it appears advisable to review the group. This will orient them with relation to the internal parasites and to the animal kingdom in general.

Basically, external parasites are all those living forms which, for the purpose of

securing food, live on the exterior of the host's body. Thus might be included not only animal parasitic forms but also certain viruses, and parasites belonging to the plant kingdom, such as the bacteria, molds, fungi, and yeasts, some of which attack the skin or feathers. However, of chief concern are those *animal* forms that live as parasites on birds. Even some of these do not confine themselves entirely to the surface, although probably at some remote period of evolution they were strictly external parasites. Examples of this peculiarity include the scaly-leg mite that tunnels into the epithelium of the lower legs, certain quill mites that enter the quill bases, and the subcutaneous and airsac mites that live beneath the skin and in the internal organs, respectively.

Certain ectoparasites of birds actually eat the dead cells of the skin and its appendages, e.g., lice. However, for most of them the skin merely serves as a conven-

[925]

ient medium through which they draw blood or lymph and from which they obtain warmth and shelter.

Ectoparasites may be closely confined to their hosts during the entire life cycle, as is true for bird lice, transmission taking place by host contacts. Others wander freely from bird to bird. Some are highly host specific, which contradicts the viewpoint that chicken lice, for example, propagate on horses or other animals. On the other hand, some species may maintain a rather loose relationship to their food supply. Adapted as they are to living on birds, they do not always confine their activities to one particular host species or even to birds as a group. Such forms include certain of the host-cosmopolitan insects: the gnats, mosquitoes, bedbugs, and fleas. Other external parasites, e.g., the fowl tick and the common red mite, attack birds only at night, hiding in surrounding shelters during the daytime.

Variations in habits such as noted above are important when control measures are to be considered. Mites, as a group, cannot be successfully controlled by any single method of attack because of habit variations among species. This indicates the necessity for accurate identifications as a preliminary. In case of doubt the various state and national diagnostic services may be called upon for assistance.

CLASSIFICATION

Practically all external parasites of birds belong in the invertebrate animal group (phylum ARTHROPODA). The arthropods are jointed-limbed animals without a vertebral column. Nearly all those parasitic on birds and on other animals are further characterized by having tracheal tubes for breathing.

Arthropods with antennae include the parasitic insects (class INSECTA), such as lice, "bedbugs," fleas, beetles, flies, and gnats. Of these, only the last three have wings. The insect body is divided into head, thorax, and abdomen. The legs and the wings (if present) are attached to the thorax. Insects are further distinguished by having three pairs of legs in the adult stage.

Arthropods not having antennae include the spider-related arachnids (class ARACHNIDA) of which many of the mites and all of the ticks are parasites. The arachnid body consists of a combined head and thorax (cephalothorax) not usually marked off from the unsegmented abdomen. The legs of arachnids are attached to the cephalothorax. There are typically four pairs of legs in the adult and the nymphal stages, whereas the larval arachnid is provided with only three pairs.

CONTROL IN GENERAL

The use of insecticides and acaricides on domesticated poultry may be divided into two eras: prior to 1940 and after 1940.

Prior to 1940 the following chemicals and methods had been used for many years: Dust baths containing wood ashes, "road" dust, tobacco, slaked lime, and sulfur; liquids, powders and ointments containing sulfur, caraway oil, balsam of Peru, mercury compounds, pyrethrum, derris, sodium fluoride, sodium fluosilicate, naphthalene; fumigants such as sulfur dioxide, hydrogen cyanide; the use of heat by the application of scalding water to buildings and equipment.

Many of the preceding therapies were quite effective and economical but, since 1940, most of them have been abandoned.

Attempts to control external parasites of poultry by means of chemicals administered internally (systemic therapy) via feed and water apparently originated on a commercial scale in the early 1920's. Parman and associates (1928) tested 30 such substances but none was of practical value. From 1937 to 1951 other workers attempted systemic therapy without significant success (Emmel, 1937; Creighton et al., 1943; Richter and Insko, 1948a; and Menon et al., 1951). More recently there is renewed interest in systemic therapy. The results are somewhat encouraging as described by Kraemer and Furman (1959),

Hoffman (1961), and Furman and Pieper (1962) and others.

After 1940 and especially since 1945 (the end of World War II) an impressive number of organic chemicals have been manufactured for the control of ectoparasites. Beginning with DDT the list has grown rapidly and is still increasing almost monthly. The poultry producer and feeder are confronted with a rather confusing array of products and claims for efficiency. Limitations of space in this chapter make it impossible to discuss each of the newer pesticides; their formulation, dosage, methods of application, efficacy, toxicity, and the contraindications to their use. Instead, it might be advisable to first summarize the more important criteria for an acceptable insecticide or acaricide as follows:

1. It should kill one or more species or groups of parasitic insects, mites, or ticks.

2. It should be economical to the user and profitable to the manufacturer and dealer.

3. It should be in an easily prepared form and it must maintain its potency for a reasonable length of time.

4. Directions for its dosage and application should be plainly and completely stated. The user must be informed whether it is to be applied to individual birds or to flocks directly; or to litter, nests, roosts, dropboards, walls, soil, or to the air of the poultry building. Mechanical devices such as sprayers and powder blowers should be specified. The exact method of dilution, if any, should be stated.

5. Any possible toxicity to birds should be clearly indicated; especially the effects on production and fertility (Smyth, 1956; Albert, 1962).

6. The user should be warned regarding toxicity of pesticides to man during their application, or later as the result of chemical accumulations (residues) in and about poultry buildings and on clothing.

7. Obviously, a chemical must not be toxic to the consumers of poultry meat and eggs (Smyth, 1956) nor should its use have

any detectable effect upon the odor or flavor of poultry products.

Research may eventually bring about the development of efficient and safe insecticides and acaricides. Until then the factor of human error must constantly be considered. The newer chemicals should be field-tested until their value in all respects is proved. Perhaps the present-day pesticides may eventually be replaced by nonchemical biological control methods (see Rietz, 1960; deOng, 1960) including preventive and therapeutic immunization of poultry against external parasites.

SPECIFIC RECOMMENDATIONS FOR CONTROL

Several recent publications may be used as guides to the development and use of pesticides (deOng, 1956; Metcalf, 1957; Frear, 1961, 1962).

Specific control measures may be obtained from manufacturers and their representatives, from veterinary parasitology books and related periodicals as well as from the *Journal of Economic Entomology* and from *Poultry Science*. The bulletin offices of state agricultural experiment stations and the office of information of the United States Department of Agriculture may be appealed to for publications on external parasites of poultry. Local veterinary practitioners, extension veterinarians and entomologists, also veterinary diagnostic laboratories are excellent sources of information and service.

Annually the entomology staff of the Iowa State University of Science and Technology prepares a "Summary of Iowa Insect Pest Control Recommendations" under the sponsorship of the Cooperative Extension Service (Publication IC-328). The following information is quoted from that publication which was issued January 1961:

I. Against chicken lice, bedbugs, and roost mites:

CO RAL: Add 6 ounces of 25 per cent Co Ral wettable powder to 15 gallons of water for spraying 500 to 600 chickens. Spray roosts and nests also. In dust boxes, use 1 ounce

of 25 per cent Co-Ral wettable powder to 3 pounds of sand, dust, or talc for 50 birds. Do not use within 7 days of slaughter.

MALATHION: Use 1 pint of 50 to 57 per cent malathion emulsifiable concentrate in 6½ gallons of water (enough for 6,500 square feet of surface). Spray walls, ceilings, roosts, nests, and litter. Spray birds lightly.

OR: Use 1 pound of 4 or 5 per cent malathion dust scattered on 50 to 60 square feet of litter. Put a handful in each nest. The spray method does a faster job of control.

SEVIN: Use 2 pounds of 50 per cent Sevin wettable powder in 25 gallons of water Spray 1 to 2 gallons for 1,000 square feet of wall, bedding, litter, and roost surfaces Do not treat litter in nests

OR: Use 1 pound of 5 per cent Sevin dust per 100 birds. Apply by means of a shaker can or hand duster Apply 1 pound of dust to each 40 square feet of litter and roosts. Do not treat litter in nests.

2. Against the northern fowl mite or feather mite:

CO-RAL Use dust boxes as recommended against lice, bedbugs, and roost mites

MALATHION: Use 1 pint of 50 to 57 per cent emulsifiable concentrate in 6½ gallons of water. Spray the vent area of each chicken lightly, as well as the entire house. Also use a dusting box containing 1 pound of 4 or 5 per cent malathion dust in 3 pounds of talc, flour, or wood ashes.

SEVIN: Use as recommended against lice.

3 Against lice on turkeys on range:

CO RAL: Apply 15 ounces of 25 per cent Co-Ral wettable powder in 25 gallons of water per 2,500 to 3,000 turkeys. Do not use within 7 days of slaughter.

MALATHION: Use 2 quarts of 50 to 57 per cent emulsifiable concentrate in 25 gallons of water to treat 5,000 turkeys Use a crop-sprayer boom on the ground. Spray upward with a fine spray and drive the birds over the boom. Do not use within 7 days of slaughter.

SEVIN Use as for lice on chickens.

Continuing to quote from the Iowa State University, Cooperative Extension Service, Publication IC-328 (January 1964):

Urge insecticide users to read and follow di rections on the label. Avoid insecticide use when wind currents are such that the chemical might drift onto adjacent forage crops or pastures. Failure to take all precautions may result in excessive residues appearing in meat, milk, or harvested crops. Such contamination may result in seizure by governmental agencies. ALL INSECTICIDES ARE POISONS AND SHOULD BE USED WITH CARE. Do not overdose. Wash hands following use of chemicals, and if any is spilled on the clothing, change to clean, dry garments. Completely destroy all empty insecticide containers. Do not reuse. Many of the organic phosphorus insecticides break down rapidly in alkaline water (pH above 7.0). We find that the pH of municipal water supplies in all of Iowa's larger cities and towns ranges from 8.0 to 9.0. This is alkaline enough to reduce the killing power of the insecticide in a short time. To counteract alkalinity, add 1 to 2 teaspoonfuls of vinegar per gallon of water. Unsoftened well water ranges from pH 7.2 to 7.5. The addition of one half teaspoonful of vinegar per gallon will make such water slightly acid. You can determine the pH of your water supply by using a soil testing kit; or consult your city water department.

LICE

These insects are the most common and widespread external parasites of birds. They all belong in the order MALLO-PHAGA, these lice having chewing mouthparts. Most authorities agree that there are more than 40 species of lice reported from domesticated fowls. A survey of the literature, however, shows considerable variance in the listing of North American species and a decided disagreement on the scientific names assigned to them. Fortunately, as far as the veterinarian and the poultry raiser are concerned, the various species of bird lice are at present all controlled by the same methods. Birds frequently harbor several species of lice at the same time.

The following list of lice of North American poultry is from Hopkins and Clay (1952) and from Emerson (1956).

Chicken lice:

Cuclotogaster heterographus, head louse
Goniocotes gallinae, fluff louse
Goniodes dissimilis, brown louse
Goniodes gigas, large body louse

Lipeurus caponis, wing louse
Menacanthus cornutus, body louse
Menacanthus pallidulus, small body louse
Menacanthus stramineus, body louse
Menopon gallinae, shaft louse

Turkey lice:
Chelopistes meleagridis, large body louse
Menacanthus stramineus, body louse
Oxylipeurus polytrapezius, slender louse

Guinea fowl lice:
Goniocotes gallinae, fluff louse
Goniodes dissimilis, brown louse
Goniodes gigas, large body louse
Goniodes numidae, feather louse
Menacanthus stramineus, body louse
Menopon gallinae, shaft louse

Duck and goose lice:
Anaticola anseris, slender louse
Anaticola crassicornis, slender louse
Anatoecus dentatus, duck and goose louse
Menopon gallinae, shaft louse
Menacanthus stramineus (rarely), body louse

Pigeon lice:
Campanulotes bidentatus, small louse
Coloceras damnicorne, little feather louse
Colpocephalum turbinatum, narrow body louse
Columbicola columbae, slender louse
Hohorstiella lata, large body louse

Lousiness (pediculosis) of birds is diagnosed by finding on the birds wingless, dorsoventrally flattened, brownish-yellow, quickly moving insects. In size, bird lice vary from somewhat less than 1 mm. in length to the largest species which are slightly more than 6 mm. long (Figs. 33.1, 33.2, 33.3, 33.4, and 33.5). See also line drawings in Whitehead (1942) and Emerson (1956).

Lice spend the entire life cycle on the host. Eggs are attached, often in clusters, to the feathers. The entire life cycle takes about 2 to 3 weeks for completion. One pair of lice may produce 120,000 descendants within a period of a few months. Their normal life span is several months, but away from the birds they can remain alive only 5 or 6 days.

Although bird lice ordinarily eat cast-off bits of skin and feathers and fragments of feces that adhere around the vent, it has been shown by Wilson (1933) that *Menacanthus stramineus*, the body louse of chickens, may puncture soft quills near the bases and consume the blood that oozes out. This was confirmed by Crutchfield and Hixson (1943), and, in addition, they stated that the body louse draws blood by gnawing through the covering layers of the skin itself.

Severe lousiness in poultry originally was thought to follow malnutrition and lead to weight loss as well as to low production. There is conflicting evidence on these hypotheses. Warren et al. (1948) found no effect on laying records even following rather heavy louse infestation. In 1961, Tower and Floyd (1961b) studied the effect of the body louse on egg production in New Hampshire pullets; they found no significant differences between infested and noninfested birds. Kartman (1949) concluded that lousiness is not necessarily an expression of malnutrition of the host; indeed the contrary appeared to be true.

He also noted that debeaking the birds increased the number of lice present. Edgar and King (1950), studying the effect of moderate infestation by the common body louse, concluded that louse-free hens averaged about 11 per cent greater egg production than did those infested, a difference in net income of 75 to 85 cents per bird. Differences in body weight and in mortality between the two groups were not significant. A more recent study by Gless

and Raun (1959) revealed that an average of 23,000 body lice per chicken reduced egg production from 15 to 84 per cent during a 14-week period.

It might be concluded that lice are not highly pathogenic to mature birds. However, there appears to be clinical evidence that lice irritate nerve endings, thus interfering with the rest and sleep so necessary to immature animals. Louse-infested chicks may die. Also, lousiness frequently
FIG. 33.1 — Menopon sp. Chicken louse, male. ×53. (Reis and Nobrega.)
FIG. 33.2 — Cuclotogaster heterographus. Head louse of chickens, male. Greatly enlarged. (U.S.D.A., Bur. Entom. and Plant Quaran.)
FIG. 33.3 — Goniocotes sp. Chicken louse, male. X20. (Reis and Nobrega.)

accompanies manifestations of poor husbandry such as internal parasitism, infectious diseases, malnutrition, and insanitation.

Howitt et al. (1918) isolated the virus of equine encephalomyelitis from the body louse (Menacanthus stramineus). More recently, Meyer and Eddie (1960), also Eddie, Meyer, Lambrecht, and Furman (1962) isolated the virus of ornithosis from Menopon gallinae, the shaft louse, and from mites on chickens and turkeys.

Control of lice. This problem primarily involves the birds themselves, although in heavy infestations the houses should be cleaned and disinfected. Lice multiply most rapidly during cold weather when birds are in closer contact; therefore, it is essential to combat them during the mild days of the fall season so that birds may go into production in the best of health. Once a flock is free from lice, it is important to isolate new additions until their freedom from these parasites has been assured. The use of insecticides against poultry lice is discussed on page 926 under Control in General.

"BEDBUGS" AND ALLIED INSECTS

The insect order HEMIPTERA includes the true bugs, several species of which parasitize birds by sucking blood. Two families are of particular interest. The family Cimicidae contains the true "bedbugs," and the family Reduviidae includes the "assassin bugs." The latter ordinarily are predaceous on other insects; however, some species do attack man and animals.

The true "bedbugs" are flattened dorsoventrally, thus allowing them to creep into crevices where their young are raised. The adults measure about 2 to 5 mm. in length by 1.5 to 3 mm. in width. The color varies according to species from brown to yellow or red. They have small padlike wing remnants. The suctorial mouthpart structure or "beak," which is jointed, folds under the head and part of the thorax when not in use. Deeply pigmented eyes are prominent on the head. The abdomen has eight segments. Stink glands provide the common "bedbug" and its surroundings with an unpleasant odor.

The female "bedbug" lays several 1 mm. sized eggs per day in crevices until about 200 have been deposited. The eggs hatch in about 10 days. There are five nymphal stages, the nymphs feeding at each stage and hiding to digest the meal of blood and to molt their skins. From egg hatching to adulthood requires about 40 days. Nymphs may withstand starvation for about 70 days, and the adults may live about 1 year without food. Feeding usually occurs at night, the bugs becoming engorged with blood within 10 minutes.

If attacked by large numbers of bugs, young birds especially may be seriously depleted of blood. The bites are usually followed by swelling and itching due to the injection of saliva into the wound.

The most widespread of the "bedbugs" is Cimex lectularius (Fig. 33.6), which attacks man and most mammals and poultry. It is most prevalent in temperate and subtropical climates. Poultry houses

FIG. 33.4 — Goniodes sp. Chicken louse, male. ×42. (Reis and Nobrega.)
and pigeon lofts may become heavily invaded.

Other "bedbugs" reported to attack birds include the following species:

Haematosiphon inodora, the Mexican chicken bug, adobe bug, or "coruco," which also occurs in southern and western United States and in Central America. Usinger (1947) has found it in the nests of the California condor and of the great horned owl in Oklahoma Lee (1955a) gives an account of its biology and mentions the turkey as a new host in New Mexico and Arizona. It also attacks man.

Oeciacus vicarius, commonly found in the nests of swallows (particularly barn swallows) whence they may spread to poultry and to man (Myers, 1928).

In addition to the above, numerous other species of the true "bedbug" family have been reported on birds in various countries outside the United States. The insect order HEMIPTERA also includes bugs of the family Reduviidae as previously mentioned. These are usually of minor interest in avian parasitism. "Assassin bugs," "cone-nosed bugs," and reduviids are terms applied to such insects, of which there are many species. Only a few of them have learned to suck the blood of mammals and birds. They are larger than true "bedbugs," being up to 25 mm. in length, and they have well-developed wings; otherwise their morphology, life cycles, and behavior are quite similar. Species of reduviid bugs reported as attacking poultry in the United States include *Triatoma sanguisuga* in Maryland, Florida, California, and Texas, and *Triatoma protracta* in Utah and California. It is of interest to note that in 1910, *Triatoma sanguisuga* was found to harbor the virus of equine encephalomyelitis in
FIG. 33.5 — Columbicola columbae. Slender pigeon louse, female. ×48. (Reis and Nobrega.)

FIG. 33.6 — Cimex lectularius. Common bedbug, male. ×15. (Benbrook and Sloss.)

Kansas by Kitselman and Grundmann (1910). This virus has also been found in natural infections in pigeons and pheasants.

Control of "bedbugs" and allied insects. Treatment must be directed at the birds' surroundings during the daytime, because the bugs ordinarily feed at night. In the past, fumigation with hydrocyanic acid gas or with the sulfur dioxide released by burning sulfur was considered to be an effective control method. The use of in-secticides against "bedbugs" is discussed on page 926 under Control in General.

FLEAS

Many species of fleas have been found on birds, but only six species have been reported from poultry in this country. However, fleas are very adaptable blood-sucking insects and may attack various host species. They are cosmopolitan in distribution although more abundant in temperate and warm climates.

They may be recognized as brown to black, laterally flattened insects having the ability to run rapidly along the skin and to propel themselves in the open by leaping. In size they vary from 1.5 to 4 mm. in the adult stage. The adults suck blood one or more times during the day, although some species are nocturnal. The sticktight flea usually remains attached to the host for days or weeks at a time. Female fleas deposit several eggs per day which roll off the host into surrounding litter where they incubate. Dampness is

essential for further development. The eggs are white, almost spherical bodies less than 1 mm. in diameter. Within one to several weeks, depending upon species and climate, the eggs hatch, liberating tiny maggotlike larvae that feed partly on organic matter found in dust and litter, but their principal food is flea feces deposited conveniently by the adult fleas. This flea feces is rich in host bloodproducts, thus providing a highly nutritious diet for the larvae. After the larvae have grown and shed their skins, usually twice in a period varying from one to several weeks, they proceed to spin silken cocoons, entangling the thread with various particles of dust and dirt. Then follows the inactive pupal stage for a period varying from one week to months, depending upon the temperature. During this period the pupae transform into white, then yellow, then brown fleas. Emerging from the pupal cocoons, the young fleas seek a host, suck blood, and reach maturity within a few days.

Immature fleas may live for weeks or months without food. Adult fleas may also live for weeks without feeding, but when a host is available their life span may extend over many months to a year or more. The total length of the life cycle is thus seen to vary greatly depending upon such factors as temperature, humidity, exposure, and host availability.

The fleas of domestic poultry in North America include the following species: *Echidnophaga gallinacea*, the sticktight flea; *Ceratophyllus gallinae*, the European chicken flea; *Ceratophyllus niger*, the western chicken flea; *Ctenocephalides felis*, a cat flea; *Pulex irritans*, the human flea; and *Orchopeas howardii*, a squirrel flea. These will be discussed before flea control is considered.

Echidnophaga gallinacea (Fig. 33.7), the cosmopolitan sticktight or tropical chicken flea, more often occurs in the southern United States, although occasionally it is found as far north as New York. The adult is about 1.5 mm. long and is reddish-brown in color. These fleas usually
FIG. 33.7 — *Echidnophaga gallinacea*. The sticktight or tropical chicken flea, female. Greatly enlarged. (U.S.D.A., Bur. Entom. and Plant Quaran.)

attach to the skin of the head, often in clusters of a hundred or more. The mouthparts are deeply embedded into the skin so that it is difficult to dislodge them. The adult females forcibly eject their eggs, so that they reach surrounding litter, one to four eggs per day being produced. Incubation takes from 4 to 14 days; the larval period lasts from 14 to 31 days; the pupal period for 9 to 19 days; and the newly emerged fleas mature from 11 to 18 days.

The sticktight flea has been reported from the following hosts: chicken, turkey, pigeon, blackbird, bluejay, hawk, owl, pheasant, quail, sparrow; also man, horse, cattle, swine, dog, fox, cat, badger, coyote, deer, ground squirrel, lynx, mouse, opossum, rabbit, raccoon, rat, ring-tailed cat, and skunk.

This flea has not been accused of carrying infectious disease agents to chickens. The irritation and blood loss attributed to it may damage poultry seriously, especially young birds, in which death may occur. Production is lowered in older birds. Alicata (1942) experimentally transferred the rickettsia of human endemic (murine) typhus from infected rats to guinea pigs through the agency of sticktight fleas, thus indicating a possible public health importance of this parasite.

Ceratophyllus gallinae (Fig. 33.8), the European chicken flea, also occurs in the United States. It has been reported from Maine, Massachusetts, Connecticut, New York, Delaware, Michigan, and Iowa. Undoubtedly, it has a much wider distribution. The hosts include the chicken, pigeon, bluebird, sparrow, and tree swallow; also man, dog, chipmunk, rat, and squirrel. The adult female measures from 3 to 3.5 mm. in length. This flea behaves like most fleas in that it stays on birds only long enough to feed, its breeding activities occurring in the nests and other surroundings. Otherwise, its effects are like those of the sticktight flea.

Ceratophyllus niger, the western chicken flea or black hen flea is reported mainly from the Pacific Coast area, although Bigland (1955) found it in Alberta, Canada. It may attack various mammals and birds including the chicken, turkey, cormorant, gull, magpie, sparrow, and woodpecker; also man, mouse, and rat. Its principal breeding place is in birds' nests. Grossly and in habit it resembles *C. gallinae*.

Ctenocephalides felis is known as the cat flea. It has also been reported from the chicken, pheasant, dog, fox, man, bobcat, coyote, opossum, rabbit, raccoon, rat, shrew, squirrel, and woodchuck. This flea is only an incidental pest of poultry in North America. The adult female may be 3 mm. in length.

Pulex irritans is a flea primarily of man but it may attack chickens. Other hosts are swine, dog, fox, cat, badger, coyote,

deer, ground squirrel, guinea pig, lynx, mountain lion, opossum, prairie dog, rabbit, raccoon, rat, skunk, squirrel, weasel, wild swine, and burrowing owl. The adult female may be 4 mm. long.

Orchopeas howardii, a flea ordinarily found on squirrels, has been noted to attack chickens in Massachusetts, according to Shaw and Clark (1953). Other hosts include the dog, fox, cat, man, bobcat, chipmunk, coyote, mink, mole, mouse, opossum, rabbit, raccoon, rat, shrew, squirrel, weasel, woodchuck, owl, and swallow. The adult female is about 2.5 mm. in length.

Fox (1940) and Hubbard (1947) report many other species of fleas found on birds other than domesticated poultry.

Control of fleas. This involves not only ridding the birds themselves of fleas, particularly the sticktight flea, but also ridding the nests and housing areas of these parasites. In this respect, flea control methods are quite similar to those used against red mites and bedbugs.

Many homemade and commercial therapeutic agents have been recommended against fleas as pests of man and animals, for example, see Eads (1946), Roberts *et al.* (1947), Stage (1946), Smith (1951), U.S. Department of Agriculture (1955), and Iowa State University (1964). Control of the sticktight flea, *Echidnophaga gallinacea* was reported by Rodriguez and Riehl (1961) using 4 per cent malathion dust. This was applied twice at 28-day intervals and effective control lasted for 150 days after the second application. The mala-

thion dust was placed in dusting boxes or in soil wallows at the rate of 15 pounds per 100 chickens. In addition, the floors were covered with the 4 per cent malathion dust at the rate of 1 pound per 20 square feet.

Poultry, dogs, cats, and rats should be screened away from under buildings, as they may serve to perpetuate flea invasions. Sunlight, hot dry weather, excessive moisture, and freezing hinder the development of fleas; whereas darkness, coolness, dampness, and warmth favor them.

ADULT BEETLES AND BEETLE LARVAE

Beetles are included in the insect order COLEOPTERA. They are stoutly armored insects, having two pairs of wings, the membranous hind wings being covered by horny, sheathlike fore wings termed elytra. The adult female beetle lays eggs from which hatch larvae, commonly called grubs, followed by a pupal stage. The adults and larvae show great variation in habits. Some live on land, others in water. Certain species feed on animal matter, others on plants; thus many species are useful as scavengers or in reducing other insect populations. Numerous species cause considerable harm by destroying plants and plant products or by acting as pests to animals. Other species serve as intermediate hosts for internal parasites.

As far as birds are concerned, certain adult beetles and their larvae may act as pests or may serve as intermediate hosts for internal parasites, particularly certain of the tapeworms. Numerous species of beetles are known to transmit the following tapeworms of poultry: *Raillietina cesticilus*, *Choanotaenia infundibulum*, *Hymenolepis carioca*, *Hymenolepis cantaniana*, and *Raillietina magninumida*. Because beetles make up part of the diet of birds and because some beetles eat avian carcasses, they may transmit bacterial or virus infections; but of this little is known. Theodoridès (1949) lists past records on the beetles injurious to domestic birds and mammals.

Beetle larvae acting as pests of poultry include the following species:

Tenebrio molitor, the yellow mealworm, is ordinarily found in the adult and grub stages consuming grain products stored in mills, warehouses, bakeries, and groceries. The beetles are shiny brown to almost black in color and about 15 mm. long. They may infest setting hens, attacking mainly the feet where the loss of skin may be followed by severe hemorrhage. The larvae or grubs, known as flour, meal, or bran "worms," are smooth, hard, yellow, cylindrical, wormlike creatures about 30 mm. long. These grubs have been found to erode the skin of young pigeons. According to Levi (1957), other related mealworm beetle larvae may produce similar damage.

Alphitobius diaperinus, the lesser mealworm, usually lives on stored grain products. Harding and Bissell (1958) found a heavy infestation of these beetles and their larvae in ground corncobs used as litter for baby chicks. Healthy chicks were not molested but the mealworm larvae had bored into the tissues of those that were dying. This damage might be mistaken for an attack on the living chicks.

Dermestes lardarius, the larder beetle, and related species, ordinarily destroy stored grain products and meats (especially ham and bacon) or feed on hides, skins, furs, museum specimens, or decaying animal matter, notably the accumulated droppings in pigeon lofts. The adult larder beetle is about 7 mm. long, black in color, and the basal half of each wing cover is brownish-yellow crossed by a band of three black spots. The larvae are about 12 mm. long, dark brown above, gray below, and are covered with brown hairs. The larvae may attack the skin of nestling pigeons.

Silpha thoracica, *Silpha apaca*, *Necrophorus vestigator*, and possibly other species of the beetle family, Silphidae (carrion beetles), may also breed in pigeon droppings. The larvae, which are about 15 mm. long, and black, are reported to invade the skin of squabs, and the wounds produced may be secondarily infested by fly maggots.

Control of beetle larval invasions. This

is based upon cleanliness of houses or lofts, from which droppings should be removed frequently. Grain and feed storages and hides and skins should be kept away from birds. If infested, such substances should be fumigated or otherwise treated according to directions that may be obtained from the United States Department of Agriculture. Wounds produced by beetle larvae should be gently cleaned, using commercial benzol to destroy the grubs, followed by daily irrigation with a mild disinfectant solution until healing occurs.

Reporting on the control of bedbugs in chicken houses, Kulash and Maxwell (1945) found that a 5 per cent solution of DDT in kerosene also killed adult dark mealworms, *Tenebrio obscurans*. Harding and Bissell (1958) controlled adult and larval lesser mealworms in brooder house litter by spraying with 0.7 per cent emulsifiable concentrate of malathion; or, with 0.5 per cent DDT spray.

Macrodactylus subspinosus, the rose chafer, is a leaf-chewing beetle that, according to Lamson (1922), is highly poisonous when ingested in quantity by chicks, ducklings, goslings, poults, and young game birds. These beetles are found mainly in the regions of the Atlantic Coast, central states, and Middle West. Symptoms of poisoning appear about 4 to 5 hours after ingestion. The birds become sleepy, the wings droop, and muscular weakness develops. Death may occur in 5 to 24 hours. The condition is diagnosed by finding the beetles in the crop. No specific treatment for affected birds is available, although a saline laxative is advisable. Plants infested with rose chafers may be sprayed with lead arsenate solution.

MOSQUITOES

Although mosquitoes are not as important to poultry as they are to man and other mammals, they are of some direct and indirect interest. Some 110 species have been described from North America. How many of these suck blood from poultry is not known.

Mosquitoes are recognized as two-winged insects belonging to the family Culicidae of the order DIPTERA. Most species are about 5 mm. in length, and the wings are characteristically veined and scaled. The legs and the abdomen are long and slender, and the small spherical head of the female is provided with elongated mouthparts for piercing the skin. The male does not suck blood, but does live from plant juices, nectar, and other fluids.

Mosquitoes deposit their eggs on pools of water in which the larval and pupal stages are passed. The adults emerge from the pupal cases, quickly breed, and then seek a host. In warm weather the life cycle is completed in about 7 to 16 days for the more common species. The adults are most active on quiet days, especially toward evening.

That mosquitoes may attack poultry in swarms is stated by Bishopp (1933), who reported the deaths of numerous chickens in Florida. The offending species was *Psorophora confinnis* (syn. *P. columbiae*). Besides blood loss, the birds appeared to show toxicity from the bites. Edgar and Williams (1948) and Edgar et al. (1951) found that over 99 per cent of the mosquitoes in or near chicken houses in Alabama were *Culex quinquefasciatus*, the southern house mosquito. Others belonged in the genera *Culex*, *Anopheles*, and *Aedes*. Mosquito attacks appeared to reduce egg production.

Yates (1953) stated that although the mosquitoes *Culiseta incidens* and *C. inornata* bite man in the Pacific Northwest; they were more important as pests of livestock, including poultry.

Dow et al. (1957) noted a preference for birds, including chickens, as hosts, by *Culex tarsalis*.

MacCreary and Catts (1951) in Delaware, noted loss of blood and restlessness of roosting chickens when poultry houses were invaded by *Aedes sollicitans*, a salt-marsh breeding mosquito. They also remarked on the large numbers of other species of mosquitoes seen in poultry houses, notably *Culex pipiens*, the house mosquito, also *Culex salinarius* and *Anopheles crucians*.

Fowl pox virus is transmitted by the mosquitoes *Aedes stimulans*, *A. aegypti*, and *A. vexans* according to Brody (1936) and also Matheson *et al.* (1931). The first-named species harbored the virus for 2 days, whereas the last named species continued to infect birds up to 39 days after contacting the virus of fowl pox and pigeon pox Mosquitoes also transmit one type of avian malaria (*Plasmodium* sp.) according to Herman (1938a). For the most part the birds affected are the smaller wild species including canaries Davis (1940) has called attention to the relationship of birds and mosquitoes as hosts for the virus of eastern equine encephalomyelitis. Smith *et al.* (1948) infected seven species of mosquitoes with the virus of St Louis encephalitis of man by feeding them on infected chickens. The mosquitoes transferred the virus back to chickens.

Control of mosquitoes. Mosquito control methods, as applied to dwellings and other buildings and their surroundings, may be used to equal advantage in and around poultry houses and poultry-raising areas.

Iowa State University, Cooperative Extension Service (1964) makes the following recommendations for mosquito control:
DDT: Drain seepage or flood pools where possible, or treat all such pools inaccessible to livestock with one-half cup of 2.5 per cent DDT water emulsion per 1,000 square feet of water surface. Treat brush, weeds, and other mosquito resting places with 2.5 to 5 per cent DDT water emulsion every 7 days. Use malathion in gardens and pastures where livestock are grazing.

DDVP: Use 0.75 per cent DDVP water emulsion on stagnant water at the rate of 2 quarts per 1,000 square feet or as 0.75 per cent DDVP oil solution as a fog to control adults. DDVP does not affect birds or wild mammals in the area.

MALATHION: Spray brush, weeds, and low trees around standing water accessible to livestock with 1 per cent malathion water emulsion every 5 to 7 days.

Keep grass and weeds cut around buildings and spray or dust (4 per cent malathion dust) gardens, flower beds, hedges, and shrubs every 5 to 7 days as long as needed.

A concise discussion of mosquitoes and their control may be found in a leaflet from the U.S. Department of Agriculture (1962c).

Preventive measures by screening and the use of repellents are of doubtful practical value in poultry husbandry.

FLIES AND GNATS

The insect order DIPTERA includes not only the mosquitoes but also many families of flies and gnats. Certain species of these groups may cause harm to poultry in several ways: by sucking blood, by injecting toxic substances, by acting as intermediate hosts for certain tapeworms, by harboring botulinus toxins, or by larval invasion of body openings and skin wounds.

The Pigeon Fly

Pseudolynchia canariensis (Fig. 33.9), the pigeon fly, louse-fly, or flat fly is a rather important parasite of domesticated pigeons in warm or tropical areas. It has been known since 1896 in the southern half of the United States and also occurs in many other countries.

The adult fly is dark brown and about 6 mm. in length. The two transparent wings are somewhat longer than the body. These flies move rapidly through the feathers, and they suck blood, particularly from nestling pigeons about 2 to 3 weeks of age. They may also bite man, inflicting a painful skin wound that persists for several days.

The female pigeon fly deposits on the birds her white larvae, about 3 mm. in length, each enclosed in a pupal case. These roll off the host into the nest, and in a few hours the pupal case hardens and turns black. After a pupal stage of about 30 days, the flies emerge, living for about 45 days, during which time the female deposits four or five young.
FIG. 33.9 — Pseudolynchia canariensis. The pigeon fly, louse-fly, or flat fly. Enlarged. (Drake and Jones.)

Infested pigeons suffer from blood loss and from irritation. Also, the pigeon fly may transmit a protozoan blood-cell parasite, *Haemoproteus columbae*, the cause of a malarialike disease of pigeons.

There are several other louse-flies related to the pigeon fly that infest various species of wild birds, notable among which is the fly *Lynchia hirsuta*, a transmitter of *Haemoproteus lophortyx*, the cause of California valley quail malaria.

Control of the pigeon fly. Because these flies breed in pigeon nests, it is essential to clean the nests and surroundings at 15- to 20-day intervals and to burn or bury the cleanings. Pigeon lofts may be rid of adult flies, according to Levi (1957), by using a pyrethrum-containing fly spray (1 part pyrethrum extract to 2 parts of kerosene). This should not be sprayed on unhatched eggs. Pigeons may be freed from the flies by applying to them several pinches of fresh pyrethrum or derris powder, rubbing it into the skin. Dipping may be resorted to, in which case derris powder, one-half to 2 ounces, is added to 1 gallon of soft water containing 2½ ounces of laundry soap. Yager and Gleiser (1946)

reported complete kill of pigeon flies on a flock of Signal Corps pigeons by dusting each bird with 3 grams of 10 per cent DDT in talc.

Black Flies

These dipterous insects, variously called turkey gnats and buffalo gnats (Fig. 33.10), belong to the fly family of Simuliidae. They are blood suckers, of which more than 600 species are known (Herms and James, 1961). More than 20 species have been reported to attack domesticated poultry in North America. At times they may cause serious damage to man and to livestock. Their importance to poultry raisers is that they may attack in swarms, depleting the birds' blood volume and injecting toxic material. They also transmit certain blood protozoa belonging to the genus *Leucocytozoon*.

Black flies are tiny, hump-backed, two-winged flies from about 1 to 5 mm. in length and black or nearly black in color. The females are vicious blood suckers during daylight hours. They breed in running or slowly moving water from which they may travel several miles in

FIG. 33.10 — Simulium sp. One of the black flies, buffalo gnats, or simuliids. Enlarged. (Iowa State University)

search of blood. Eggs are laid on solid objects at the edge of water. The larvae emerge in 5 to 30 days and enter the water, attaching to stones or other objects. After about 3 to 10 weeks, during which the larvae molt six times, the pupal stage is reached. This stage, too, occurs under water, lasting from a few days to a month. The adult flies emerge during warm weather. Hibernation occurs in the egg or larval stage.

Simuliids are widely distributed, but they occur mostly from the north temperate to the subarctic regions. Reports of their occurrence in this country date back to the early part of the last century when buffalo gnats seriously interfered with homesteading operations in the South. It was then noted that they would swarm on poultry, forcing setting chickens and turkeys to leave their nests, they killed young birds by forcing their way in large numbers under the wings where they sucked blood.

Walker (1927) reported that Simulium bracteatum fatally attacked goslings in Canada, and Gibson (1930), also of Canada, found that Simulium sp. caused losses to chickens and turkeys. Underhill (1939) stated that Simulium jenningsi (syn. S. nigroparvum) and S. slossonae attacked turkeys in Virginia, as far as 15 miles away from their breeding places. In 1923 heavy losses in chicks occurred in western Iowa. Swarms of gnats produced severe anemia,

leaving a hemorrhage at each skin area punctured. The chicks ingested enormous numbers of the gnats so that their crops were distended with them. Edgar (1953), in Kansas, studied the effects of black fly (Simulium meridionale) bites on egg production in April and May. Production dropped from 70 per cent to 20 per cent in 8 days. One hen died but production became normal shortly after the flies disappeared.

It was not until 1932 that disease transmission by gnats to poultry was proved. Skidmore (1932a), of Nebraska, found that Simulium occidentale could transmit Leucocytozoon smithi, a blood protozoan of turkeys. O'Roke (1934) showed that Simulium venustum transmitted Leucocytozoon simondi to tame and wild ducks in Michigan. Fallis et al. (1956), in Canada, reported the transmission of Leucocytozoon simondi, a blood protozoon of domesticated ducks, by the black flies Simulium croxtoni and S. euradminiculum, also Simulium rugglesi. Anderson (1956), also in Canada, found that six species of black flies transmitted the blood microfilariae of a nematode, Ornithofilaria fallisensis, to domesticated and wild ducks.

Black fly control. This is difficult because these pests breed in streams containing rocks, brush, and logs. Stream clearance may help, but it is an expensive procedure. Sweeping the downstream faces of dams may dislodge many pupae. The drifting smoke of smudge fires will repel the adult flies. Birds may be kept within screened enclosures during the daytime, using screen of 24 mesh per inch or smaller. Repellents are helpful, for example, oil of citronella 1 part in light mineral oil 4 parts may be sprayed on the outside feathers. Dove (1945) quoted Hutson's report on the use of 1 per cent DDT dust for the control of the black fly, Simulium venustum, on golf course greens, tees, and shrubbery in Michigan. A liberal dusting kept the premises practically free of flies for approximately 1 week.

Hocking (1953) attempted chemical

control of the black fly *Simulium venustum* in Manitoba streams. Eight compounds were tested in the laboratory and in streams, including heptachlor, DDT, gamma BHC, and parathion. Results were promising, especially for DDT applications made by helicopter.

Common House Fly

Musca domestica, the common house fly, is frequently eaten by birds. It is an intermediate host for two species of poultry tapeworms, namely: *Raillietina cesticillus* of the chicken, turkey, guinea fowl, and quail; and *Choanotaenia infundibulum* of the chicken and turkey. Skidmore (1932b) reports that common house flies that have fed on infected fowl cholera blood can transmit this disease when fed to turkeys. The common house fly as well as *Lucilia sp.*, a blowfly, were capable of carrying eggs of the cecal worm, *Heterakis gallinae*, which contained the protozoan cause of histomoniasis of turkeys, according to Frank (1953).

Biting Midges

Culicoides spp. are biting midges, "punkies," or "no-see-ums," some 35 species of which have been reported from North America. They attack birds and mammals. Fallis and Wood (1957) report them as intermediate hosts for *Haemoproteus nettionis*, a blood protozoon of domesticated ducks in Canada. MacCreary and Catts (1954) found *Culicoides canithorax* on chickens near salt marshes in Delaware, but they could not determine its relationship to disease.

Stable Fly

Stomoxys calcitrans, the blood-sucking stable fly, attacks most mammals and birds. Fortunately, the bite is not poisonous, although such areas may become infected, and the blood that oozes from bites may attract maggot-producing flies. The stable fly is an intermediate host for *Hymenolepis carioca*, a tapeworm of the chicken, turkey, and quail.

Myiasis

Invasion of birds by fly larvae (maggots) is not as common as in mammals. Knipling and Rainwater (1937) mention that *Cochliomyia hominivorax*, the primary screwworm fly, will deposit eggs in wounds on chickens, turkeys, and geese. Maggots hatching from these eggs actively destroy living tissue. Stewart (1929) reported a case of cloacal invasion of a hen by screwworm larvae. Invaded wounds may be treated with Smear No. 62 or 335, developed in the United States Department of Agriculture and reported by Melvin *et al.* (1941).

The nests of wild birds may become infested by the maggots of various species of flesh and blowflies, with disastrous effects on the nestlings.

Certain fly larvae are of interest because, by breeding on decomposing cadavers, they may ingest toxins of the bacterium *Clostridium botulinum*, according to Bishopp (1923). If poultry eat such maggots, the disease botulism may occur. This has been called "limberneck," a term descriptive of one symptom but not characteristic of botulism alone. The larvae of the following species of flies have been incriminated as transmitters of botulinus toxins, Types A and C: *Lucilia illustris* and *Phaenicia sericata* (blowflies); sarcophagid larvae (flesh flies); and larvae of *Cochliomyia macellaria*, the secondary screwworm fly. Prompt burial, burning, or other sanitary disposal of animal cadavers will do much to prevent botulism from these sources.

Schalk (1928) noted that "fly larvae" developing on tuberculous chicken cadavers could transmit *Mycobacterium tuberculosis* when fed to nontuberculous chickens.

MITES

Numerous and important species of mites may affect domesticated and wild birds. Mites belong in the invertebrate animal group (phylum) ARTHROPODA, in the class ARACHNIDA, and, with the

ticks, in the order ACARINA. For classifications of mites, reference may be made to Baker and Wharton (1952) and Baker et al. (1956).

Parasitic mites are microscopic or barely visible to the unaided eye. The main body parts include a usually unsegmented, soft abdomen broadly continued anteriorly by a combined head and thorax (cephalothorax) to which the legs are attached. Some mites breathe through tracheal tubes, others by absorption of oxygen through the soft skin.

The typical mite life cycle consists of the egg, the larva (six-legged), the nymph (eight-legged but sexually immature), and the adult (eight-legged). The cycle, in general, takes from 1 to 4 weeks for completion, depending upon species, climate, and availability of a suitable host.

Most kinds of birds use blood or lymph for food, hence anemia is a more or less constant symptom. It might be expected that blood-sucking mites could easily transmit bacterial and viral infections. The common nest mite, Dermanyssus gallinae, has been reported by Hertel (1904) and by Plasaj (1925) as a transmitter of fowl cholera organisms; and of the fowl spirochaete, Borrelia anserina, by Hart (1938). The same mite from chickens has been shown by Sulkin (1945) to harbor the virus of equine encephalomyelitis, western type; and by Howitt et al. (1948) to harbor the virus of the eastern type. Reeves et al. (1947) recovered western type equine encephalomyelitis virus from the northern feather mite, Ornithonyssus sylviarum, obtained from the nests of English sparrows and yellow-headed blackbirds.

Hofstad (1949) found that the northern feather mite carried the virus of New castle disease (pneumoencephalitis) of poultry after feeding on infected chickens. Hammon et al. (1948) isolated from the northern feather mite of wild birds a virus or a mixture of viruses from which the St. Louis and western equine encephalomyelitis viruses were obtained.

Smith et al. (1944) isolated human St. Louis encephalitis virus from the red mite, Dermanyssus gallinae, in nature, following which they infected mites from experimental chickens and also infected chickens from mites (Smith et al., 1945, 1946, 1947, 1948). Baker et al. (1956) believe the reported transmission of St. Louis encephalitis virus of man by the chicken mites to be inconclusive. Sulkin and Izumi (1947) recovered the virus of western equine encephalomyelitis from the tropical feather mite, Ornithonyssus bursa. This was confirmed by Miles et al. (1951). On the other hand, three later studies with bird mites from natural sources failed to demonstrate their role as vectors of the viruses of St. Louis encephalitis, or of the eastern and western strains of equine encephalomyelitis virus, according to Chamberlain and Sikes (1955), Reeves et al. (1955), and Sulkin et al. (1955). Meyer and Eddie (1960) isolated the virus of ornithosis (Bedsonia sp.) from feather mites (Ornithonyssus sp.) and also from nonparasitic mites found in the nests of turkeys, two and one-half months after the nests had been abandoned because of ornithosis in the flock.

Those mites that move rapidly over the skin will irritate birds to a considerable degree. Other species burrow into the epithelium, causing tissue proliferation and scab formation. Feather loss results from invasion of feather follicles by certain species, the feather bases being destroyed, or the birds may pull out the affected feathers. Although mites are considered ordinarily to be external parasites, several species invade the subcutis or the internal organs of birds. Red mites and feather mites of birds may bite man, producing papules with itching, according to Boyt (1937), Arnold and Arnold (1943). Mandoul et al. (1945), Berndt (1952), Brown (1955), and Judd (1956).

The rearing of bird mites for experimental purposes has been described by Wisseman and Sulkin (1947) and by Chamberlain and Sikes (1950).
FIG. 33.11 — Dermanyssus gallinae. The red or roost mite, female, after feeding. Greatly enlarged. (U.S.D.A., Bur. Entom. and Plant Quaran.)

Red or Roost Mite

Dermanyssus gallinae (Fig. 33.11), the red or roost mite, is probably the commonest and most widespread of all the mites of birds. Because it breeds in the birds' surroundings, attacking mostly at night, it is apt to be overlooked. The adult female measures about 0.69 by 0.1 mm., varying in color from gray to deep red, depending upon its blood content. Wisseman and Sulkin (1917) have described the life cycle, which may be completed in as little as 7 days. Adult females lay eggs in the hosts' surroundings 12 to 24 hours

after their first blood meal. Eggs hatch in 48 to 72 hours when warm. The six-legged larvae, without feeding, molt in 24 to 18 hours, becoming first stage blood-sucking nymphs; they then molt to second stage nymphs in another 24 to 48 hours, soon afterwards molting to the adult stage. Chickens are the commonest hosts, but turkeys, pigeons, canaries, several wild birds, and man may be attacked. English sparrows frequently transmit this parasite because of the habit of lining their nests with chicken feathers.

Red mites may live for several months without food. When hosts are available

they may not only produce anemia, thereby seriously lowering production, but may actually kill birds through extraction of blood. This is particularly true of young birds and of setting and laying hens. Birds in production may refuse to lay in infested nests. This symptom indicates that poultry houses should be examined for mites.

Control of Red Mites. Among the methods for control were those proposed by Emmel (1942), Alicata *et al.* (1946), Hixon and Muma (1947), Peterson (1949), and Moore and Schwardt (1954). More recent recommendations will be found in references such as Linkfield and Read (1958), Hoffman (1960), Rodriguez and Riehl (1958, 1960b), Hoffman and Drummond (1961), and the U.S. Department of Agriculture (1962b).

In summarizing the more recent methods for red mite control, refer to the Iowa State University Summary of Iowa Pest Control Recommendations on page 927.

To prevent red mite infestation, inspect houses frequently; quarantine new birds until inspected; disinfect old houses before admitting birds, and destroy nearby sparrow nests if possible.

Northern Feather Mite

Ornithonyssus sylviarum (Fig. 33.12) is the northern feather mite, so-called because it occurs mostly in temperate and north temperate as well as in subtropical areas. It has been reported from 22 species of birds, including domesticated poultry and English sparrows, also from rats, and accidentally from man. It resembles the common red mite, but differs from it in that it occurs both on birds and on their surroundings more or less continuously, even during the daytime. When infested birds are handled, the mites quickly crawl over the examiner's hands and arms. Parting the feathers reveals the mites, their eggs, cast-off skins, and excrement on the body surface and feathers, making the bird appear soiled. Feather mites are vicious blood suckers. They also cause
FIG. 33.12 — *Ornithonyssus sylviarum*. The northern feather mite, female. X73. (Benbrook and Sloss.)

scabs to form, thus injuring the appearance of dressed poultry (Payne, 1930).

Control of feather mites. This involves both the birds *and* their surroundings. Among the methods for control were those proposed by Payne (1929), Cutright (1929), Povar (1946), Richter and Insko (1948b), Furman *et al.* (1953), Moore and Schwardt (1954), Edgar and McAnnally (1955), Reid *et al.* (1956), Hoffman (1956), and Furman and Coates (1957).

For reports on more recent methods for controlling the northern feather mite, reference is made to Linkfield and Reid (1958), Kraemer (1959), Kraemer and Furman (1959), Rodriguez and Riehl (1959, 1960b), Bigley *et al.* (1960), Knapp and Krause (1960), Simco *et al.* (1962b), and the U.S. Department of Agriculture (1962b).

Specific treatments to control the northern feather mite are found on page 926 under Control in General.
FIG. 33.13 — Ornithonyssus bursa. The tropical feather mite, female. Enlarged. (Reis and Nobrega.)

Tropical Feather Mite

Ornithonyssus bursa (Fig. 33.13), the tropical feather mite, is closely allied to the northern feather mite. It is more prevalent in warm or hot climates although it has been found in the northern United States. Control is accomplished in much the same manner as for the northern feather mite, particular attention being paid to the birds themselves and their nests. See page 926 for specific control methods under Control in General.

Chiggers

Trombicula alfreddugèsi, a chigger, is the six-legged larval stage (Fig. 33.14) of a mite that may infest the skin surface of various bird hosts as well as mammals, including man. The adults are not parasitic. Unfed chigger larvae are from 0.1 to 0.45 mm. in diameter, hence hardly visible unless they are engorged, when they appear as minute red dots. The adults breed on the ground, especially along fence rows or in undisturbed wooded or brushy areas. The larvae attach to the skin, often in groups, by means of their mouthparts, and inject a highly irritant substance into the wound. There follows a liquefaction of the skin which provides the larval chigger with food (Wharton and Fuller, 1952; Jones,

1950). Itching vesicles or even abscesses may form at the points of attachment, surrounded by a zone of hyperemia and edema. Apparently a toxemia may occur as is indicated by the mortality that follows infestation of chicks, especially quail.

Trombicula batatas is a tropical chigger of importance from southern United States to Brazil according to Michener (1916), Doetschman and Furman (1949), and Baker *et al.* (1956). It attacks chickens, tur-
FIG. 33.14 — Trombicula alfreddugèsi larva. A chigger. X130. (Benbrook and Sloss.)

keys, wild birds, man, and domesticated mammals.

Neoschöngastia americana, the chicken chigger, is an important pest of chickens (Ewing, 1929) and turkeys in the southern United States. It also infests quail. Wharton is quoted by Baker *et al.* (1956) as stating that, in North and South Carolina, lesions on the skin of turkeys have to be removed before marketing the carcasses.

Acomatacarus galli, a chigger usually found on the rabbit, rat, and mouse, may be a pest of the chicken, according to Loomis (1956).

Control of chiggers. Most of the recommendations for poultry are based upon those used to combat chiggers on man, or for chiggers on the ground. The older preventive methods, such as the use of powdered sulfur, sulfur ointment, balsam of Peru, and phenol have more or less been replaced by dimethyl phthalate, dimethyl carbate, ethyl hexanediol, and benzyl benzoate. Efficient as they are on man, their use on flocks of birds appears to be impractically expensive at present

Sprays are useful for controlling chiggers on the ground. The Iowa State University Cooperative Extension Service (1964) recommends a spray containing 50 to 57 per cent malathion emulsifiable concentrate at a dilution of one-half pint to 10 gallons of water for 1,000 square feet of vegetation.

Reference is also made to a leaflet on chigger control from the U.S. Department of Agriculture (1956).

Scaly-Leg Mite

Knemidocoptes mutans (Fig. 33.15), the scaly-leg mite, and related species are of common occurrence on various birds, particularly the older ones that should ordinarily be culled from flocks. The mites are almost spherical in shape, short-legged, and adult females are about 0.5 mm. in diameter. The male is less than half the size of the female, and the legs are longer. Lesions are produced on the unfeathered portions of the host's legs and occasionally on the skin of the comb and wattles. Tunnels are bored into the epithelium, causing
FIG. 33.15 – Knemidocoptes mutans. The scaly-leg mite, gravid female. ×150. (Benbrook and Sloss.)

FIG. 33.16 — Lesions produced by Knemidocoptes mutans, the scaly-leg mite. (Benbrook and Sloss.)

proliferation and the formation of scales and crusts (Fig. 33.16). This type of mite invasion of birds corresponds to sarcoptic mange of mammals. Affected birds may be crippled if the infestation is severe. The mites pass through their entire life cycle in the skin. Transmission to uninfested birds progresses slowly by contact with those infested and with their surroundings.

Control of scaly-leg mites should begin by culling or by isolating the affected birds. Additions to the flock should be inspected for lesions. Houses should be cleaned frequently, especially the roosts, which should be sprayed as recommended for red mites.

For individual treatment of birds having scaly-leg, Griffiths and O'Rourke (1950) recommended benzene hexachloride (BHC) as a 0.1 per cent emulsion to be applied to each leg for 30 seconds with a nail brush. Its odor may be transmitted to eggs. Cleland (1953) used 0.5 per cent by

weight of lindane (gamma BHC) in raw linseed oil, which has a less objectionable odor. It may be necessary to repeat scaly-leg therapy at two-week intervals.

Depluming Mite

Knemidocoptes laevis var. gallinae, the depluming or body mange mite, resembles the scaly-leg mite in general structure although it is smaller, the adult female being about 0.3 mm. in diameter. It invades the feathered areas of the epidermis of chickens, pigeons, and pheasants, especially around the feather bases. Intense irritation induces the host to pull out body feathers. The mites are more prevalent in the spring and summer at which time the infestation may spread rapidly by contact. Depluming mites produce injury by interfering with the control of body heat. Some of the affected birds will lose weight and show lowered production.

Control is not easily accomplished. Prompt isolation of affected birds and disinfestation of houses as recommended for red mites should come first. Treatments recommended for individual birds include:

A. Dipping in sulfur 2 ounces, soap 1 ounce, and warm water 1 gallon. This mixture should be thoroughly soaked into the skin and especially into the feet of cockerels. If lice are also present, there may be added to the dip, sodium fluoride or sodium fluosilicate 1 ounce.

B. Ointments may be used, consisting of sulfur 1 part, petrolatum 4 parts; or caraway oil 1 part, petrolatum 5 parts.

C. Moisten affected areas with soapy water, then apply powdered pyrethrum or powdered sulfur with the aid of a powder blower.

D. Possibly 0.1 per cent lindane emulsion may control this mite according to Baker et al. (1956).

Air-Sac Mite

Cytodites nudus (Fig. 33.17) is a mite that has learned to live as an internal parasite of the respiratory system, includ-

FIG. 33.17 — Cytodites nudus. The air-sac mite, male. ×100 (Benbrook and Sloss.)

ing the bronchi, lungs, air-sacs, and bone cavities connected therewith in birds. Air-sac mites have been found in chickens, turkeys, pheasants, and pigeons from many parts of the world. Although not ol common occurrence, these mites are often overlooked because of their small size and peculiar habitat.

The adult female mites are whitish specks, measuring about 0 5 to 0.6 mm. in length and 0.4 mm. in width. No details are known of the life cycle, although the usual speculation is that the mites lay larvae in the lower air passages, that these are coughed up and probably are swallowed, reaching the ground in the droppings. The mode of infection is not known.

There is considerable conflict among observers as to the damage done by air-sac mites. Some are of the opinion that they are practically harmless because their presence has been noted in apparently healthy birds. Others state that the mites are responsible for emaciation, peritonitis, pneumonia, obstruction of air passages, and that they are predisposing factors for tuberculosis. Heavy invasions have definitely been associated with weakness and grave loss in weight, so that the affected birds resemble clinical cases of tuberculosis.

Close inspection of the opened cadaver of an affected bird soon after death will show whitish dots moving slowly over the transparent air-sac surfaces. Identification may easily be made by placing mites in a drop of water on a slide, applying a cover glass, and examining under magnification of 100 diameters. Little information has been published as to the control of air-sac mites. Most writers recommend the destruction of the cadavers of affected birds, followed by disinfection and cleaning of the poultry house. Baker et al. (1956) suggest the possible use of a dust inhalant containing DDT or BHC as a control measure.

Subcutaneous Mite

Laminosioptes cysticola (Fig. 33.18), the subcutaneous or flesh mite, is another example of an originally external parasite invading deeper tissues. It has been
FIG. 33.18 — Laminosioptes cysticola. The subcutaneous mite, female. ×376. (Hirst.)

reported mainly from chickens, also from turkeys, pheasants, geese, and pigeons in many parts of the world.

Perhaps it normally is a parasite of the surface or upper layers of skin cells. However, it is most frequently noticed in the loose subcutaneous connective tissue. It has even been reported as occurring in the muscles, abdominal viscera, lungs (pigeons), and on the peritoneum.

Ordinarily, subcutaneous mites do not appear to influence the health of infested birds, although the lesions produced may make carcasses unpalatable as food for man.

The female mite measures about 0.25 to 0.26 mm. long by about 0.11 mm. wide. A distinctive feature is the transverse constriction around the body posterior to the second pair of legs. The life cycle is unknown except that the female lays embryonated eggs. Neveu-Lemaire (1938) states that the mite will pass through all stages of its development even in the deeper tissues of the host.

Attention is most often called to subcutaneous mites by the occurrence of yellowish nodules up to several millimeters in diameter in the subcutis. These areas are often mistaken for tuberculous lesions. The nodules appear to be caseo-calcareous deposits formed by the bird so as to enclose the mites after they die in the tissues. Large numbers of nodules are most often found in aged emaciated birds. Kasparek (1907) reported *L. cysticola* in pigeons in which the mites were surrounded by nodules in the lungs, causing death.

Perhaps more careful examination of the skin and subcutis of birds under a dissecting microscope might reveal the presence of this parasite more frequently. Otherwise, diagnosis will depend upon finding the characteristic nodular lesions and by seeing the mites or their remains in nodules that have been crushed under a cover glass in a drop of acidulated water, according to Lindquist and Belding (1949).

Apparently no attempt has been made to control subcutaneous mites except by the destruction of affected birds.

Other Mites

Following is a brief discussion of the less frequently reported mites of poultry. They variously damage the skin, eat feathers, or damage feather quills.

Epidermoptes bilobatus (Fig. 33.19) is a skin mite frequently reported from Europe and more rarely from South and North America, according to James *et al.* (1930). It occurs on chickens and apparently may or may not produce lesions. The adult female is about 0.17 to 0.22 mm. long. When lesions are produced, they consist first of a fine scaly dermatitis. This may be followed by the formation of thick, brownish, sharply-edged scabs. Neveu-Lemaire (1938), of France, suggests that the more severe lesions may be due partly to a concomitant fungous infection by *Lophophyton gallinae*; also that birds affected with scaly-leg mites often have depluming mites at the same time. Epidermoptic scabies may at times result in emaciation and even death. Pruritus is a common symptom.

Treatment of infested birds is recommended as for depluming scabies. In addition, Neveu-Lemaire (1938) suggests the use of balsam of Peru and alcohol, equal parts, applied to the skin.

Rivoltasia bifurcata, a feather-eating mite similar to *Epidermoptes*, has been reported on chickens in Europe, by Reis (1939) in Brazil, and by Bushnell and Twiehaus (1945) in a Kansas publication. In size it is said to be 0.25 by 0.15 mm. Only slight damage to feathers has been noted.

Syringophilus bipectinatus is commonly known as a quill mite. Originally described in Europe in 1880, it was not until 1932 that it was reported in the United States by Rebrassier and Martin (Ohio) from the chicken, turkey, and golden pheasant. Schwabe (1956) found this mite on chickens in New Jersey. Hwang (1959) reported *S. bipectinatus* on chickens in Mary-
FIG. 33.19 — Epidermoptes bilobatus. The epidermoptic scabies mite, female. ×200.
(Reis and Nobrega.)

land and Pennsylvania. His paper is illustrated by photographs of affected and healthy quills; also by photomicrographs of adult female and male mites. He also differentiates this mite from *Syringophilus columbae* of pigeons. A similar mite, *S. columbae*, has been described from pigeons by Hirst (1922). Lavoipierre (1953) had previously described the female and the male pigeon quill mite. Wild birds harbor related species. *S. bipectinatus* females measure up to 0.9 mm. in length and to 0.15 mm. in width. The mites appear to cause partial or complete loss of feathers. The remaining quill stumps contain a powdery material in which the mites may be detected under low power magnification. No specific method for control has as yet been described. It would appear advisable to dispose of affected birds, then disinfect and clean their quarters.

Falculifer rostratus (Fig. 33.20), another feather-damaging mite, occurs principally between the barbs of the large wing feathers of pigeons. Although reported mainly in Europe, this mite has been noted
FIG. 33.20 — Falculifer rostratus. A feather mite of pigeons, male. ×68. (Reis and Nobrega.)

in the United States, and it may be more or less widespread. In size, the mite may be 0.8 mm. long (Hollander, 1956). Levi (1957) states that he has not found the feathers to be harmed. There is some evidence that the nymphal stage of the mite may occur in the subcutis or the internal organs.

Pillers (1927) and others recommend that infested pigeons be fumigated with sulfur dioxide gas. This appears to be a tedious and rather dangerous procedure. Yager and Gleiser (1946) treated a group of Signal Corps pigeons for infection by Falculifer rostratus, using 10 per cent DDT in talc. Slight control was achieved in 24 hours, with great reduction of the mites in 5 days, and there was no evidence of toxicity to the pigeons.

Freyana (Microspalax) chanayi, also a feather-inhabiting mite, has been reported from turkeys in Maryland by Chapin (1925). Its prevalence in Texas and Louisiana is mentioned by Bushnell and Twiehaus (1945). These mites congregate in the grooves on the under sides of the shafts of the wing feathers.

Megninia gallinulae is a rarely reported mite, according to Wickware (1921), in Canada. Apparently it is associated with loss of scales from the lower legs of chickens and with a crusty dermatitis in the head region. Neveu-Lemaire (1938) lists a similar species, M. cubitalis, from the body of chickens and turkeys in Europe and North America. The latter species is about 0.4 mm. long. Alicata et al. (1946) were able to reduce drastically the numbers of body mites, Megninia cubitalis, by applying 10 per cent Lethane A-70, NH dust, 5 per cent DDT, undiluted sodium fluoride, or undiluted sodium fluosilicate to Hawaiian chickens. They also found that good control could be obtained for the wing mite, Pterolichus obtusus, by using 10 per cent Lethane A-70 or by undiluted NH dust.

Levi (1957) states that pigeons in South Carolina may have the feathers of the neck and body infested by Megninia columbae.

Nasal Mites

Neonyssus columbae, a nasal mite of pigeons in Texas, was first described by Crossley (1950). It is about 0.7 mm. in length. No further information is available regarding it.

Neonyssus melloi, also a nasal mite of pigeons, was found by Crossley (1952) in Texas and Kansas. Formerly it had been first reported in Brazil.

Speleognathus striatus, a third nasal mite of pigeons, was first found in Texas by Crossley (1952). The mite is white and to 0.5 mm. in length. Clark (1957) reviewed the avian nasal mites belonging to the family Speleognathidae, stating that no pronounced lesions had been found in the hosts.

In addition to the mites listed, numerous other species have been noted on birds in various parts of the world. Some of these no doubt will be found invading

domestic poultry. For the present they may be considered of minor importance.

TICKS

Although ticks are quite important parasites of mammals, they are of relatively minor significance to birds.

Both ticks and mites are invertebrate arthropods of the class ARACHNIDA, order ACARINA. The ticks constitute a blood-sucking superfamily, namely the Ixodoidea. They are distinguished from the mites by being usually larger (to 15 mm. in length) and by the presence of a pair of respiratory openings, one on each side of the leathery abdomen. These openings, called spiracles or stigmal plates are situated either between the bases of the last two pairs of legs (family Argasidae) or posterior to the last pair (family Ixodidae).

A typical tick life cycle includes the egg, the larva (seed tick), the nymph, and the adult stages. After engorging with blood, the female tick drops from the host to hide in soil, humus, litter, tree bark, or crevices during the pre-ovulation and egg-laying periods. From several hundred to several thousand eggs are laid. This takes weeks to months after which the female tick dies. The male previously had died following copulation. After an incubation period, the minute six-legged larvae (seed ticks) emerge from the eggshells and await contact with a suitable host. Feeding on blood is followed by molting of the larval skin and emergence of the eight-legged nymphs that resemble the adults except for maturity of the reproductive organs. One or more additional molts follow before the adult female and male ticks fully develop.

The total length of the tick life cycle varies greatly, depending upon the species of tick, availability of suitable hosts, and climatic conditions. Some ticks complete the cycle within 6 weeks; others may require 2 years. In general, warmth and relative dryness favor tick development, although many species can withstand extremely cold weather. On vacated premises the adults, especially, may remain alive for many months or even several years.

Disease caused by ticks may be of three general types. Foremost is the loss of host blood, which may result fatally. Secondly, there must be considered loss in production, no doubt associated with blood loss, but also possibly due to tick-produced toxic substances. Thirdly, ticks in general are notorious transmitters of other parasites, such as those of avian spirochaetosis, tularemia, babesiosis, anaplasmosis, dirofilariasis, encephalomyelitis, and certain rickettsial diseases, notably Rocky Mountain spotted fever. The first two diseases are of particular interest to poultry raisers. Other avian diseases may be associated with tick transmission as has been suggested by Brown and Cross (1941) for avian leukosis.

Few species of ticks are host-specific, and those found on birds are no exception. The principal ticks reported from birds in North America are:

Argas persicus, the chicken tick that also occurs on geese, ducks, turkeys, guinea fowl, ostriches, pigeons, canaries, various wild birds, and rarely on cattle and on man (Cooley and Kohls, 1944).

Haemaphysalis leporis-palustris, the rabbit tick, is found mainly on rabbits and hares, also on dogs, cats, horses, and rarely on man. It may infest the chicken, quail, and various other wild birds.

Haemaphysalis chordeilis, a wild bird tick, has also been recorded from the turkey in North America, as well as from various domesticated mammals and man (Cooley, 1946).

Amblyomma americanum, the lone star tick, has been found on chickens and turkeys although it is usually a parasite of the horse, cattle, many other mammals, and several wild bird hosts.

Amblyomma tuberculatum, the gopher-tortoise tick, has been found on the chicken. Other hosts include cattle and the dog, several species of wild birds, and the gopher-tortoise.

Ornithodoros hermsi, is one of the ticks that may transmit a spirochete of relaps-

ing fever to man. It has also been found on "fowl," bat, chipmunk, deer, and mouse.

The Fowl Tick

Argas persicus, the fowl tick (Fig 33.21), is the most important tick parasite of birds. Among its many common names are chicken tick, blue "bug," tampan, and adobe tick. In the United States it is distributed mainly in those states along the Gulf of Mexico and the Mexican border. It is also established in many other tropical and temperate areas of the world. Although primarily a parasite of birds, it may be found on mammals. In North America it has been reported from the following hosts: chicken, duck, dove, hawk, magpie, owl, quail, sparrow, thrush, vulture, and wild turkey; also from cattle, dog, and man.

The mature, blood-engorged female measures about 10 mm. in length and about 6 mm. in width, the mature male being about half that size. This tick is relatively easily recognized by its flattened ovoid shape and reddish-brown color. There is no scutum or dorsal shield, which thus distinguishes it as belonging to the tick family Argasidae. The mouthparts are on the ventral anterior surface, hidden from above by the projecting body.

The female fowl tick may lay a total of 700 eggs at several layings, between which she seeks a host for a meal of blood. The eggs are laid in sheltered crevices, including the bark of trees. They hatch from 10 days in warm weather to 3 months during cool periods. The almost microscopic larvae or seed ticks immediately seek a host, although they may live for several months without eating. After feeding on blood for several days, the larvae leave the host for a hiding place nearby, and generally in 1 to 9 days they reach the nymphal stage. Nymphs may do without food for as long as 15 months. However, if a host is available, the nymphs feed during a night, then hide for 10 or 12 days, shed their skins, and reach a second nymphal stage. After about an hour's feeding at night and about a week in hiding, the adult ticks emerge from the nymphal skins, now ready to engorge with blood and reproduce over a period of about 30 days. The adult fowl tick may live for more than 2 years in an unfed state. Loomis (1961), working under laboratory conditions, found the complete life cycle of *Argas persicus* to be from 7 to 8 weeks.

Birds suffer to the greatest degree from attacks of these ticks during the warmer,

FIG. 33.21 – *Argas persicus*. The fowl tick or blue "bug," female, nearly engorged with blood. Dorsal and ventral views. (U.S.D.A., Bur. Entom. and Plant Quaran.)

dryer seasons of the year. The loss of blood may reach the proportions of a fatal anemia. At least there may be expected to be emaciation, weakness, slow growth, and lowered production. Ruffled feathers, poor appetite, and diarrhea are symptoms suggesting tick infestation. Turkeys usually suffer even more than chickens, and recently hatched poults and chicks show the highest mortality

The fowl tick is capable of transmitting a spirochete from the blood of infected birds to that of susceptible birds in many parts of the world. This organism, *Borrelia anserina*, is highly pathogenic. Burroughs (1947) claimed to be the first to find tick-borne avian spirochaetosis in the United States. He allowed fowl ticks (*Argus persicus*) to feed on an apparently normal chicken, which, in 6 days, was positive for *Borrelia anserina* in blood smears. Apparently Brazil is the area nearest to the United States in which avian spirochaetosis commonly occurs. Rokey and Snell (1961) described epizootics of avian spirochaetosis in Arizona associated with infestations by the fowl tick. *Argus persicus* may also act as a vector of *Aegyptianella pullorum*, an erythrocyte-invading protozoan (piroplasm) of birds. The disease thus produced, aegyptianellosis, has not been reported from the Americas. Brown and Cross (1941) found evidence that fowl ticks are agents for the transmission of the virus of fowl paralysis. Howell

et al. (1943) reported that occasionally the fowl tick may transmit the protozoan parasite of anaplasmosis of cattle. Micks (1951) described methods for the laboratory rearing of the common fowl tick.

Control of the fowl tick. This is difficult because the ticks are found on their hosts for about a week and then they hide in the birds' surroundings in order to complete the life cycle.

Among the previous reports on control are those of Bishopp (1911), Dove (1915), Edgar *et al.* (1953), Furman and Weinmann (1956), Lapage (1962), Le Roux (1956), also Rodriguez and Richl (1956, 1957b).

At the present time, malathion and Sevin are recommended as sprays for the hiding places of fowl ticks and red mites. Concise directions for their use are given on page 926 under Control in General. Control methods are also described in a leaflet from the U.S. Department of Agriculture (1962a).

Tickicides should be used according to the instructions of the manufacturer or distributor, keeping in mind their potential toxicity to man and animals.

Other methods for the control of fowl ticks include the use of metal construction, the elimination of tree roosting, using roosts suspended from the ceiling. Frequent inspection is necessary in order to combat ticks before their number has increased to a harmful extent.

Nematodes and Acanthocephalids of Poultry

Nematodes

Nematodes or roundworms are usually elongated, cylindrical, and unsegmented worms. The body is covered with a tough, noncellular layer known as the cuticle. These worms have a well-developed alimentary tract and, in contrast to the tapeworms, are usually bisexual.

The class Nematoda is divided into a number of orders, the members of which are parasitic, semiparasitic, and free-living. In the present article, only those forms that are parasitic in poultry are discussed.

The following key will aid in differentiating the eight families containing species of poultry-parasitic nematodes.

1. Worms with free-living adult generation, that is, males and females developing outside of body; in digestive tract, hermaphroditic females only . . . . Strongyloididae
   Worms without a free-living generation, that is, incapable of producing males and females outside of body 2
2. Worms hairlike or threadlike; esophagus tubular and capillary, the tube embedded in or otherwise in relation to a single row of cells; in crop and small intestine . . . . Trichuridae
   Worms thick as compared with above; esophagus well developed and muscular and with definite triangular lumen, not in relation to a single row of cells 3
3. Cordons or other cephalic ornamentations present . . . . Acuariidae
   Cordons or other cephalic ornamentations absent 4
4. Preanal sucker present 5
   Preanal sucker absent 6

5. Esophagus with distinct posterior bulb containing a valvular
   apparatus . . . .   Heterakidae
   Esophagus without a distinct posterior bulb . . . .   Ascarididae
6. Bursa present   7
   Bursa absent   8
7. Buccal capsule well developed and containing at least six teeth at base;
   oral opening hexangular . . . .   Syngamidae
   Buccal capsule reduced and containing not more than three teeth at base
   or none . . . .   Trichostrongylidae
8. Pseudolabia absent . . . .   Thelaziidae
   Pseudolabia present . . . .   Spiruridae

General Morphology. In general the body of a nematode is spindle-shaped with the anterior and posterior ends attenuated. The body covering or cuticle is usually marked by transverse grooves, and sometimes longitudinal folds or alae may be present. These alae may be confined to the anterior end of the body, in which case they are termed cervical alae; or they may be confined to the posterior part of the body, being then termed caudal alae. The latter are found on the tail of the male worm and, in the case of certain groups, are modified to form a bursa. Cuticular ornamentations are occasionally found on the anterior extremities of certain small groups of roundworms. These ornamentations may take the form of spines, cordons, or shields.

The mouth opening is located at the extreme tip of the anterior end of the body and is usually surrounded by lips bearing sensory organs. In the more generalized type of nematodes, the mouth leads directly into a mouth cavity. This cavity may be considerably reduced or absent in the more specialized groups of nematodes. Directly posterior to the mouth cavity is the esophagus. This part of the intestinal tract may be simple, i.e., consisting of one undivided part, or it may be more complex, consisting of a short, anterior muscular part and a long posterior glandular part. A bulb may or may not be present at the posterior end of the esophagus. Following the esophagus is the intestine which is connected with the anal or cloacal opening in the posterior end of the body by a short rectum.

The nematodes are, with very few ex-

ceptions, sexually distinct. The male can usually be distinguished from the female by the presence of two—sometimes only one—chitinous structures known as spicules which are located in the posterior end of the body. The spicules have been considered as intromittent organs for use during copulation. That the spicules do take an active part in copulation has been observed many times. They have been observed to withdraw and insert alternately over extended periods during coitus. It has been reported that the primary functions of the spicules is to keep the vulva and vagina open and, to some extent, guide the sperm into the female. The female reproductive products are discharged through the vulva, the position of which varies considerably in different groups of nematodes.

Sexual dimorphism is remarkably demonstrated by some species of nematodes. One of the most striking examples of this interesting phenomenon is *Tetrameres americana*, a nematode occurring in the proventriculus of certain kinds of poultry. The globular-shaped females enter the glands of the proventriculus or glandular stomach when very young, and as they begin to swell with eggs, their bodies assume the shape of the lumen of the glands. The adult male worm of this species is very much smaller than the female and retains the usual elongated nematode shape and usually lives free in the lumen of the proventriculus.

Nematodes are found in a variety of locations within the bodies of their hosts. The eyes, air sacs, thoracic and abdominal cavities, and the tracheae are some of the

unusual places that nematodes occur as parasites of avian hosts. The intestinal tract is, of course, the habitat of the largest number of species of roundworms.

Development. Nematodes have both a direct (monoxenous) and an indirect (heteroxenous) type of development. Those worms with life histories of the first type require no invertebrate intermediate hosts to complete their life cycles and constitute approximately one-third of all the nematode species infecting poultry. However, the majority of the species of roundworms found in poultry are of the second type and depend upon such intermediate hosts as insects, snails, and slugs for the early stages of their development.

Regardless of the type of development that a certain species of nematode may have, it normally passes through four developmental stages before it becomes an adult; the latter is the final or fifth stage. Beginning with the second stage, each succeeding developmental stage in the life cycle is preceded by a molt. A molt is usually referred to as a shedding of the skin. In the case of some nematodes the loosened skin or cuticle may sometimes be retained for a short time as a protective covering, while in others it is shed at once.

Aside from the fact that certain nematodes require intermediate hosts to complete their development and others do not, the life histories of most nematodes infecting poultry are essentially the same. The eggs, which are deposited in the location in which the female worms are found, ultimately reach the outside in the droppings. This exo-corporal existence is apparently essential in order that the eggs may be rendered infective for the next host, be it avian or arthropod. The conditions existing within the body of the definitive host are usually inimical to the development of the eggs. However, when once outside the body of the bird host and in the presence of optimum moisture and temperature requirements, these eggs undergo development. The time required for the eggs to embryonate depends somewhat upon the species of parasite since,

under similar environmental conditions, the eggs of some nematodes require only a few days to complete embryonation, while others require several weeks. In the case of nematodes with a direct life cycle, the final host becomes infected by eating the embryonated eggs or the freed larvae. On the other hand, in the case of nematodes with an indirect life cycle, the intermediate host ingests the embryonated eggs or free larvae and retains the larvae within its body tissues. When a suitable final host eats the infested intermediate host containing infective larvae, it will become infected.

Importance of nematodes of poultry. Nematodes, as a whole, constitute the most important group of helminth parasites of poultry. Both in number of species affecting poultry and in the amount of damage done, this group of parasites far exceeds the flukes and cestodes.

Some of our most important individual worm parasites of poultry are found in this group. One species, *Heterakis gallinarum*, plays an important role in the transmission of the protozoan disease known as blackhead. Although considered of little economic importance as parasites of the domestic fowl, this species apparently has caused serious and enormous losses to the poultry industry in the role of a carrier of the blackhead organisms. The gapeworm is perhaps the most serious nematode parasite of young poultry, particularly chickens and turkeys. Until recently, this worm was responsible for considerable losses among young birds both in this country and in Europe. Before changed poultry husbandry practices and other effective control measures reduced its devastating losses, this parasite was dreaded as much as blackhead. Despite all of our efforts to control this worm, serious outbreaks of epidemics among pheasants continue to be reported as due to the poultry gapeworm. Suffice to say, most of the nematodes parasitic in poultry and closely related birds may inflict serious injury to their respective hosts if infections are sufficiently large.

The following list shows species of nematodes found in poultry in this country, with their intermediate hosts, usual locations, and kinds of poultry affected.

NEMATODES OF THE EYE
Thelaziidae

The eyes of poultry are the seat of infection for a single species of nematode, *Oxyspirura mansoni*. This nematode belongs to the Thelaziidae. Members of this family have a buccal capsule which may be well developed or rudimentary, and the vulva may be anterior or posterior to middle of body.

Oxyspirura mansoni (Cobbold, 1879)

Synonym. *Filaria mansoni* Cobbold, 1879.

Description. Mouth circular, surrounded by a 6-lobed chitinous ring (Fig. 34.1A). Two pairs of subdorsal and 1 pair of subventral teeth in mouth cavity.

Male 8.2 mm. to 1.6 cm. long by 350μ wide. Tail curved ventrally, without alae.

Four pairs of preanal and 2 pairs of postanal papillae (Fig. 34.1B). Spicules unequal (Fig. 34.1C); one is 3 to 4.55 mm. long and the other 180 to 240μ long.

Female 1.2 to 2 cm. long by 270 to 430μ wide. Vulva 780μ to 1.55 mm. from tip of tail. Eggs embryonated when deposited.

This roundworm is found beneath the nictitating membrane, conjunctival sacs, and naso-lacrimal ducts of poultry in the states of Florida and Louisiana, and possibly other southern states.

Life history. Sanders (1929) found that an intermediate host was necessary for the successful transmission of this parasite from one bird host to another.

The complete life cycle of the eyeworm as worked out by Sanders is as follows: The eggs of the mature female worm are deposited in the eyes of the bird host. They are then washed down the tear ducts, swallowed, and passed to the exterior in the droppings. The cockroach, *Pycnoscelus (Leucophaea) surinamensis*, which is an
FIG. 34.1 — Oxyspirura mansoni. (A) Front view of head. (B) Ventral view, and (C) lateral view, of male tail. (After Ransom, 1904.) (D) Tail of second stage larva. (After Fielding, 1928.)

Nematodes	Location	Intermediate hosts	Definitive hosts
Oxyspirura mansoni	Eye	Cockroaches	Chicken, Turkey, Peafowl, Ducks
Syngamus trachea	Trachea	None	Chicken, Turkey, Guinea fowl, Goslings, Pheasant
Cyathostoma bronchialis	Trachea	Unknown	Geese
Capillaria annulata	Esophagus, Crop	Earthworms	Chicken, Turkey, Guinea fowl, Pheasant, Bobwhite quail
Capillaria contorta	Esophagus, Crop	None	Turkey, Duck, Bobwhite quail, Hungarian partridge, Ring necked pheasant
Gongylonema ingluvicola	Crop	Unknown	Chicken, Turkey, Bobwhite quail
Dispharynx nasuta	Proventriculus	Sowbugs Pillbugs	Guinea fowl, Turkey, Chicken, Pigeon, Bobwhite quail
Seurocyrnea colini	Proventriculus	Cockroaches	Turkey, Bobwhite quail, Sharp-tailed grouse, Prairie chicken
Tetrameres americana	Proventriculus	Grasshoppers Cockroaches	Chicken
Cheilospirura hamulosa	Gizzard	Grasshoppers Beetles Sandhoppers Weevils	Chicken, Turkey
Amidostomum anseris	Gizzard	None	Duck, Goose
Ascaridia galli	Small intestine	None	Chicken, Turkey
Ascaridia columbae	Small intestine	None	Pigeon
Ascaridia numidae	Small intestine	Unknown	Guinea fowl
Ascaridia dissimilis	Small intestine	None	Turkey
Capillaria obsignata	Small intestine	None	Pigeon, Chicken, Turkey
Capillaria caudinflata	Small intestine	Earthworms	Chicken, Turkey
Ornithostrongylus quadriradiatus	Small intestine	None	Pigeon, Mourning dove
Heterakis gallinarum	Cecum	None	Chicken, Turkey
Strongyloides avium	Cecum	None	Chicken, Turkey
Trichostrongylus tenuis	Cecum	None	Chicken, Duck, Goose, Guinea fowl
Subulura brumpti	Cecum	Grasshoppers Beetles Mealworms	Chicken, Turkey, Bobwhite quail
Subulura strongylina	Cecum	Unknown	Chicken, Guinea fowl, Bobwhite quail

omnivorous feeder, ingests the nematode eggs deposited in the droppings of infected birds. Within approximately 50 days following the ingestion of the infective eggs under experimental conditions, the cockroach contains in its body cavity mature larvae, which are capable of infecting a susceptible host. The mature larvae are often contained within cysts which are located deeply in the adipose tissue or along the course of the alimentary tract of the insect host. Some of the larvae release themselves from the capsules and are found free in the body cavity and legs of the cockroach. When an infected cockroach is swallowed by a chicken or other susceptible host, the infective larva is freed in the crop of the bird host, from which it later passes up the esophagus to the mouth and through the naso-lacrimal duct to the eye.

Experimental evidence indicates that various wild birds are capable of becoming infected with the eyeworm of poultry and, as a result, may serve as sources of infection for domestic birds. Such birds as the blackbird, *Agelaius phoeniceus*, the bobolink, *Dolichonyx oryzivorus*, the wild pigeon, *Columba livia*, the loggerhead shrike, *Lanius ludovicianus*, and the blue jay, *Aphelocoma cyanea*, have been experimentally infected with the eyeworm of poultry. Schwabe (1951) reported the eyeworm to occur naturally in the English sparrow, mynah, Chinese dove, Japanese quail, and pheasant (*Phasianus torquatus torquatus* and *P. versicolor versicolor*) in Hawaii. During the course of an investigation as to the role of the natural reservoir hosts in the spread of the eyeworm in Hawaii, Schwabe decided that the local wild birds are of little importance in the dissemination of this poultry parasite.

Pathology. Birds harboring eyeworms show a peculiar ophthalmia. They appear uneasy and continuously scratch at the eyes, which are usually watery and show much inflammation. The nictitating membrane becomes swollen and projects slightly beyond the eyelids at the corners of the eyes and is usually kept in continual motion as if trying to remove some foreign object from the eye. The eyelids sometimes become stuck together, and a white cheesy material collects beneath them. If left untreated, severe ophthalmia may develop, and as a result the eyeball may be destroyed. The worms are seldom, if ever, found in the eyes when severe symptoms are manifested, presumably due to unfavorable conditions existing there.

NEMATODES OF THE RESPIRATORY TRACT
Syngamidae

These roundworms, commonly designated as gapeworms, inhabit the trachea of young chickens, turkeys, and guinea fowls (Fig. 34.2). They are the cause of the disease known as "gapes." The gapeworm belongs to the family Syngamidae. Members of this family are characterized by having the vulva in the anterior part of the body, with stoma well developed and hexagonal in cross section, and with corona radiata reduced or absent.

Syngamus trachea (Montagu, 1811)

Synonyms. *Fasciola trachea* Montagu, 1811; *Syngamus trachealis* Siebold, 1836.

Description. Red worms, the color more pronounced in female. Mouth orbicular, with a hemispherical chitinous capsule, usually with 8 sharp teeth at the base. Mouth surrounded by a chitinous plate, the outer margin of which is incised to form 6 festoons opposite each other. Male permanently attached in copula to female, forming a Y (Fig. 34.3B).

Male 2 to 6 mm. long by 200μ wide. Bursa obliquely truncated, provided with rays, sometimes with strikingly asymmetrical dorsal rays. Spicules equal, slender, short, 57 to 64μ long.

Female 5 mm. to 2 cm. long (longer in the turkey) by 350μ wide. Tail end conical, bearing a pointed process. Vulva prominent, about one-fourth of body length from anterior end, but the position varies with age. Eggs 90μ long by 49μ wide, ellipsoidal, operculated (Fig. 34.3A).

The gapeworm, *Syngamus trachea*, is

FIG. 34.2 — Syngamus trachea. Trachea showing attached gapeworms.

FIG. 34.3 — Syngamus trachea. (A) Enlarged egg showing fully developed embryo. (B) Drawing of male and female gapeworms.
sometimes designated as the "red-worm" or "forked-worm" because of its red color and because the male and female are joined together so that they appear like the letter Y. This parasite is cosmopolitan in distribution.

Life history. The life history of the gapeworm is peculiar in that transmission of this parasite from bird host to bird host may be successfully accomplished either directly by the feeding of embryonated eggs or infective larvae, or indirectly by the ingestion of earthworms containing free or encysted gapeworm larvae which they had obtained by feeding on contaminated soil. The female gapeworm deposits its eggs through the vulvar opening underneath the bursa of the attached male into the lumen of the trachea. The eggs reach the mouth cavity, are swallowed, and pass to the outside in the droppings. Following a period of incubation of approximately 8 to 14 days under optimum conditions of moisture and temperature, these eggs become embryonated. Soon after embryonation, some of the eggs may hatch, the larvae living free in the soil. Should specimens of the earthworms, *Eusenia (H) foetidus* and *Allolobophora (H) caliginosus*, and perhaps others, be present in the soil which has been contaminated with feces containing the eggs of gapeworms, these annelids will become infected with gapeworm larvae. Within the earthworm, the larvae penetrate the intestinal wall, enter the body cavity, and finally invade the body musculature in which they may encyst for an indefinite period. Taylor (1938) stated that gapeworm larvae may remain infective to young chickens in the earthworm for as long as 4½ years. This author also found that slugs and snails may also serve as transfer hosts of *Syngamus trachea* larvae and that live gapeworm larvae were obtained from snails over a year after infection. These mollusks are not essentially true intermediate hosts in the strict sense of the word, since they are not absolutely necessary for the successful transfer of the gapeworm to other susceptible bird hosts.

Clapham (1934) and other investigators have observed that strains of *Syngamus trachea* taken from various wild and domestic birds were more readily transferred to young chickens and with a greater degree of success if the earthworm was employed as an intermediary.

The exact path of migration of the gapeworm larva after it has once entered the intestinal tract of the avian host until it reaches the lung is not known. Walker (1886) believed that the larvae, *after being swallowed by the definitive host, passed through the esophageal wall and entered the lungs directly from the outside*. More recent observations have indicated that the path of migration may be via the blood stream. However, convincing evidence which tends to show the true path of migration is still lacking.

Observations by Wehr (1937b) have shown that the infective larvae reach the lungs in an apparently unchanged condition within at least 6 hours after they have been ingested by the bird. By the third day following inoculation, the larvae have developed to the fourth stage, and by the seventh day several fourth-stage larvae and a few immature adults — one pair of the latter in copula — were found in the lungs; five pairs of immature adults in copula were found in the trachea. It is evident from these and other observations that the male and female of *Syngamus trachea* may copulate as young adults while in the lungs sometimes between the third and seventh days following infection, and that the worms reach the trachea about the seventh day after ingestion of the embryonated eggs and larvae. *These findings differ from those of Ortlepp (1923) who believed that the fourth stage was the final stage in the development of this nematode, and that the second-stage larvae represented the infective stage. This latter observation is obviously an error,* since the gapeworm embryo has been observed to molt twice inside the egg.

Approximately two weeks are required for the infective larvae to reach sexual maturity and for eggs to appear in the

droppings. About one-half of this time is spent in the lungs and the other half in the trachea.

The role played by the wild birds in the spread of gapeworm disease is still undecided. So far as it is known at the present time, wild birds probably are not an important factor in the spread of gapeworm disease in this country.

Pathology. Young birds are most seriously affected with gapeworms. The rapidly growing worms soon obstruct the lumen of the trachea and cause the birds to suffocate and die. Turkey poults, baby chicks, and pheasant chicks are very susceptible to infection with gapeworms, whereas the young of the other species of poultry which have been experimentally inoculated with the infective eggs and larvae of gapeworms are not so seriously affected. Turkey poults usually do not develop gapeworm symptoms earlier and begin to die sooner following gapeworm infection than young chickens. Experimentally infected guinea fowls, pigeons, and ducks do not exhibit characteristic symptoms of gapeworm infections. Young pheasants, however, suffer from the disease to an extent comparable to that of young chicks and turkey poults. Full-grown birds rarely show characteristic gapeworm symptoms, unless heavily infected. Investigators in this country have indicated that chickens 10 weeks or older are very difficult to infect experimentally with gapeworms. However, Crawford (1940) reported that gapeworms occurred commonly in the trachea of fowls of all ages, even in 3-year-old hens in Ceylon. He stated that the number of worms found in the trachea of each fowl was usually small and that adult hens not infrequently were seen to exhibit typical symptoms of gapeworm disease. He considered the adult fowl to be an important factor in the perpetuation of gapeworm disease in Ceylon. Olivier (1943) reported the occurrence of *Syngamus trachea* in mature chickens in Maryland. One of these birds was heavily infected and exhibited typical clinical symptoms.

Young birds infected with gapeworms show symptoms of weakness and emaciation, and usually spend much of their time with the eyes closed and the head drawn back against the body. From time to time they throw their heads forward and upward, and open the mouth wide in order to draw in air. It is not an uncommon occurrence to see an infected bird give its head a convulsive shake in an attempt to remove the obstruction from the trachea so that normal breathing may be resumed. Little or no food is taken by birds in the advanced stages of infection, and death is usually the end result.

An examination of the trachea of infected birds shows that the mucous membrane is extensively irritated and inflamed; coughing is apparently the result of this irritation to the mucous lining. Lesions are usually found to be present in the trachea of turkeys and pheasants, but seldom if ever seen in the trachea of young chickens and guinea fowls. Observations have shown that these lesions or nodules are produced as a result of an inflammatory reaction set up at the site of the attachment of the male worm. Since the attachment has been observed only at the lesions or point of attachment of the male worm and observations have shown that the head of the male is deeply embedded in the nodular tissue, it is, therefore, believed that the male worm usually remains permanently attached to the tracheal wall throughout the duration of its life. The female worms apparently detach and reattach from time to time in order to obtain a more abundant supply of food.

It must be remembered, however, that there are other diseases which may cause birds to gape, such as bronchitis and laryngotracheitis. In order that one may be sure just what is the cause of the gaping, it is necessary to make a postmortem examination of one or more of the affected birds. If gapeworms are not present in the trachea, bronchitis, laryngotracheitis or some other disease causing symptoms similar to gapeworm disease must be diagnosed.

Cyathostoma bronchialis (Muehlig, 1884)

Synonym. *Syngamus bronchialis* Muehlig, 1884.

Description. Very similar to *Syngamus*, but larger and less firmly united in copula. Buccal capsule somewhat wider than deep, usually six but occasionally seven triangular buccal teeth.

Male 8 to 12 mm. long by 200 to 600μ wide. Spicules long and slender, 540 to 700 mm. long, with tips slightly incurved.

Female 16 to 30 mm. long by 750μ to 1 5 mm. wide. Vulva with fairly prominent lips, situated in posterior part of anterior third of body. Tail acute. Eggs 68 to 90μ long and 43 to 60μ wide, with slight operculum in mature ones.

Life history. Unknown. Probably similar to *Syngamus trachea*. This species of gapeworm is apparently widespread in domestic geese in Europe and to some extent in wild geese of the United States. The following record of its appearance in domestic geese of this country appears to be the only one.

Pathology. Griffiths *et al.* (1954) reported a morbidity of 80 per cent with a mortality of about 20 per cent in a flock of domestic geese near Duluth, Minnesota. The course of the disease extended over a period of 5 months, during which time the birds showed symptoms of respiratory distress as evidenced by throwing back their heads and gaping for air. Severely affected birds died soon after the appearance of respiratory disturbances. The symptoms exhibited were similar to those of laryngotracheitis. Recovered birds showed growth retardation. Cram (1928) reported infections of this gapeworm in Young Blue, Cackling, Snow, and Canada geese in Illinois.

NEMATODES OF THE ALIMENTARY TRACT

CROP

At least three species of nematodes, commonly referred to as crop worms, occur in the crop of domestic fowls. Two of these are commonly known as capillarid worms or hairworms and belong to the family Trichuridae, while the third is designated as the gullet worm and is a member of the family Thelaziidae.

Trichuridae

The members of this family are characterized by having the body more or less clearly divided into an esophageal portion and a posterior portion which contains the other organs. The esophagus is a cuticular tube embedded in one side of a single or double row of esophageal glands. The male possesses only a single spicule. Vulva is located at junction of esophageal and posterior portions of body.

Capillaria annulata (Molin, 1858)

Synonyms. *Trichosoma annulatum* Molin, 1858; *Thominx annulata* (Molin, 1858) Cram, 1925.

Description. Worms long and threadlike. Cuticle inflated just behind head in adult specimens to form a bulbous swelling (Fig. 34.4A). Not far behind this, the cuticle is thrown into wavy transverse folds for a short distance.
FIG. 34.4 — *Capillaria annulata.* (A) Head end. (B) Male tail. (After Cirurea, 1914.)

Male usually 1 to 2.5 cm. long by 52 to 74μ wide. Tail ends in two inconspicuous round lateral flaps, united dorsally by a cuticular flap. Spicule sheath beset with fine spines (Fig. 34.4B). Spicule 1.12 to 1.63 mm. long.

Female usually 2.5 to 6 cm. long by 77 to 120μ wide. Posterior portion of body (posterior to vulva) about 7 times as long as anterior portion. Vulva circular, located about opposite the termination of the esophagus. Eggs operculated, 55 to 66μ long by 26 to 28μ wide.

Capillaria annulata occurs naturally in the bobwhite quail, domestic chicken and turkey, pheasant, and Hungarian partridge. Worms of this species are similar in appearance to those of *Capillaria contorta* but may easily be differentiated by the presence of a cuticular swelling just back of the head.

Madsen (1951) synonymized *Capillaria annulata* (Molin, 1858) with *Capillaria contorta* (Creplin, 1839). Because of the presence of a cuticular inflation around the head and experimental evidence which points to the necessity of an intermediate host for its complete development, *Capillaria annulata* has been recognized as a distinct species.

Life history. Eggs of this parasite pass out in the droppings of the infected birds. They develop very slowly; a period of 24 days to over 1 month is sometimes necessary before they have reached the stage at which they contain an active embryo. Wehr (1936) discovered that the earthworm is required in order successfully to transmit *C. annulata* from one bird host to another. He demonstrated that under both natural and artificial conditions two species of earthworms, *Eisenia* (H) *foetidus* and *Allolobophora* (H) *caliginosus*, served as intermediate hosts of this crop worm. Chickens and other susceptible hosts become infected with this crop worm by swallowing infected earthworms.

Pathology. Cram (1926c) reported this worm as being associated with the deaths of turkeys in Maryland. The habit of burrowing into the crop mucosa causes a thickening of the crop wall and an enlargement of the glands in the areas in which the worms are located. Usually there is a slight or severe inflammation of the crop and esophageal walls, depending upon the severity of the infection. In heavy infections, the inner surface of the crop is immensely thickened, roughened, and badly macerated, the masses of worms concentrated primarily in this sloughing tissue (Fig. 34.5).

In pheasants, quail, and other gallinaceous game birds, infections with this

FIG. 34.5 — *Capillaria annulata*. Damage done to crop of quail, as compared with the thin-walled normal crop.

parasite often prove fatal. In these birds the symptoms reported are principally malnutrition and emaciation, associated with severe anemia. Allen and Gross (1926) reported severe anemia in an infected ruffed grouse, shortly before death.

Hung (1926) made a histopathological study of three cases of varying intensity and reported the following changes: "On the basis of the above observations it is quite evident that the pathological changes caused by *C. annulata* may be divided into three stages. The first stage is the hyperemic stage in which only hyperemia and lymphocytic infiltrations are present. In the second stage the yellowish-white nodules are present, and the lymphatic apparatus is enlarged and sometimes necrotic. *The enlargement of the lymph follicles gives the appearance of nodules* The third stage is that of the formation of the pseudomembrane, in which the mucosa is covered with a membrane containing fibrin."

Capillaria contorta (Creplin, 1839)

Synonyms. *Trichosoma contortum* Creplin, 1839, *Thominx contorta* (Creplin, 1839) Travassos, 1915.

Description. Body threadlike, attenuated anteriorly and posteriorly.

Male 8 mm. to 1.7 cm. long by 60 to 70μ wide Two terminal laterodorsal prominences on tail and Spicule very slender and transparent, about 800μ long, according to Travassos. Spicule sheath covered with fine hairlike processes (Fig. 34.6B).

Female 1.5 to 6 cm. long by 120 to 150μ wide. Vulva prominent, circular, 140 to 180μ posterior to beginning of intestine (Fig. 34.6A).

Capillaria contorta has been reported from a large number of hosts, including the duck, turkey (both domestic and wild), pheasant, quail, and ruffed grouse.

Life history. Eggs are apparently deposited in tunnels in the crop mucosa and escape into the lumen of crop and esophagus with the sloughed mucosa. They are found abundantly in droppings from infected birds. Approximately 1 month or slightly longer is required for embryos to develop within the eggs. Worms mature and eggs pass to the outside in the droppings of susceptible avian hosts from 1 to 2 months after feeding the embryonated eggs. Attempts to experimentally infect chickens, guinea fowls, and pigeons were unsuccessful.

Pathology. When present in large numbers these worms are highly dangerous. In light infections the wall of the crop and esophagus become slightly thickened and inflamed. In heavy infections, there is a marked thickening and inflammation, with a flocculent exudate covering the mucosa and with more or less sloughing of the mucosa (Fig. 34.7).

Affected birds become droopy, weak, and emaciated. Many deaths due to infection with this worm have been observed among wild turkeys and Hungarian partridges in this country.

The author visited a flock of domestic turkeys in Virginia, among which several birds were reported to have died from heavy infections with this crop worm. A number of visibly affected birds had been segregated from the main flock and were held in a pen by themselves. These birds moved only when disturbed, and then very slowly and with an unsteady gait. Occasionally a bird was seen to fall back on its hock joints and assume a penguin-like position. Others extended and retracted their heads and necks as if attempting to relieve an obstruction in their throats. The crops of the most severely affected birds were filled with a fetid liquid. Emmel (1939) observed that infection with this crop worm appeared first in the older birds, and later those of all ages became affected. Affected birds appeared indisposed, weak, and droopy, with the forepart of the body slightly elevated. The birds were not inclined to move unless forced to do so. He also observed that the birds occasionally assumed a penguinlike posture, with the head drawn close to the body, and that affected birds frequently swallowed and in doing so always extended and "ducked" their heads.
FIG. 34.6 — *Capillaria contorta*. (A) Region of vulva. (After Eberth, 1863.) (B) Male tail. (After Travassos, 1915.)

Thelaziidae

For family diagnosis, see page *969*.

Gongylonema ingluvicola Ransom, 1904

Description. Anterior end of body with a zone of shieldlike markings, few and scattered near head, numerous, and arranged in longitudinal rows farther back (Fig. 34.8A).

Male 1.7 to 2 cm. long by 224 to 250μ wide. Cervical papillae about 100μ from head end. Tail with two narrow bursal asymmetrical membranes. Genital papillae variable in number and asymmetrical; preanal papillae up to 7 on *left side* and up to 5 on the right side (Fig. 34.8B). Left spicule as long, or nearly as long (1.7 to 1.9 cm.) as body and 7 to 9μ wide, with a barbed point; right spicule 100 to 120μ long and 15 to 20μ wide.

Female 3.2 to 5.5 cm. long by 320 to 490μ wide. Vulva 2.5 to 3.5 mm. from tip of tail.

This worm has been reported from the chicken, turkey, and quail in the United States.

Life history. Cram (1931a) fed larval roundworms collected from the beetle,

FIG. 34.8—*Gongylonema ingluvicola.* (A) Head. (B) Male tail. (After Ransom, 1904.)

Copris minutus, to a chicken and recovered a single male specimen of a species of *Gongylonema,* tentatively identified as *G. ingluvicola.* Cram subsequently infected cockroaches by feeding embryonated eggs of *G. ingluvicola* derived from mountain quail. Some of the larvae recovered from the cockroaches were fed to a chicken. No worms were found when the chicken was killed 79 days later.

Pathology. The only damage that has been associated with these worms is the local lesions in the form of burrows in the mucosa of the crop.

General Discussion

Crop worms penetrate into the mucosa of the crop and esophagus and make tortuous burrows in which they live. Wehr (1937a) observed that each of these species of crop worms, when seen in their normal positions in the mucosa of the turkey, displayed a different body contour. The value of this observation lies in the fact that identifications of the worms involved may be made with a reasonable degree of accuracy without resorting to the time-consuming task of making a detailed microscopic examination of each worm. In situ, all three species of worms assume a folded position, differing, however, in the character of the folds. In the case of the so-called gullet worm, *Gongylonema ingluvicola,* the perspective is one of a series of folds approximately uniform in size and shape, following one another in close succession and usually extending in a straight line. The body shape of the two species of *Capillaria* consists of a series of irregularly shaped folds. *Capillaria annulata* may be differentiated from *Capillaria contorta* by its slightly smaller size. In case of any doubt as to the identity of the two species, the specimens may be removed from their burrows and examined under the microscope. Should a cuticular swelling be present directly back of the head, the worm is *C. annulata;* if this structure is absent, it is *C. contorta.*

Capillaria contorta is frequently found in large numbers in wild and domestic
birds. In the United States, this crop worm has been reported to occur naturally in the Hungarian partridge, wild turkey, ring-necked pheasant, California valley quail, wild and domestic ducks, the domestic turkey, and possibly others.

STOMACH

Nematodes inhabiting the proventriculus of domestic poultry belong to two families, namely, Acuariidae and Spiruridae.

Acuariidae

The acuariids are characterized by having well-developed pseudolabia and cuticular ornamentations on the anterior part of the body.

Dispharynx nasuta (Rudolphi, 1819)

Synonyms, *Spiroptera nasuta* Rudolphi, 1819; *Dispharagus spiralis* Molin, 1858; *Acuaria spiralis* (Molin, 1858) Railliet, Henry, and Sisoff, 1912. Goble and Kutz (1945) concluded that all the forms of *Dispharynx* which have been recently recorded from galliform, columbiform, and passiform birds in the Western Hemisphere are nonspecific and that a morphological study of these forms leads them to consider their identity as *Dispharynx nasuta* (Rudolphi, 1819) Stiles and Hassall, 1920. *Dispharynx nasuta* (Rudolphi, 1819) Stiles and Hassall, 1920, has priority over *Dispharynx spiralis* (Molin, 1858) Skrjabin, 1916.

Description. Four wavy cuticular cordons on anterior end, originating at base of lips, recurrent, the distal extremity of the cordons turning forward and extending anteriorly a short distance (Fig. 34.9A). Postcervical papillae small, bicuspid, situated between the recurrent branches of the cordons. Body usually rolled in a spiral (Fig. 34.9B).

Male 7 to 8.3 mm. long by 250 to 315μ wide. Five pairs of postanal and 4 pairs of precanal papillae (Fig. 34.9C). Long spicule 400μ long, slender and curved; short spicule 150μ long, navicular.

Female 9 to 10.2 mm. long by 360 to 565μ wide. Small mucro on tip of tail.

Vulva in posterior portion of body. Eggs embryonated when oviposited.

This parasite has been encountered in the proventriculus of the chicken, turkey, guinea fowl, pigeon, pheasant, ruffed grouse, bobwhite quail, Hungarian partridge, and other gallinaceous birds. In addition, it has been found in a number of passerine birds in the United States. Yeatter (1934) found the incidence of this parasite among Hungarian partridge in the Great Lakes region to be 31.6 per cent. Bump (1935) stated that this worm was the most important parasite recovered from the ruffed grouse in New York State.

Life history. The pillbug, *Armadillidium vulgare*, and the sowbug, *Porcellio scaber*, were demonstrated to serve as intermediate hosts in experimental infections by Cram (1931b). The writer has repeatedly confirmed Cram's studies, using pigeons as definitive hosts. Within 4 days after the ingestion of the embryonated eggs by these isopods, the larvae have escaped from the eggs and are found among the tissues of the body cavity of the crustacean. The larva completes its development in the isopod within approximately 26 days; it has then reached the third or infective stage.

The definitive host becomes infected with the above nematode by swallowing infected pillbugs or sowbugs with the food or water. According to Cram (1931b) the female worms become sexually mature and are depositing eggs 27 days after ingestion by a susceptible vertebrate host.

Pathology. These roundworms are usually seen with their heads buried deeply into the mucosa. The formations of ulcers are often observed in the proventriculi of infected birds. In case of heavy infections, the wall of the proventriculus becomes tremendously thickened and macerated, tissue layers are indistinguishable, and the parasites become almost completely concealed beneath the proliferating tissue.

Allen (1925) believed that *D. nasuta* (*D. spiralis*) was the chief cause of "Grouse Disease" in northeastern United

States. Heavy infections of this parasite resulted in the death of many carrier pigeons of the Signal Corps of the United States Army, Fort Sam Houston, Texas, a number of years ago, according to Cram (1928). Several wild pigeons trapped at the Balboa Zoological Park, San Diego, California, and examined by the writer were found to be heavily infected with this parasite.

Seurocyrnea colini

Seurocyrnea colini is of common occurrence in the bobwhite quail of the southeastern states and has occasionally been collected from this same host in closely related birds in some of the northeastern states. It has also been reported from the turkey in Georgia, the prairie chicken in Wisconsin, and the sharp-tailed grouse in Wisconsin and Montana.

The preferred location of this nematode is in the wall of the proventriculus at its junction with the gizzard. The slender, yellowish-white worms are similar in appearance to *Cheilospirura hamulosa*, but are smaller and lack the so-called cordons or cuticular ornamentations on the an-
FIG. 34.9 → **Dispharynx nasuta.** (A) Head end. (After Seurat, 1915). (B) Female. Enlarged. (After Piana, 1897.) (C) Male tail. (After Cram, 1928.)

terior part of the body. The head structures are quite complicated, and the tail of the male has winglike expansions or alae (Fig. 34.10 A, B, C, D, and E).

The life history of this nematode is indirect, requiring the cockroach, *Blatella germanica*, as a temporary host. Since this intermediate host has been incriminated in an experimental role only, it is not known whether it actually serves in this same capacity under natural conditions.

There has been little or no pathological change observed in connection with infections of this parasite.

Spiruridae

The spirurids are characterized by having well-developed pseudolabia, cephalic papillae usually posterior to pseudolabia, and interlabia present or absent. The only
FIG. 34.10—*Seurocyrnea colini*. (A) Head, oblique lateral view. (B) Head, ventral view. (C) Tail of third-stage larva. (D) Male tail. (E) Head. En face view, *semidiagrammatic*.
[After Cram, 1927.]

member of this family found in poultry of this country have interlabia, and the sexes are distinctly dimorphic.

Tetrameres americana Cram, 1927

Description. Mouth surrounded with 3 small lips; buccal cavity present.

Male 5 to 5.5 mm. long by 116 to 133μ wide. Two double rows of posteriorly directed spines extend throughout whole body length, in the submedian lines. Cervical papillae present. Tail long and slender. Two unequal spicules, 100μ and 290 to 312μ long, respectively.

Female 3.5 to 4.5 mm. long by 3 mm. wide. Body globular, blood red in color, with 4 longitudinal furrows (Fig. 34.11). Uteri and ovaries very long, their numerous coils filling the body cavity.

The female of this species occurs in the glandular stomach of chickens and bobwhite quail (Fig. 34.12). At necropsy, these bright red worms are often observed through the wall of the unopened proventriculus. The male of this species is very small, almost microscopic in size, and resembles other nematodes in shape. It is very seldom observed elsewhere than on the surface of the mucosa of the proventriculus. However, the males of some of the species of *Tetrameres* occurring in wild birds have been found on several

occasions together with the females in the same glands. From all indications, it seemed that the two sexes, in the cases cited, were permanent residents of the glands in which they were found. When the male of *T. americana* enters the glands of the proventriculus, it apparently does so only long enough to mate with the female.

Cram (1931a) found this parasite to be common in quail which had been raised in captivity and in close proximity to poultry in Virginia. Stoddard (1931) reported *T. americana* as being found occasionally in quail raised in its natural habitat in the southeastern part of the United States.

Swales (1933) described *T. crami* from the proventriculus of a domestic duck in Canada. He stated that this species, of which the female only is known, differs from *T. americana* chiefly in the shorter muscular esophagus and the relative positions of the anus and vulva.

Another species of *Tetrameres*, *T. fissispina*, a species closely related to *T. americana*, has been reported from wild and domestic ducks and chickens in Europe. Sugimoto and Nishiyama (1937) stated that this roundworm was fairly common in chickens in Formosa.

Life history. Cram (1931b) discovered that *T. americana* required an intermediate host for its complete development. She fed embryonated eggs of this worm to two species of grasshoppers, *Melanoplus femurrubrum* and *M. differentialis*, and a species of cockroach, *Blatella germanica*, and recovered infective larvae from the body cavities of these insects in about 42 days after the ingestion of the eggs. When the grasshopper or cockroach is swallowed by a suitable bird host and digested in its stomach, the larvae escape; they remain in the proventriculus and develop into adults within a few days. The complete life cycle of *T. fissispina* involves such intermediate hosts as the amphipod, *Gammarus pulex*; the cladoceran, *Daphnia pulex*, and several species of grasshoppers, cockroaches, and earthworms.
FIG. 34.11 — Tetrameres americana. Enlarged drawing of female. Original.
FIG. 34.12 — *Tetrameres americana.* Proventriculus showing female worms in glands. (After Cram, 1930.)

Pathology. According to Sugimoto and Nishiyama (1937), infected chickens become emaciated and anemic as a result of heavy infections. Cram (1931a) reported that *T. americana* has not been observed to produce any damage in quail. Barber (1916) stated that this proventricular worm was the cause of a serious catarrhal condition in chickens in Guam. In his report, he mentioned that the walls of the proventriculus were so thickened that the lumen was almost entirely obliterated; as many as 47 worms were found embedded in the wall.

GIZZARD

Gizzard nematodes belong to two families, namely, Acuariidae and Trichostrongylidae.

Acuariidae

For family diagnosis, see page 979.

Cheilospirura hamulosa (Diesing, 1851)

Synonyms. *Spiroptera hamulosa* Diesing, 1851.

Description. Two large, triangular, lateral lips. The 4 cuticular cordons double, irregularly wavy, and extending almost to

posterior extremity; not anastomosing or recurring anteriorly (Fig. 34.13A).

Male 9 mm. to 1.9 cm. long. Spicules very unequal and dissimilar, the left long and slender, the right short and curved. Tail tightly coiled; 2 very wide caudal alae present. Ten pairs of caudal papillae (Fig. 34.13B).

Female 1.6 to 2.5 cm. long. Vulva slightly posterior to middle of body. Tail pointed. Eggs embryonated when deposited.

This roundworm occurs commonly underneath the horny lining of the gizzard near the openings of the proventriculus and intestine in chickens and has occasionally been reported from the same locations in turkeys. It is widely distributed in the United States.

Life history. Investigations have shown that grasshoppers, beetles, weevils, and sandhoppers serve as intermediate hosts of *C. hamulosa* under natural as well as experimental conditions. Chickens and other susceptible avian hosts become infected with the adults of this roundworm by ingesting grasshoppers, beetles, weevils,

984   EVERETT E. WEHR
FIG. 34.13 — Cheilospirura hamulosa. (A) Head. (After Drasche, 1884.) (B) Male tail. (After Cram, 1931.)

and sandhoppers which are infected with larvae of this worm.

The infective or third stage larva may be recognized easily by the 2 prominent liplike structures at the anterior end of the body, the dorsal curvature of the posterior portion of the body, and the presence of four digitiform processes at the tip of the tail.

Pathology. When present in small numbers, these worms cause no evident effect on the health of the birds. In such infections, the lining of the gizzard may show small local lesions which may also involve the muscular tissue. Soft nodules enclosing parasites may be found in the muscular

portion of the gizzard. In heavy infections, the wall of the gizzard may be seriously damaged. Le Roux (1926) reported that this parasite may weaken the wall to such an extent as to cause it to rupture, with ultimate formation of a sac or pouch.

Trichostrongylidae

Members of this family are characterized by having reduced or rudimentary mouth cavity, corona radiata absent, and usually a well-developed bursa.

Amidostomum anseris (Zeder, 1800)

Synonyms. *Strongylus anseris* Zeder, 1800 in part; *Amidostomum nodulosum* (Rudolphi, 1803) Seurat, 1918.

Description. Worms slender and reddish. The short wide buccal capsule has 3 pointed teeth at its base (Fig. 31.14A).

Male 10 to 17 mm. long by 250 to 350μ wide. Bursa with 2 large lateral lobes and a small median lobe (Fig. 31.14C). Dorsal ray short, bifurcating posteriorly and the bifurcations forked and terminating in 2 tips. Spicules 200μ long, slender, and cleft near their middle. Gubernaculum slender and 95μ long.

Female 12 to 21 mm. long, 300 to 400μ wide at vulva, thinning toward both extremities. Vulva transverse, in posterior part of the body (Fig. 31.14B). Eggs thin-shelled.
FIG. 34.14 — Amidostomum anseris. (A) Head end. (After Railliet, 1893.) (B) Vulva and tail of female. (After Reinhardt, 1922.) (C) Male tail. (After Railliet, 1893.)

This worm occurs very commonly underneath the horny lining of the gizzard of wild ducks and geese. In the United States it has been reported from domestic geese in the states of New York, Delaware, Pennsylvania, and Washington. No doubt this parasite has a much wider distribution in this country than the present records indicate.

Life history. Eggs pass out in the droppings of infected birds in a partly developed stage, active embryos developing within a few hours and hatching taking place within a few days. Susceptible bird hosts become infected by swallowing with their food or drinking water these infective larvae. Adult worms are recovered within approximately 40 days after the feeding of infective larvae.

Pathology. In the United States, Cram (1926a) reported an outbreak of amidostomiasis in a flock of geese in New York in which a large number of deaths occurred. Heavy losses among geese in Europe have been attributed to this nematode. Young birds show symptoms of loss of appetite, dullness, and emaciation. At necropsy, the lining of the gizzard of a heavily parasitized bird appears necrotic, loosened, often sloughed in places, and is dark brown or black in color in areas adjacent to the site of the worms.

Bunyea and Creech (1926) found a very noticeable leukocytic invasion of the mucosa propria, with eosinophilic cells strikingly predominant.

INTESTINAL TRACT

Ascaridiidae

The members of this family are characterized by having 3 prominent lips, valvulated bulb absent, and preanal sucker sometimes present.

Ascaridia galli (Schrank, 1788)

Synonyms. *Ascaris galli* Schrank, 1788; *Heterakis lineata* Schneider, 1866; *Heterakis inflexa* (Zeder, 1800) Schneider, 1866.

Description. Worms large, thick, yellow-
FIG. 34.15 — Roundworms (*Ascaridia galli*) from small intestine of a chicken. (J. E. Ackert.)

ish-white (Fig. 34.15). Head with 3 large lips.

Male 5 to 7.6 cm. long by 490µ to 1.21 mm. wide. Preanal sucker oval or circular, with strong chitinous wall with a papilliform interruption on its posterior rim. Tail with narrow caudal alae or membranes, and 10 pairs of papillae. Spicules equal and narrow.

Female 6 to 11.6 cm. long by 900µ to 1.8 mm. wide. Vulva in anterior part of body. Eggs elliptical, thick-shelled, not embryonated at time of deposition (Fig. 34.16).

This large roundworm is one of the most common nematode parasites of the chicken in the United States and elsewhere. It occurs occasionally in turkeys, but no serious pathologic effects have been reported from its presence in that host.

Specimens of this parasite have been recovered on a number of occasions from broken eggs. The worms had presumably wandered up the oviduct from the intestine via the cloaca with subsequent inclusion in the developing egg.

Life history. The life history is simple and direct. According to Itagaki (1927), the infective eggs which are swallowed by the susceptible host hatch either in the proventriculus or in the duodenum. Ackert (1931) observed that the young larvae, after hatching from the eggs, live free in the lumen of the posterior portion of the duodenum for the first 9 days, fol-

FIG. 34.16 — Ascaridia galli ova.
X400. (E. A. Benbrook, 1928)
lowing which they penetrate the mucosa and cause hemorrhages. The young worms have again entered the lumen of the duodenum by the seventeenth or eighteenth day and remain there until maturity, which is reached within approximately 50 days after the ingestion of the embryonated eggs. Tugwell and Ackert (1952) reported studies which showed that the Ascaridia larvae may enter the tissues as early as the first day and remain there as late as the twenty-sixth day after infection. The authors stated, however, that the large majority of the larvae spend from the eighth to the seventeenth day in the intestinal mucosa.

Under optimum conditions of temperature and moisture, the eggs in the droppings will develop to infectivity in 10 to 12 days; under less favorable conditions a longer time is necessary. The eggs are quite resistant to low temperatures. Ackert found that, in the early stages of development, eggs survived freezing at −12° to −8° C. for 15 hours, but not for 22 hours; fertile eggs kept at 0° C. for 1 month were unable to reach the infective stage subsequently, whereas eggs from the same culture, kept concurrently at 10° C. for a month, developed normally to the infective stage when incubated at a higher temperature. Fair (1956) recovered Ascaridia galli larvae from experimental birds fed embryonated eggs of this worm which had been exposed continuously to outdoor conditions at Beltsville, Maryland, for 60 weeks. As regards high temperatures, 12 hours' exposure to 43° C. proved lethal for eggs in all stages of development.

Pathology. Ackert (1919) found that chickens infected with a large number of ascarids suffer from loss of blood, reduced blood sugar content, increased urates, shrunken thymus glands, retarded growth, and greatly increased mortality. Droopiness, emaciation, and diarrhea are the common clinical symptoms manifested by heavily parasitized birds (Fig. 34.17A and B).

Experimental evidence is available to show that chickens 3 months or older manifest considerable resistance to infec-
FIG. 34.17 — (A) Chicken infected with large roundworms of intestine. (B) Chicken of same age free of roundworms. (Ackert and Herrick.)

tion with *Ascaridia galli*. Ackert *et al.* (1939) reported that the increased number of goblet cells found in the epithelial lining of the duodenum of chickens at 3 months or older may in some measure be responsible for the greater resistance to this nematode developed by these birds. The age at which the peak of the goblet cell formation occurred was found to correspond very closely to the development of the maximum resistance of the chickens to the growth of the nematodes.

Ackert and Beach (1933) showed that diets consisting chiefly of animal proteins and with little or no plant protein were important in aiding the chicken to build up resistance to infection with ascarids, and that diets consisting chiefly or wholly of vegetable proteins lowered the resistance to ascarid invasion. Alicata (1935), likewise, observed that birds given a diet consisting principally of animal protein con-

centrates developed fewer worms than those which were given a diet low in animal protein. Diets high in vitamins A and B (complex) have been shown to increase the fowl's resistance to *Ascaridia galli*, and diets low in these vitamins definitely favor parasitism.

Experiments conducted by Ackert *et al.* (1935), which extended over a period of years and involved 1,351 chickens, showed that the heavier breeds such as the Rhode Island Reds and White and Barred Plymouth Rocks were more resistant to ascarid infections than the lighter White Leghorns and White Minorcas.

Large roundworms, similar in size and appearance to *Ascaridia galli*, occur in the small intestines of pigeons, guinea fowls, wild turkeys, and other game farm species. *Ascaridia numidae* of the guinea fowl, and *Ascaridia columbae* of the pigeon are shorter and somewhat thicker than *A. galli* of the chicken. The guinea fowl ascarid is the smallest of the three species. *Ascaridia dissimilis* has been found commonly both in the domestic and wild turkey of this country and has been reported by Vigueras (1931) from the domestic turkey in Cuba. This ascarid is very similar in appearance to *A. galli*, but is somewhat smaller. Shillinger (1942) reported *Ascaridia compar* as a parasite of the small intestine of the bobwhite quail in the United States.

The life history of all the above ascarids is probably similar to that of *Ascaridia galli*. Although the life histories of *Ascaridia columbae* and *A. dissimilis* have been shown by the writer to be direct, a detailed account of the hatching of the eggs, the period the larvae spend in the mucosa of the intestine, such as has been recorded for *Ascaridia galli* by Ackert, has not been worked out for these ascarids. The life history of *Ascaridia numidae* has not been experimentally demonstrated.

Birds heavily infected with either *Ascaridia dissimilis*, *A. columbae*, or *A. numidae* are probably affected in a somewhat similar manner as those heavily infected with *A. galli*.
FIG. 34.18 — Heterakis gallinarum. (A) Male tail. (B) Female tail. (After Lane, 1917.) (C) Egg. (After Cram, 1931.)

Heterakidae

Heterakis gallinarum (Schrank, 1788)

Synonyms. *Ascaris gallinae* Gmelin, 1790; *Heterakis papillosa* Railliet, 1885, not *Ascaris papillosa* Bloch, 1782.

Description. Worms small, white. Head end bent dorsally. Mouth surrounded by 3 small, equally sized lips. Two narrow lateral membranes extend almost entire length of body. Esopbagus ending in a well-developed bulb containing a valvular apparatus.

Male 7 mm. to 1.3 cm. long. Tail straight, ending in a subulate point; 2 large lateral bursal wings. Preanal sucker well developed, with strongly chitinized walls and small semicircular incision in posterior margin of wall of sucker. Twelve pairs of caudal papillae; 4 pairs distinctly postanal, 4 pairs of raylike papillae and 2 pairs of sessile papillae adanal, and 2 pairs of raylike papillae in vicinity of sucker (Fig. 34.18A). Spicules dissimilar, the long one 2 to 2.17 mm. long, the short one 700μ to 1.1 mm. long.

Female 1 to 1.5 cm. long. Tail long, narrow, and pointed (Fig. 34.18B). Vulva not prominent, slightly posterior to middle of body. Eggs thick-shelled, ellipsoidal, unsegmented when deposited (Fig. 34.18C).

H. gallinarum has been reported from the ceca of chickens, turkeys, guinea fowls,

bobwhite quail, pheasants, and many other birds.

Life history. The eggs pass out in the feces in an unsegmented state. In approximately 2 weeks or less, under favorable conditions of temperature and moisture, these eggs will have reached the infective stage. When the latter are swallowed by a susceptible host, the embryos hatch from the eggs and develop to adult worms in the ceca. Roberts (1937) stated that the eggs hatched in the upper part of the intestine, and at the end of 24 hours the majority of the young worms have reached the ceca. Aside from a short period in the cecal mucosa, 2 to 5 days, according to Uribe (1922), the entire life of the cecal worm is spent in the lumen of the cecum. At necropsy, the majority of the adult worms are found in the tips or blind ends of the ceca. Earthworms may ingest the eggs of the cecal worm and may be the means of causing an infection in poultry, as the latter are very fond of earthworms.

Pathology. Riley and James (1922) observed that the ceca of experimentally infected birds showed marked inflammation and thickening of the walls.

The chief economic importance of the cecal worm lies in its role as a carrier of the blackhead organism, *Histomonas meleagridis*. Graybill and Smith (1920) demonstrated by experimental methods that blackhead may be produced in sus-

ceptible birds by feeding embryonated eggs of *Heterakis gallinarum* taken from blackhead-infected birds. These authors were of the opinion that the cecal worms lowered the resistance of the host to such a degree that the protozoan parasites already present were able to multiply to disease-producing proportions. Tyzzer (1926) presented evidence which indicated that the protozoan parasite is incorporated in the worm egg; however, he was unable to demonstrate the presence of the protozoan parasite within the egg. Kendall (1959) saw organisms which resembled *Histomonas* in a young larval *Heterakis gallinarum* worm. Gibbs (1962) identified the *Histomonas* organism in the gut wall and in the reproductive system of the male and the female and in the developing eggs of this cecal worm. Farr (1956) recovered *Histomonas* organisms from experimental birds fed droppings containing *Heterakis gallinarum* and other nematode eggs that had been exposed continuously on soil to natural weather conditions from 17 to 66 weeks, inclusive. Several of the test birds which had been fed this material died of blackhead disease.

Two other species of cecal worms, *Heterakis beramporia* and *Heterakis isolonche*, occur in the ceca of chickens and pheasants, respectively. So far as is known, the former species does not occur in birds of the United States. However, the latter species has been found in pheasants in Pennsylvania and Connecticut. Both of these heterakids produce nodules in their respective hosts.

Subulura brumpti (Lopez Neyra, 1922)

Subulura brumpti has been reported by Alicata (1940) to be a common pinworm of chickens in the Hawaiian Islands. Cram (1926b) and Dikmans (1929) reported this pinworm as occurring in the turkey in Puerto Rico. Foster (1939) collected it from the fowl in Panama, and Ward (1915) listed it as a parasite of the quail in Mississippi (Fig. 34.19A and B).

No evidence that the larvae penetrated the cecal wall of the bird host for any
FIG. 34.19 – *Subulura brumpti*. (A) Posterior end of male, ventral view. (B) Posterior end of female, lateral view. (From Cuckler and Alicata, 1944.)

part of its development, nor that they produced any extensive inflammatory tissue reaction was reported by Alicata (1940). Various insects, such as beetles and earwigs, serve experimentally as intermediate hosts of this cecal worm.

Another cecal worm, *Subulura strongylina*, has been reported by Venard (1933) from the bobwhite quail in Ohio; by Cram (1927) from the chicken and guinea fowl in Puerto Rico; by Dikmans (1929) from the guinea fowl and by Van Volkenberg (1938) from poultry in Puerto Rico.

Trichuridae

For family diagnosis, see page 974.

Capillaria obsignata Madsen, 1915

Synonyms. *Capillaria dujardini* Travassos, 1915, nec Travassos, 1914; *Capillaria columbae* (Rudolphi, 1819) of Graybill, 1924.

Description. Worms hairlike.

Male 8.4 mm. to 1.2 cm. long by 49 to 55μ wide. Cloacal aperture almost terminal, with a small bursal lobe on either
FIG. 34.20 — Capillaria obsignata. (A) Ventral view, and (B) Lateral view, of male tail. (After Graybill, 1924.) (C) Region of vulva. (After Eberth, 1863, slightly modified.)

side, the two lobes connected dorsally by a delicate bursal membrane (Fig. 34.20A). Spicule sheath with transverse folds; spicule 1.1 to 1.58 mm. long.

Female 1 to 1.8 cm. long by approximately 80μ wide. Vulva on slight prominence, slightly posterior to union of esophagus and intestine (Fig. 34.20C). Eggs slightly brownish, lemon-shaped, thick-shelled.

This hairworm occurs in the small intestine of the domestic and wild pigeon, chicken, and turkey in the United States.

Life history. Capillaria obsignata has a direct development. The freshly deposited eggs are unsegmented and require from 6 to 8 days to develop completely formed embryos. The embryos do not escape from the eggs until after they have been swal-

lowed by a susceptible host. The larvae enter the mucosa of the duodenum and apparently complete their development there. A few sexually mature adults were removed by the writer from the small intestine of a pigeon necropsied 19 days after the ingestion of the embryonated eggs, and a large number of similarly developed adults were removed from the small intestine of a pigeon necropsied 26 days after infection. Fecal examination of the latter pigeon at the time of necropsy showed the presence of eggs.

It has been experimentally demonstrated that pigeons, when once infected with Capillaria obsignata and held under conditions designed to preclude reinfection, will remain infected for about 9 months.

Capillaria obsignata has been reported from the small intestines of chickens and turkeys raised under natural conditions. Graybill (1921) stated that as a result of many necropsies of chickens and turkeys, this roundworm was never observed in these birds in large numbers. Wehr (1939) was successful in obtaining natural infections in chickens and turkeys, but no heavy infections were encountered in the latter.

Pathology. Birds heavily infected with Capillaria obsignata spend much of their time apart from the rest of the flock, huddled on the ground, underneath the roosts, or in some corner of the room. Such birds show definite symptoms of emaciation and diarrhea. The feathers around the vent frequently appear ruffled and soiled, and the skin and visible mucous membranes are more or less pale. Death is often the result of heavy infections. Levine (1938) reported that the first clinical symptoms of infection in chickens appeared on the twelfth day after experimental inoculation of embryonated eggs. At this time the feces contained much pinkish material composed of mucus, necrosed epithelial cells, and numerous erythrocytes, granulocytes, and lymphocytes. From the twelfth to the sixteenth days the feces of the birds were watery and contained large quantities of epithelium and inflammatory exu-

date which was being eliminated from the intestinal tract. Following this period, most of the infected birds regained their normal appearance, and the feces became normal. However, many of the birds lost weight steadily, became extremely emaciated, and either died or were destroyed because of a weakened condition. In fatal and in advanced cases of infection, the intestines showed extensive destruction of the mucosa, often with complete sloughing of the mucous membrane. The intestines usually contain a large quantity of fluid. In nonfatal experimental cases the intestinal wall was thickened considerably owing to the edematous infiltration.

Another threadworm, *Capillaria caudinflata*, has been occasionally found in chickens, turkeys, and pheasants in the United States. This species of capillarid worm may be differentiated easily from other species of the same genus found in poultry of this country by the presence on the male tail of two large lateral transparent membranes just anterior to the cloacal aperture, and on the female of a membranous tubular or trumpet-shaped projection in the region of the vulva.

Allen and Wehr (1942) experimentally infected turkeys with *Capillaria caudinflata* by feeding to them earthworms of the species *Allolobophora caliginosa* which were removed from poultry yards in which were confined turkeys known to harbor this threadworm. Morehouse (1944) demonstrated that the above earthworm was an essential intermediate host for the successful transmission of *Capillaria caudinflata* from turkey to turkey. Attempts by Wehr to transmit this threadworm by using species of the earthworm, *Eisenia foetida* and *Lumbricus terrestris*, were unsuccessful. Wehr and Allen (1945) introduced directly into the alimentary tracts of several earthworms, *Eisenia foetida*, embryonated eggs of *Capillaria caudinflata*, and later adults of this worm were recovered at necropsy from turkeys to which these earthworms had been fed.

Barile (1912) found these worms in turkeys showing hemorrhagic, croupous enteritis but was unable to state positively whether the worms were responsible for this pathological condition. Baker (1930), in connection with frequent findings of this worm in the province of Quebec, Canada, noted that the worms were associated with ulcerous patches varying in size from pin-point areas to greatly extended and hardened areas. An infected chicken observed by Graham *et al.* (1929) in Illinois showed weakness, anemia, and emaciation before death. At necropsy, the intestine just anterior to the ceca was markedly dilated, with a follicular diphtheritic enteritis present.

Trichostrongylidae

For family diagnosis, see page 964.

Ornithostrongylus quadriradiatus (Stevenson, 1904)

Synonym. *Strongylus quadriradiatus* Stevenson, 1904.

Description. Worms delicate, slender, red when freshly collected, apparently from ingested blood in intestine. Cuticle about head inflated to form vesicular enlargement (Fig. 34.21A).

Male 9 mm. to 1.2 cm. long. Bursa bilobed, with no distinct dorsal lobe. Dorsal ray much shorter than other rays, not extending halfway to bursal margin, bifurcating near its tip to form 2 short tips, and a stumpy process present on each side near base of ray. Spicules equal, 150 to 160μ long, somewhat curved, each terminating in 3 pointed processes (Fig. 34.21 B). Telamon 57 to 70μ long, with 2 longitudinal processes extending backward and forward along dorsal wall of cloaca, and 2 lateral processes forming a partial ring through which the spicules protrude.

Female 1.8 to 2.4 cm. long. Vulva near end of tail. Vagina short, followed by 2 powerful muscular ovejectors. Tail tapers to a narrow, blunt end, bearing a short spine. Eggs segmenting when deposited.

This bloodsucking nematode occurs in the small intestine of pigeons and mourning doves in the United States.

Life history. The oval, thin-shelled eggs
FIG 34.21 — Ornithostrongylus quadriradiatus. (A) Anterior end. (B) Caudal bursa of male. (After Stevenson, 1904.)

are voided in the droppings and hatch in approximately 19 to 24 hours under favorable conditions of moisture and temperature. After escaping from the egg, the young larva molts twice within the next 3 or 4 days. It has now reached the infective stage. When the infective larva is swallowed by a pigeon or other susceptible host, it grows to maturity in the small intestine. The female worm begins to deposit eggs in 5 or 6 days following ingestion of the larva.

Pathology. Stevenson (1904) observed that this parasite was the cause of many deaths among a flock of fancy pigeons in Washington, D.C. Le Roux (1926, 1930) mentioned this roundworm as having caused serious losses in a flock of valuable imported pigeons. Vigueras (1929) reported similar losses among pigeons in Cuba, and Kamarov and Beaudette (1931) attributed large numbers of deaths among squabs as having been due to this bloodsucking parasite. These investigators are agreed that deaths among the birds were attributable principally to a catarrhal enteritis and a loss of blood due to hemorrhage.

Birds heavily infected with Ornithostrongylus quadriradiatus behave much the same as birds heavily parasitized with other bloodsucking parasites. They become droopy, remain squatted on the ground or floor, and if disturbed, they try to move but usually tip forward on the breast and head. Food is eaten sparingly and is frequently regurgitated, along with bile-stained fluid. There is a pronounced greenish diarrhea, and the bird gradually wastes away. Symptoms of difficult and rapid breathing usually precede death. The intestines of fatally infected birds are markedly hemorrhagic and have a greenish mucoid content, with masses of sloughed epithelium (Fig. 34.22).

Trichostrongylus tenuis (Mehlis, 1846)

Synonyms. Strongylus tenuis Mehlis, 1846 (in Creplin, 1846); Strongylus pergracilis Cobbold, 1873; Trichostrongylus pergracilis (Cobbold, 1873) Railliet and Henry, 1909.

Description. Worms small and slender. Body gradually attenuated in front of genital opening. Mouth surrounded by 3 small, inconspicuous lips. Cuticle of an-
FIG. 34.22 — Section of duodenum of pigeon during later stage of infection with *Ornithostrongylus quadriradiatus*, showing: (a) Sloughing of mucosa; (b) Necrotic areas; and (c) Lymphocytic infiltration. ×150. (After Cuvillier, 1937.)

terior end of body lacking conspicuous striations for a distance of about 200 to 250μ from extremity, then with distinct serrated appearance for a distance of about 1 to 2 mm. more.

Male 5.5 to 9 mm. long by 48μ wide near center of body. Cuticle inflated on ventral surface just anterior to bursa. Bursa with one dorsal and two lateral lobes, the dorsal one not distinctly marked off from the lateral. Each lateral lobe supported by 6 rays (Fig. 34.23A). The dorsal ray bifid at its distal third, and each of these divisions again bifid and very finely pointed (Fig. 34.23B). Spicules dark brown in color, slightly unequal in length, the longest 120 to 164μ long, the shortest 104 to 150μ long: both much twisted, especially at distal ends, and provided with an earlike structure on proximal end (Fig. 34.23C). Both spicules apparently surrounded in distal two-thirds by a thin membrane extending for a short distance beyond distal ends. Gubernaculum strongly cuticularized along margins, spindle-shaped in ventral and dorsal views (Fig. 34.23D and E).

Female 6.5 mm. to 1.1 cm. long by 77 to 100μ wide at level of vulva. Vulva in posterior part of body, with crenulated edges. Uteri divergent. Eggs thin shelled.

It was concluded by Cram and Wehr (1934), as the result of a critical study of a large number of specimens of the genus *Trichostrongylus* collected from the ceca of both American and European domestic and wild game birds, that the material thus examined represented only one species instead of two, as previously suspected. Although *Trichostrongylus pergracilis* had been described from the ceca of many birds, the differences between the description of this species and that of *T. tenuis* were inconsequential and not of specific value. As a result of the above study, therefore, the authors concluded that *T. pergracilis* and *T. tenuis* were identical morphologically, and since the specific name *tenuis* had priority over *pergracilis*, the former name was accepted as the valid name.

In the United States, *T. tenuis* has been collected from the pheasant, *Phasianus colchicus;* the blue goose, *Chen caerules-*
FIG. 34.23 – Trichostrongylus tenuis. (After Cram and Wehr, 1934.) (A) Bursa, lateral view, semidiagrammatic. (E) Gubernaculum, dorsal view. A and B from European partridge, C to E from red grouse. Scale refers to camera lucida drawings, B to E, inclusive.

cens; the Canadian goose, Branta canadensis; the domestic goose, Anser anser domesticus; the guinea fowl, Numida meleagris; the chicken, Gallus domesticus; the turkey, Meleagris gallopavo; and the bobwhite quail, Colinus virginianus. The red grouse, Lagopus scoticus, and the European partridge, Perdix perdix, are the only two hosts from which T. tenuis has been collected in Europe. According to Cram (1931a), this trichostrongyle occurs widely among the quail of the southeastern United States.

Life history. This worm has a direct life history. The eggs hatch within 36 to 48 hours after they have been passed in the droppings of the infected bird. The larvae become infective within approximately 2

weeks following expulsion of the eggs in the droppings. Within this time the larvae have molted twice. When the latter are picked up by a susceptible host, the infective larva molts twice more within the ceca of the bird before finally becoming an adult.

Trichostrongylus tenuis from pheasants has been successfully transmitted to the domestic turkey, guinea fowl, and chicken.

Pathology. T. tenuis produces definite clinical symptoms when present in large numbers. The changes in the ceca consist of a thickening and a reddening of the walls, and small hemorrhages are sometimes present. Loss of weight, anemia, and chronic toxemia have been reported as symptoms resulting from heavy infections.

Strongyloididae

Members of this family are characterized by having an alternation of generations, the free-living generation consisting of males and females while the parasitic generation consists of hermaphroditic females only.

Strongyloides avium Cram, 1929

Description. Parasitic generation, consisting of parthenogenetic females only, in intestine of avian host, and free-living generation, consisting of both males and females, in soil.

Parasitic adult. 2.2 mm. long by 40 to 45μ wide. Vulva with projecting lips, located 1.4 mm. from head end. Uteri divergent from vulva; ovaries recurrent in simple "hair-pin bends," their course not sinuous. Eggs with very thin shells, segmenting when deposited.

Cram (1929) reported the occurrence of this extremely small roundworm from the ceca of chickens in Louisiana. Later (1936h), this same author reported this species from the ceca and small intestines of chickens in Puerto Rico. The junco, Junco hyemalis hyemalis, in Virginia, and the coot, Fulica americana, in North Carolina have been found to harbor natural infections of this parasite.

Life history. The eggs hatch soon after

being passed in the droppings, sometimes as soon as 18 hours. The young worms develop in the soil to adult males and females. *Shortly thereafter the females give rise to young, which feed, molt, and develop into other adult free-living males and females, or they may transform into another type of larvae known as the infective larvae.* When these infective larvae are swallowed by a susceptible host, infection results. Unlike most species of nematodes, the parasitic cycle of *Strongyloides avium* consists of females only, no parasitic males having been found.

Pathology. During the early or acute stage of the infection the walls of the ceca are greatly thickened; typical pasty *cecal contents almost disappear, the dis-*charge being thin and bloody. If the fowl survives this acute stage, the ceca gradually become functional again, and the thickening of the walls decreases. Young birds suffer most from infections with this worm. If the infection is light or if the birds are adults, little, if any, clinical effect has been noted.

CONTROL OF POULTRY NEMATODES

Prevention. Preventive measures for the control of poultry roundworms have been developed along the lines of sanitation, *hygiene, and management, and it is along* these lines that the greatest progress has been made.

The proper selection of a permanent site for the poultry runs is one of the first essentials to the maintenance of health among the birds. The land should be sloping and of a sandy or gravelly nature to provide for proper drainage. If the soil is heavy, or the lay of the land is such as to render natural drainage impossible, artificial drainage should be provided. The nonparasitic stages of helminth parasites require moisture for their proper development. Therefore, the presence of surface water, which birds are apt to drink, must be regarded as unhealthful, and provisions should be made to eliminate it as soon as possible. Damp places and water holes are ideal breeding places for many of the intermediate hosts of poultry nematodes.

The practice of rotating the birds from one area of land to another in order to reduce parasitism among the birds has been followed with reasonably good success in some sections of the country. The four-yard system is the one most widely advocated and probably the one best suited for general use. A given area of land—the amount depending upon the number of birds raised—is cross-fenced so that it is divided into four equal lots. The shelter or house is placed in the center of the plot and so constructed that a door opens into each pen. The birds are rotated from one pen to another, keeping them in each pen no longer than 2 or 3 *months. After removing the birds from* one of the pens, the ground in that pen may be prepared for planting to some green crop or left undisturbed to undergo self-sterilization by exposing the infected droppings to the direct action of the sun, wind, and cold. The planting of the yards to a permanent or temporary crop serves a twofold purpose: (1) It furnishes abundant green food for the growing birds, and (2) there is some evidence to indicate that birds are less likely to pick up contaminated soil when plenty of green food is available, thus reducing parasitism in the birds. The house and adjacent grounds should be cleaned as often as is deemed necessary to maintain good sanitation. The practice of removing the soil about the house to a depth of 6 to 8 inches and replacing it with sand or coarse ashes has sometimes been followed. During the summer months, birds spend a great deal of their time in the shade of the house, and it is necessary that extra precautions be taken to improve the sanitary conditions around the house.

The frequent removal of the droppings and the proper disposal of them cannot be recommended too highly. (See discussion of manure disposal under control of cestodes, p. 1030.)

The raising of the different species of birds together or in close proximity to each other is a dangerous procedure as re-

gards parasitism. Ransom (1921) showed by careful investigations that adult turkeys served as carriers of gapeworms in transmitting gapeworm disease to little chicks and that the older chickens were almost entirely insusceptible to infection with the above worms. Adult turkeys carrying natural infections of gapeworms apparently suffer only slightly, while young chicks and turkey poults suffer very severely from infections with gapeworms.

It is also dangerous for turkeys to associate with chickens. Tyzzer (1928) established the fact that blackhead occurs in young and old chickens, the latter usually recovering from the disease without suffering a great deal. However, this same investigator also demonstrated that the recovered chickens remained carriers of the blackhead organism for an indefinite period, and that turkeys contract blackhead by exposure to infected poultry or runs occupied by the latter.

It follows from the work of Ransom, Tyzzer, and others that anyone wishing to raise poultry would do well to decide in the beginning to raise turkeys or to raise chickens but not to raise both on the same land or in close proximity to each other. Should a person desire to raise both chickens and turkeys, he should keep the two kinds of birds on ranges well separated from one another

It is dangerous too for turkeys and chickens to associate with guinea fowls. Wehr (1959b) showed experimentally that the guinea fowl is susceptible to infection with the poultry gapeworm, *Syngamus trachea,* at any age and that this bird may carry the parasites for as long as 98 days.

Treatment Satisfactory remedial agents have been discovered for the removal of the poultry gapeworm, *Syngamus trachea,* the large intestinal roundworm of the chicken, *Ascaridia galli,* and the cecal worm, *Heterakis gallinarum,* but equally effective drugs for the removal of the other poultry nematodes are lacking.

Wehr *et al.* (1939) found that the compound, barium antimonyl tartrate, successfully removed a very high percentage of gapeworms from chicks, turkey poults, and adult turkeys when administered as an inhalant.

For treatment the birds are placed in a suitable container, such as a tight box. The drug is introduced into the box as a very fine powder by means of a dust gun. Because of its fluffiness, the powder remains suspended in the air for a long time. As the dust-laden air is breathed in by the infected birds, the fine particles of barium antimonyl tartrate apparently adhere to the moist surfaces of the worms and act as a contact poison.

The size of the dose of the powder to be administered is determined by the cubic capacity of the treatment box. One ounce of barium antimonyl tartrate has been found to be sufficient for a box having a capacity of 8 cubic feet. Approximately one-third of the powder is introduced into the treatment box at the first operation. If the box is of a convenient size to lift, it is tilted slowly from side to side several times. Tilting the box causes the birds to flap their wings, thus aiding in redispersing any powder that may have settled on the feathers of the birds or on the floor of the box. Tilting also causes the birds to breathe deeper and more frequently. Deep breathing is necessary to bring the powder in contact with the worms that may be found in the lower part of the trachea. In the case of mature birds, when the treatment box is likely to be too large and heavy to tilt by hand, a small electric fan may be placed on the floor of the box to keep the powder agitated during the process of treatment. After about 5 minutes, one-half of the remaining powder is blown into the box and the tilting or the use of the fan is repeated. The remaining one-third of the powder is introduced into the treatment box about 15 minutes following the introduction of the first one-third, and the box is again tilted or the fan used. The birds are released 5 to 10 minutes after the last of the powder has been blown into the box.

Rectal injections of a mixture of oil of chenopodium and of olive oil or cottonseed oil, given with a hard rubber syringe, in doses of 0.1 cc. in 5 cc. of the oil in case of birds weighing 1.5 pounds and double this amount of chenopodium and oil for adult birds weighing 3 pounds or over, have been found by Hall and Shillinger (1923b) to be approximately 90 per cent efficacious for the removal of the cecal worm of chickens and turkeys. McCulloch and Nicholson (1940) reported that phenothiazine, when given either in repeated or single doses, was very effective for the removal of the cecal worm from chickens. Doses ranging between .05 and 0.5 grams were found to be the most satisfactory individual doses. These authors found repeated doses and the administration of the drug in individual capsules to be slightly more satisfactory, although they indicated that flock medication appeared to be practical. They experimentally determined that doses up to 500 times the smallest amount found to be therapeutically effective had no apparent harmful effect on the birds; such massive doses also had no antiheterakid effect. The administration of phenothiazine in doses of 0.5 grams per bird had no appreciable effect on a flock in egg production and was not followed by enteritis or other digestive disturbances, except for a slight softening of the feces 24 hours after treatment. For flock treatment one pound of powdered phenothiazine is mixed with as much wet mash as 900 to 1,000 birds will consume in approximately one hour. The mash and the phenothiazine should be thoroughly mixed when dry, then moistened to increase palatability. Great care must be taken that there are plenty of feed hoppers to permit all birds in the flock to eat at the same time.

Birds given phenothiazine should be confined to the house. Feed should be withheld for a few hours or half a day until the birds become quite hungry. Worms will be eliminated in the droppings during the 2 or 3 days following the treatment. The house should then be thoroughly dry cleaned and clean litter added. Birds that are given access to yards or the range during treatment should be removed to new soil not later than one week after treatment, and the soil exposed to action of sun and wind for several months if possible.

Hall and Shillinger (1923a) reported that carbon tetrachloride failed to remove any large roundworms from one chicken treated with 1 cc. per kilo of body weight, but removed all the worms present in three cases when administered at the rate of 2, 4, and 5 cc. per kilo of body weight. Ackert and Graham (1935) found that carbon tetrachloride was highly efficacious in removing the large intestinal roundworm from young chickens at a dose rate of 4 cc. per kilo with apparently no ill effects.

It has been known for many years that nicotine possesses a high nematocidal action against the large roundworm of poultry. However, because of its toxicity to the fowl, its use for the control of this parasite was temporarily delayed.

Herms and Beach (1916) were the first to employ tobacco stems for the removal of poultry roundworms. They found that by soaking chopped tobacco stems for 2 hours and mixing the stems and the liquid with about one-third of their normal ration of mash, many roundworms were removed. The birds were fasted for about 24 hours before they were given the medicated mash.

Freeborn (1923), of the University of California Agricultural Experiment Station, conceived the idea of mixing nicotine sulphate (Black Leaf "40") with an earthen material known as Lloyd's alkaloidal reagent, thereby rendering much less toxic a substance which by itself would not be safe to use. The mixture, which contained 6.6 cubic centimeters of nicotine sulphate and 16 grams of Lloyd's alkaloidal reagent, was placed in capsules, each capsule containing approximately 350 to 400 milligrams, and administered individually to the birds. This formula became known as the University capsule.

The introduction of this capsule marked a renewed interest in the treatment of fowls for the removal of the large intestinal roundworm. However, it was soon discovered that the gelatine capsule containing the mixture was soluble in the secretions of the upper part of the digestive tract, and toxic symptoms and, in some cases, death resulted. Moreover, necropsies on some of the treated birds revealed the presence of numerous roundworms, indicating that the dose of nicotine in the University capsule was not sufficient to remove all the worms satisfactorily

Davis (1940) stated that it was possible to mix nicotine with an organic colloidal material (name not given) to obtain a mixture which was nonlethal to the animal to which it is administered even though the amount of nicotine is in excess of a lethal dose. The use of such a mixture, he stated, satisfactorily removed roundworms from chickens, provided 70 to 80 milligrams of nicotine were administered at a single dose He further stated that it was possible in the mixing of the nicotine and the organic colloidal material to so regulate the release of the alkaloid (nicotine) that the greatest amount could be liberated where it was most needed. In the case of the intestinal roundworm, which is found to be most numerous in the anterior portion of the small intestine, the liberation of the drug would have to be delayed until after it passed through the gizzard.

Levine (1936) administered a mixture containing one-fourth pound Black Leaf worm powder (a 5 per cent nicotine compound composed of nicotine sulphate mixed with a special fuller's earth) and 5 pounds of mash to 45 pullets Feed was withheld from the birds overnight. The birds promptly cleaned up the mash the next morning. Two hundred and eighty-four worms were removed by the treatment; none was found at autopsy.

Guthrie and Harwood (1942) conceived the idea of mixing phenothiazine and nicotine-bentonite (a claylike material) and administering the mixture for the removal of both *Heterakis gallinae* and *Ascaridia galli* from chickens. Tablets containing 33 parts phenothiazine, 66 parts nicotine-bentonite (5 per cent nicotine), and 1 part sodium stearate removed 83.7 per cent of 1,012 *Heterakis* and 96.2 per cent of 131 *Ascaridia*. When administered separately and in equivalent amounts to infected chickens, the phenothiazine removed 89.9 per cent of 675 *Heterakis* and 48.2 per cent of 110 *Ascaridia*; the nicotine-bentonite removed 10.1 per cent of 1,246 *Heterakis* and 85.2 per cent of 149 *Ascaridia*.

Harwood and Stunz (1945) found that phenothiazine and nicotine-bentonite mixture gave good results in removing *Heterakis gallinae* and only fair results in removing *Ascaridia dissimilis* from the turkey.

Scientists of the Bureau of Animal Industry demonstrated that the feeding of a medicated mash containing 15 grams of nicotine sulphate (Black Leaf "40"), 151 grams of phenothiazine, 287 grams of bentonite, and 44 pounds of chick feed for 3 consecutive days at intervals of 3 weeks to chickens held continuously on worm-infected soil maintained a low level of parasitism in the treated birds.

Riedel (1951) investigated the anthelmintic value of Caricide (1-diethylcarbamyl-4-methylpiperazine hydrochloride) as a flock treatment in chickens infected with *Ascaridia galli*; he found that feeding a mash containing 1.0 per cent Caricide for a 2-week period and administration of an Epsom salt purge at the end of the first and second weeks eliminated 89.2 per cent of the worms, while none of the untreated birds passed worms. A third group of birds, treated similarly with Caricide but not purged, eliminated 72.0 per cent of their worms.

Piperazine and its derivatives have been recently shown to be highly effective as anthelmintics in man and other animals Bradley (1955) reported a very high recovery of *Ascaridia galli* in two tests in which 15,600 8-week-old broiler chicks were given a water solution containing 8

gm. of piperazine citrate per 1 gallon of drinking water for 60 hours, and 17,900 6-week-old birds were given a similar solution containing 6 gm. of piperazine citrate for 24 hours. Shumard and Eveleth (1955) reported that piperazine citrate, when administered at the rate of 8, 10, and 16 gm. per 1 gallon of drinking water for 1 to 4 days, effectively removed all *Ascaridia* but not *Heterakis*. Vianello and Vicenzoni (1955) administered piperazine citrate to fowls in doses of 300 to 400 mg. per kg. body weight and reported the complete disappearance of both mature and immature *Ascaridia*. No previous fasting was necessary, and the drug was well tolerated. Horton-Smith and Long (1956) tested three piperazine compounds (piperazine carbon bisulphide, piperazine adipate, and piperazine citrate) against *Ascaridia galli* in chickens and reported that all adult worms were completely eliminated. The compounds were administered as single doses varying from 100 to 500 mg. per kg. body weight. Two of the drugs (piperazine adipate and piperazine citrate) removed from 80 to 100 per cent of the *Ascaridia* when incorporated in the feed at the rate of 300 mg. in 100 gm. wet mash or 300 mg. per 200 ml. of drinking water. Colglazier, Foster, Enzie, and Thompson (1960) reported that 1 gm. doses of phenothiazine removed 94 per cent of the *Heterakis* and 24 per cent of the *Ascaridia* present. Piperazine citrate, given by capsule in single doses containing 200 mg. of piperazine, removed 66 per cent of the *Heterakis* present. Doses of 100 mg. and 200 mg. piperazine were both effective against *Ascaridia*. Single 1 gm. doses of 7:1 mixture of phenothiazine and piperazine removed 94 per cent of the *Heterakis* and 100 per cent of the *Ascaridia*. Comparable results were obtained against both species with a 0.75 gm. dose of a 12:1 mixture of the two chemicals. Whitney (1957) reported that piperazine citrate effectively removed *Ascaridia columbae* from pigeons by withholding drinking water overnight and giving a solution containing 8 gm. of the compound to each

gallon of water the next morning. The solution was replenished each morning for the next 3 days and clean water added at noon on the third day. No ill effects, except a slight nausea, were noted.

None of the piperazine compounds is particularly dangerous to the administrator or its recipients. Skin contact over a long period of time may produce a mild irritation, but washing of the exposed areas with copious amounts of water will alleviate the condition.

Most of the piperazine derivatives have a broad safety margin and, therefore, a very low toxicity to the host. On *Ascaridia*, these compounds exert a narcotizing effect, thus enabling the worms to be removed by means of natural peristalsis. The worms are expelled alive and may be seen wriggling if observed soon after expulsion.

The sterilization by means of fumigants of soil contaminated with the eggs and larvae of poultry parasites is receiving some attention. It has been found that methyl bromide is highly effective against ova of some of the common nematode parasites of swine (Andrews *et al.*, 1945) and of poultry (Clapham, 1950). Earthworms and other arthropods inhabiting the soil are also readily killed by methyl bromide fumigation.

For the treatment of the eyeworm, Sanders (1929) recommended a modification of that advocated by Wilcox and McClelland in 1913. The eye is first anesthetized by means of a local anesthetic. The worms are exposed by lifting up the nictitating membrane and one or two drops of a 5 per cent solution of creolin is placed directly on the worms. The eye is then immediately irrigated with pure water to remove the excess creolin solution. Inasmuch as the worms are killed immediately upon contact with the creolin solution, the irrigating of the eye does not interfere with the effectiveness of the treatment. Within 48 to 60 hours after the treatment, the eyes will begin to show improvement, provided the damage has not been too great.

Emmel (1939) reported that the feed-

ing of regular mash to which 5 per cent of flowers of sulphur had been added seemed to benefit turkeys infected with *Capillaria contorta*. At the end of 3 weeks' treatment, he stated that "recovery occurred in all affected birds which were able to eat when treatment was started."

Thienpont and Mortelmans (1962) reported that capillariasis in pigeons and chickens (*Capillaria obsignata*) could be controlled by the administration of 1 cc. of a 10 per cent methyridine solution subcutaneously in the pectoral region or into the leg (pigeon) and dorsal region between the wings (chickens). The writers stated that this drug must be administered with great care as (1) spilling of the drug on the skin may produce a small lesion, (2) nausea, slight ataxia, and incoordination were observed to some degree even with subeffective doses, and (3) death may sometimes result. The drug had no marked effect in coccidiosis and trichomoniasis, and was only slightly effective against *Ascaridia*.

Clarke (1962), following a number of investigations in the use of haloxon against *Capillaria* infection in chickens, reported that individual doses of 25 and 50 mg. per kg. body weight practically eliminated all the worms. However, it was necessary to remove the birds from the infected environment immediately after dosing to prevent reinfection. It was suggested that the most suitable time to treat was immediately prior to movement from the rearing to the laying quarters.

Poultry manure serves as a breeding place or feeding grounds for a large number of arthropods or their progeny, many of which serve as vectors of those species of poultry parasites that require an intermediate host in order to complete their development. It is here that the eggs of these parasites develop to the stage infective to the intermediate hosts.

Circumstances at times arise which do not permit the disposal of poultry manure in a sanitary manner. In order to surmount such an obstacle, the possibility of treating the accumulated manure with insecticides for the destruction of arthropods has received some attention.

Work in Hawaii on the control of arthropods breeding in poultry manure by Tanada *et al.* (1950) and Kartman *et al.* (1950) indicates that kerosene solutions of DDT and chlordane at 1 per cent and acetone solutions of benzene hexachloride at below 1 per cent gamma concentration were highly effective under simulated natural conditions. (See Control of Tapeworms, p. 1029).

Acanthocephalids

The Acanthocephala or thorny-headed worms are parasites occurring as adults in the intestinal tract of vertebrates. In form they are elongate, roughly cylindrical, or spindle-shaped. Several distinct body regions are recognizable: retractile proboscis armed with hooks, a neck, and a body proper. The retractile proboscis bears always a considerable number of recurved hooks which are arranged in rows. The number, form, and arrangement of the hooks are valuable diagnostic characters. The body proper forms the major portion of the worm. It is usually unarmed but may bear small spines of definite form and arrangement on some portion of the external surface. This group of worms is deprived of a digestive tract. Nutrition is thus provided for entirely by absorption through the body wall. The sexes are separate in all cases. The male is smaller and more slender than the female and often distinguished externally by a bell-shaped bursa that surrounds the genital pore.

So far as known, all species of *Acanthocephala* require one or more intermediate hosts before reaching a stage of development where they are infective for the final host. Various arthropods, snakes, lizards, and amphibians serve as hosts of the larval stages of these parasites.

Only three species of thorny-headed worms have been reported as parasites of domestic poultry in North America, two of these as immature forms.

Oncicola canis (Kaupp, 1909)

Oncicola canis (Kaupp, 1909) was found in about 10 per cent of the young turkeys around San Angelo, Texas, by Price (1929). The worms were encysted under the epithelial lining of the esophagus in numbers varying from a few to 100 or more. They were reported as the possible cause of death (Fig. 34.24A, B, C, and D).

The adults of this parasite occur in the dog and coyote. The presence of larval forms of this parasite in young turkeys suggests that such occurrences are accidental, the young worms encysting when taken into an unsuitable host.

Plagiorhynchus formosus Van Cleave, 1918

An immature male and two female specimens of *Plagiorhynchus formosus* Van Cleave, 1918, were reported by Jones
FIG. 34.24—Oncicola canis. (A) Male showing reproductive organs. (B) Proboscis. (C) Hooks from proboscis (numerals indicate row). (D) Egg. (From Price, 1926.)
FIG. 34.25 — *Plagiorhynchus formosus*. (A) Young female: l, lemniscus; a, ovary, pr, proboscis receptacle (from Janes 1928). (B) Male. (C) Hooks from proboscis. (D) Egg. (Enlarged.) (From Van Cleave, 1918.)

FIG. 34.26 — *Polymorphus boschadis*. (A) Male. (B) Larva from *Gammarus pulex*. (C) Proboscis of larvae. (Enlarged.) (From Lühe, 1911.)

(1928) from the small intestine of a chicken collected at Vineland, New Jersey. Other bird hosts from which this species has been reported are the flicker, collected at Bowie, Maryland, the crow, collected at Washington, D.C.; and the robin in New Jersey (Fig. 34.25A, B, C, and D).

Polymorphus boschadis (Schrank, 1788)

Wickware (1922) reported *Polymorphus boschadis* (Schrank, 1788) from the duck

in Canada. This parasite is reported as causing serious injury and death among domesticated waterfowl, especially in young birds. It causes an inflammation of the intestine with subsequent anemia and cachexia. According to Schlegel (1921), the birds are sick only a short time, the gait is staggering, and the head and wings droop (Fig. 34.26A, B, and C).

Cestodes of Poultry

The cestodes or tapeworms are flattened, ribbon shaped, usually segmented worms. As adults, they are found principally in the intestines of their hosts. These worms are hermaphroditic and lack both a mouth and an alimentary canal.

The class CESTODA has recently been subdivided into fourteen orders (Wardle and McLeod, 1952). The tapeworms which occur in poultry of this country have been grouped by these authors into one order, namely CYCLOPHYLLIDEA. The CYCLOPHYLLIDEA, or taenioid cestodes are, as adults, parasitic chiefly in the higher vertebrates and are of considerable economic and medical importance. These tapeworms are characterized by having a scolex with four cup-shaped suckers and with or without a rostellum.

The taenioid cestodes are grouped into a number of families, four of which contain species infecting poultry. The worms of the family Anoplocephalidae possess neither rostellum nor hooks. The proglot-

tids are usually wider than long, and each proglottid contains one or two sets of genital organs. The genital pores are marginal, and the eggs frequently contain "pyri-form" bodies. The species *Aporina dela-fondi* belongs to this family. The family Davaineidae is composed of tapeworms having a scolex with a simple rostellum which is armed with one or more rows of numerous hammer-shaped hooks. The suckers are usually also provided with hooks. Each proglottid contains one or two sets of genital organs. The uterus is persistent and saclike, or replaced by either numerous egg capsules or a paruterine body which later becomes transformed into a single egg capsule. Poultry tapeworms of the genera Davainea and Raillietina belong to this family. In the family Dilepi-didae, the rostellum is usually armed, but the suckers are unarmed. The genital pores are marginal, one or two in each segment. The uterus is saclike, or resolved into egg capsules — uterus with or without

paruterine body. The poultry tapeworms, *Amoebotaenia sphenoides* and *Choanotaenia infundibulum*, belong to this family. The Hymenolepididae is characterized by having a scolex with rostellum usually armed with a single row of hooks; the suckers are unarmed. The genital pores are usually unilateral, rarely two in each segment. The uterus is usually persistent and saclike. The eggs are enclosed in three envelopes. The species of poultry tapeworms belonging to the genus Hymenolepis belong to this family.

General morphology. Structurally, a complete tapeworm consists of a head, neck or growth zone, and a variable number of segments or divisions. The head or scolex of a taeniid tapeworm consists of four cuplike organs or suckers which may surround a terminal retractile organ known as the rostellum. Hooks may or may not be found on the rostellum, and deciduous spines often arm the suckers. The number, size, and shape of the rostellar hooks vary as to species, and these variations are used by systematists in differentiating species and even genera of tapeworms. The term "neck" or "growth zone" is applied to the narrowed and unsegmented region located just back of the head and in some cestodes, is not macroscopically distinct from the head. The segments or divisions of a tapeworm when taken collectively are generally spoken of as the strobila, and each segment or division as a proglottid. The size, shape, and development of proglottids vary tremendously even in the same individual worm. The anterior segments are usually broader than long and contain few, if any, recognizable internal organs. Those segments near the middle of the body of the tapeworm may have the antero-posterior diameter proportionately greater than that of the anterior segments. These segments are spoken of as mature segments, since in these proglottids both the male and female reproductive organs are distinctly differentiated. Eggs are not usually found in segments of this part of the body. The terminal or gravid segments are variable

in shape and usually contain the uteri and eggs or only eggs with the uterus either partly or wholly obliterated.

Since tapeworms lack an alimentary canal, food is absorbed through the surface of the body.

A tapeworm grows from the neck backwards, and segments are continually being budded off from the proliferating tissue found in this region. Therefore, the segments farthest removed from the growing region are the oldest from the standpoint of development. The newly formed segment contains no distinguishable organs, while the terminal segments of a completely formed tapeworm may be nothing more than egg sacs. The latter are known as gravid segments and are the ones usually found in the droppings of infected birds.

All adult tapeworms of poultry are found usually in the small intestines of their hosts. However, *Hymenolepis megalops*, the large-headed tapeworm of ducks, occurs in the cloaca and bursa Fabricius of these birds. Each species of tapeworm usually shows some predilection for a particular portion of the small intestine to which to attach. The species *Hymenolepis carioca*, *H. cantaniana*, *Amoebotaenia sphenoides*, and *Davainea proglottina* are usually found in the duodenal region of the small intestine; *Raillietina cesticillus*, *Choanotaenia infundibulum*, and *Metroliasthes lucida* in the jejunal region; and *Raillietina tetragona* and *R. echinobothrida* in the distal portion or ileum. However, in heavy infections, tapeworms may be found in portions of the small intestine other than their more normal locations.

Adult tapeworms of poultry differ considerably as to length and as to number of proglottids or segments. *Davainea proglottina* and *Amoebotaenia sphenoides* are two of the smallest tapeworms found in poultry. Mature specimens of the former species measure up to 4 mm. in length and have a range of segments from 4 to 9, while those of the latter species reach a length of from 2 to 3.5 mm. and possess approximately 30 proglottids.

Raillietina echinobothrida and *R. tetragona*, on the other hand, are two of the largest tapeworms infecting poultry. Mature specimens of both of these tapeworms may attain a length of approximately 25 cm. and possess large numbers of proglottids.

Development. In the case of every tapeworm of poultry in which the life history is known, an intermediate host is necessary for the completion of the life cycle. Investigations have shown invariably that intermediate hosts of tapeworms have always been found to be invertebrates, such as a beetle, fly, snail, slug, or crustacean. Tapeworm segments are devoured by dung-feeding insects either along with their normal food or because they are attracted to the attention of the invertebrates by their movements.

The type of intermediate host that serves a particular tapeworm in its successful transference from one bird host to another depends to a large degree on the habits of the avian host. In the case of terrestrial birds, such as chickens, turkeys, guinea fowls, etc., which deposit their body wastes principally away from ponds and streams, the intermediate hosts must necessarily have to be forms of animal life that lead a terrestrial life, or at least an amphibious one. On the other hand, tapeworms inhabiting water birds, such as ducks and geese, usually have aquatic invertebrates as natural intermediate hosts.

Invertebrates, which serve as intermediate hosts of poultry tapeworms, become infected with larval tapeworms by ingesting, along with their food, the free eggs or the egg-bearing segments voided by the infected birds. Following ingestion the eggs hatch in the digestive tract, the embryos or larvae penetrate the intestinal wall, enter the body cavity, and after a few days become transformed into small, white, bladderlike, spherical bodies, known as cysticercoids (small cysts). These cysts are distinctly visible to the unaided eye when placed in water after removal from the body of the intermediate host. Under proper magnification the head of

the tapeworm may be seen near the center of the cyst.

Approximately 3 weeks are required for the embryos to develop into the cysticercoid stage after the eggs have been ingested by the intermediate host. No further development of the tapeworm takes place in the invertebrate host. The cysticercoids may remain alive in the invertebrate host and infective to the bird host for many months.

Poultry become infected with tapeworms by swallowing, with their food and water, insects, snails, slugs, and other forms of animal life that may serve as intermediate hosts of these parasites. The cysticercoid is freed from the body of the intermediate host by the action of the digestive juices. Soon after the cysticercoid is liberated, the head evaginates and becomes attached to the intestinal wall. New segments or proglottids begin to form immediately at the neck region, and within approximately 3 weeks a mature tapeworm is formed. The entire life cycle, therefore, takes about 6 weeks for completion, but under unfavorable conditions a longer period of time may be necessary.

Gross pathology. A few tapeworms may produce little or no perceptible gross pathological changes in the intestines. However, in heavy tapeworm infections, a more or less extensive catarrhal enteritis and diarrhea may result. At least one species of tapeworm, *Raillietina echinobothrida*, causes the formation of nodules in the intestinal wall. Inasmuch as this condition closely resembles tuberculosis, it is important that the two conditions be kept in mind in attempting to arrive at a diagnosis of the condition present. The presence of intestinal nodules — sometimes distinctly visible on the outer surface of the intestinal wall — and the absence of tapeworms is strongly suggestive of tuberculosis. However, a diagnosis of intestinal tuberculosis should not be made without first eliminating tapeworms of this species as a cause of the nodules. Mature specimens of this tapeworm are usually several centimeters long, but observations

have shown that, in many cases, infections involved individual tapeworms containing only a very few segments, sometimes only the heads. In such cases, the parasites may be easily overlooked if only a casual or hurried examination is made. In doubtful cases, the intestine should be scraped with a scalpel or other suitable instrument and a careful examination made of the scrapings under suitable magnification for the presence of small tapeworms or their heads. The presence of tapeworms and the absence of tubercles in the liver and other organs are indicative of tapeworm disease. Another species of tapeworm, *Raillietina tetragona*, which is morphologically very similar to *R. echinobothrida* and often confused with it, has not been definitely associated with tuberculosislike lesions.

Leg weakness and paralysis have frequently been attributable to tapeworm infection. However, the relationship of tapeworms to these diseases is still unknown. Should these conditions be intimately associated with the presence of tapeworms, the mere removal of the parasite should clear up the condition. The fact that birds which had previously shown symptoms of leg weakness and paralysis were free from tapeworms at necropsy seems to disprove the idea that tapeworms are in a large degree responsible for these conditions. Capillary congestion; lymphocyte, polymorphonuclear, and eosinophil infiltration; proliferation of epithelium; and fibrosis are other conditions which have been associated with tapeworm infections.

There is some evidence to show that birds heavily parasitized with tapeworms are not as productive as uninfected ones. Under ordinary conditions birds may tolerate a fairly heavy tapeworm infec-

tion, at least for a time. However, young birds and hens in heavy production do not fare so well when heavily infected with these parasites.

Importance of cestodes as parasites of poultry. Chickens in this country may be infected with one to as many as seven species of tapeworms. With the exception of one or two of these species, all are of common occurrence. A few years ago, the list of intermediate hosts of poultry tapeworms was small, but investigations within the last few years have been responsible for an alarming increase in the number of invertebrate intermediate hosts that tapeworms of poultry may utilize for the development of their larvae.

The control of poultry tapeworms involves treatment for the removal of the tapeworms themselves and the reduction of the numbers of intermediate hosts by sanitary measures. Since the treatment of fowl taeniasis is still in an unsatisfactory state, sanitation has almost wholly been relied upon to prevent tapeworm infection. This method of control involves, first of all, the proper disposal of poultry manure containing the eggs of tapeworms so that the intermediate hosts cannot become infected with the larval stages of these parasites. Many of the intermediate hosts are flying insects, and once the latter have become infected with larval tapeworms they may be responsible for the spread of the disease to distant flocks. Recent investigations have indicated that clean birds held in close proximity to infected birds will invariably become infected with tapeworms within a relatively short time.

The species of cestodes parasitizing poultry of the United States belong to four families which may be differentiated by the following key:

1. Head armed with numerous hammer-shaped hooks . . . . . Davaineidae
   Head armed with hooks not hammer-shaped, or unarmed 2
2. Testes few, 1 to 4, rarely more . . . . . Hymenolepididae
   Testes numerous, more than 4 3
3. Head lacking rostellum; no paruterine organs in species occurring in poultry . . . . . Anoplocephalidae
   Head with retractile rostellum, usually armed, or, rarely, unarmed; rarely without rostellum; with or without paruterine organs . . . . . Dilepididae

LIST OF TAPEWORMS KNOWN FROM POULTRY OF UNITED STATES

The following is a list of the species of tapeworms found in poultry of this coun-try, with their primary and secondary hosts, usual location and kinds of poultry affected.

Tapeworms	Location	Intermediate hosts	Definitive hosts
Davainea proglottina	Duodenum	Slugs, snails	Chicken
Davainea meleagridis	Duodenum	Unknown	Turkey
Amoebotaenia cuneata	Duodenum	Earthworms	Chicken, Turkey
Hymenolepis carioca	Duodenum	Stable fly Dung beetles	Chicken, Turkey Bobwhite quail
Hymenolepis cantaniana	Duodenum	Beetles	Chicken, Turkey Peafowl Bobwhite quail
Raillietina cesticillus	Jejunum	Housefly Beetles	Chicken, Turkey Guinea fowl Bobwhite quail Gray jungle fowl
Choanotaenia infundibulum	Jejunum	Housefly, Beetles	Chicken, Turkey
Raillietina tetragona	Ileum	Ants	Chicken, Turkey Guinea fowl, Peafowl Bobwhite quail
Raillietina echinobothrida	Ileum	Ants	Chicken, Turkey
Metroliasthes lucida	Ileum	Grasshoppers	Turkey, Chicken Guinea fowl
Hymenolepis compressa	Intestine	Unknown	Duck, Goose
Hymenolepis introversa	Intestine	Unknown	Duck
Hymenolepis megalops	Cloaca and bursa of Fabricius	Unknown	Duck
Hymenolepis tritesticulata	Intestine	Unknown	Duck
Hymenolepis coronula	Small Intestine	Crustaceans Snails	Duck
Hymenolepis lanceolata	Small Intestine	Crustaceans	Goose
Hymenolepis tenuirostris	Small Intestine	Crustaceans Crayfish	Duck, Goose
Raillietina magninumida	Small Intestine	Beetles	Guinea fowl
Raillietina ransomi	Small Intestine	Unknown	Wild turkey
Raillietina williamsi	Small Intestine	Unknown	Wild turkey
Raillietina georgiensis	Small Intestine	Ants	Wild turkey Domestic turkey
Aporina delafondi	Small Intestine	Unknown	Pigeon
Fimbriaria fasciolaris	Small Intestine	Water flea	Chicken

CLASSIFICATION OF POULTRY TAPEWORMS

The tapeworms of poultry belong to the general group designated as taenioid cestodes, which are characterized primarily by the presence of four cup-shaped suckers upon the head. The following key will aid in the differentiation of the genera of tapeworms found in poultry of this country:

1.	Rostellum absent	2
	Rostellum present	3
2.	Paruterine organ present	*Metroliasthes*
	Paruterine organ absent	*Aporina*
3.	Mature worms small, usually not longer than 4 to 5 mm.	1
	Mature worms large, longer than above . . .	5
4.	Strobila consisting of 2 to 9 segments . . .	*Davainea*
	Strobila consisting of numerous segments . . .	*Amoebotaenia*
5.	Testes 3 in number	6
	Testes more than 3 in number	7
6.	With a well-developed pseudo-holdfast organ, in addition to a small, true holdfast organ, containing no genital primordia . . . *Fimbriaria*
	With only a true holdfast organ . . . . . *Hymenolepis*
7.	Rostellum armed with a single row of 16 to 20 hooks, each 20 to 30μ long . . . . *Choanotaenia*
	Rostellum armed with either a single row or double row of 100 or more hooks, each 6 to 15μ long . . . . . *Raillietina*

DESCRIPTIONS OF POULTRY TAPEWORMS

To facilitate somewhat the identification of the species of poultry tapeworms, they have been grouped according to their normal location within the intestine of the hosts, i.e., duodenum, jejunum, and ileum, with a brief description of each species.

Five species of tapeworms normally inhabit the duodenal region. Three of these species, *Davainea proglottina*, *D. meleagridis*, and *Amoebotaenia cuneata*, are very small worms, rarely exceeding 5 mm. in length, and possessing relatively few segments. The other species, *Hymenolepis carioca* and *H. cantaniana*, are relatively long worms and are composed of many segments.

Dilepididae

Members of this family are characterized by having a single set of reproductive organs in each proglottid. The uterus is sac-like and more or less lobed or reticulate. Paruterine bodies are present or absent.

Amoebotaenia cuneata (Linstow, 1872)

Synonyms. *Taenia cuneata* von Linstow, 1872, not Batsch, 1786; *Taenia sphenoides* Railliet, 1892; *Dicranotaenia sphenoides* (Railliet, 1892) Railliet, 1896.

Description. Mature worms 2 to 3.5 mm. long, triangular or roughly fusiform in shape (Fig. 35.1A). Suckers unarmed; rostellum armed with a single row of 12 to 14 hooks, 25 to 32μ long (Fig. 35.1B). Genital pores usually regularly alternate, located at extreme anterior point of segment margin. Testes 12 to 15 in number, usually in a transverse row across posterior part of segment. Eggs (Fig. 35.1C) not contained in capsules.

This tapeworm, which usually occurs in the duodenal region of the small intestine, is apparently not a common parasite of poultry in the United States. It has been reported from chickens in Kansas by
FIG. 35.1.— Amoebotaenia cuneata. (A) Entire worm. (From Mönnig, 1926.) (B) Rostellar hook. (C) Egg. Original.

Ferry (1934), from chickens in Texas by Adams and Ceiser (1933), from chickens in Tennessee by Todd (1946), from chickens and turkeys in Michigan by Stafseth (1940), and from chickens in Alabama by Edgar (1956).

Life history. The intermediate host of this tapeworm is the earthworm. The earthworms *Eisenia (Helodrilus) foetida*, *Pheretina pequana*, *Ocnerodrilus (Ilyogenia) africanus*, and *Allolobophora chlorotica* have been found to serve as intermediate hosts of this tapeworm. Mönnig (1927) grew the cysticercoids in earthworms (*Ocnerodrilus (Ilyogenia) africanus*) in 14 days. Four weeks were required for the cysticercoids to develop into adult tapeworms in chickens. Cysticercoids from earthworms were identified as this species by Grassi and Rovelli (1889) and Meggitt (1916). Chickens be-

come infected by eating earthworms which carry the infective larva or cysticercoids of this cestode parasite.

Pathology. The damage done by this tapeworm is comparatively slight, according to Meggitt (1926). However, deaths in poultry as being due to this parasite have been reported.

Choanotaenia infundibulum (Bloch, 1779)

Synonyms. *Taenia infundibulum* Bloch, 1779; *Drepanidotaenia infundibuliformis* (Goeze, 1782) Railliet, 1893; *Choanotaenia infundibuliformis* (Goeze, 1782) Railliet, 1896.

Description. Mature worms attain a length of 23 cm. Suckers unarmed (Fig. 35.2A); rostellum armed with a single row of 16 to 20 hooks, occasionally 22, 20 to 50μ long (Fig. 35.2B). Genital pores irregularly alternate. Testes 25 to 40, occasionally as many as 55 to 60, grouped in posterior part of segment (Fig. 35.2C). Eggs with elongated filaments, not contained in capsules (Fig. 35.2D).

This species may be readily distinguished from the other poultry tapeworms by the rostellum, which is armed with a single row of relatively few and very large hooks, and bipolar egg filaments.

This cestode inhabits principally the jejunal region of the small intestine of chickens and turkeys and is widely distributed among these birds in the United States.

Life history. Birds become infected with adults of *C. infundibulum* by eating house flies, grasshoppers, and several species of beetles. Cysticercoids have been found in house flies and in some species of beetles as natural infections, and also after the insects have been fed eggs of this tapeworm. Horsfall and Jones (1937) reported that at a temperature of 75°–90° F., 17 to 20 days is the minimum time for development of the cysticercoids to the infective stage in the grasshopper, *Melanoplus femurrubrum*. At a temperature of 60°–75° F., 48 days is the minimum time for the development of the cysticercoids in
FIG. 35.2 — *Choanotaenia infundibulum.* (A) Scolex. (B) Rostellar hook. (C) Mature segment. (D) Gravid segment. (From Ransom, 1905.)

the beetle, *Aphodius granarius.* The adult worm in the chicken requires from 2 to 3 weeks for development to maturity.

Pathology. Probably similar to *R. cesticillus.*

Metroliasthes lucida Ransom, 1900

Description. Mature worms about 20 cm. long. Suckers unarmed, rostellum lacking (Fig. 35.3A). Genital pores irregularly alternate, near middle of, or in gravid segments, definitely posterior to middle of segment margin. Uterus, when fully developed, consisting of two sacs, lying side by side and very close together in posterior part of segment (Fig. 35.3D). Paruterine organ, a conical structure, developing anterior to uterus, eventually becoming a heavy-walled egg capsule for the retention of the eggs (Fig. 35.3E).

This species is a very common tapeworm of turkeys in this country. It was reported from a chicken by Ransom (1905), but he evidently doubted the validity of the host record since he stated that the occurrence of *Metroliasthes lucida* in chickens is doubtful. However, the occurrence of this species in chickens has been reported more recently by Rietz (1930) from West Virginia, by Southwell (1921) from India, and by Schwartz (1925)

from South Africa. It is readily recognized by the large unarmed head and the prominent spherical egg capsule, which is easily seen in the posterior part of each of the transparent segments in the posterior part of the body.

Life history. Cysticercoids were obtained by Jones (1930b) from grasshoppers several weeks after feeding to the insects gravid segments of *M. lucida;* both laboratory-bred grasshoppers and those collected in the field become infected. Jones (1936a) infected turkeys and guinea fowls with *M. lucida* after being fed cysticercoids from grasshoppers (*Melanoplus* species, *Chorthippus curtipennis,* and *Paroxya clavuliger*); chicks and quail remained negative for tapeworms after being fed cysticercoids of *M. lucida* from grasshoppers or beetles. The time required for the development of the cysticercoids in the insect host varies from 2 to 6 weeks. Approximately 3 weeks are required for the development of the adult worm to maturity in the avian host.

Pathology. Probably similar to that of *R. cesticillus.*

Davaineidae

Tapeworms of this family have a scolex with a simple rostellum which is armed
FIG. 35.3 — *Metroliasthes lucida*. (A) Scolex. Original. (B) Mature segment. (C) Egg. (D) Segment showing two-part uterus and developing paruterine organ. (E) Gravid segment. (From Ransom, 1900.)

with one or more rows of numerous hammer-shaped hooks. The suckers may be armed or unarmed. One or two sets of reproductive organs may be present in each segment. The uterus is persistent and saclike, or replaced either by numerous egg capsules or by a paruterine body transforming later into a single egg capsule.

Davainea proglottina (Davaine, 1860)

Synonym. *Taenia proglottina* Davaine, 1860.

Description. Mature worms attain a length of about 4 mm. (Fig. 35.4A). The strobila consists of from 2 to 5 segments, rarely as many as 9. Each succeeding segment gradually increases in length and breadth, the last segment often being larger than the remainder of the parasite. Suckers armed with 3 to 6 rows of small hooklets, 5 to 8μ long. Genital pores usu-

ally regularly alternate, located at extreme anterior point of segment margin. Testes 12 to 21 in number (Fig. 35.4B). One egg in each egg capsule.

In the United States this tapeworm has not been found to be as cosmopolitan in its distribution as some of the other cestodes of poultry, being found chiefly in the moister parts. It has been reported from both the eastern and western coastal states and from Tennessee and Alabama.

Life history. Cysticercoids of this tapeworm develop in approximately 3 weeks in several species of snails and slugs. Levine (1938) experimentally infected the garden slug (*Agriolimax agrestis*) with cysticercoids of *D. proglottina* and, in turn, infected chickens by feeding them garden slugs containing mature cysticercoids. When infected slugs or snails are eaten by chickens, the infective larva or cysticercoid develops to the adult worm

FIG. 35.4 – Davainea proglottina. (A) Entire worm, with eggs in last segment. (B) Mature segment. (From Meggitt, 1926.)

with 4 segments in approximately 8 days.

Pathology. This tapeworm has been considered to be one of the obviously dangerous tapeworms of poultry. It has been observed that infected birds become emaciated and dull, lose weight, the plumage becomes dry and ruffled, the movements slow, and the breathing rapid. At necropsy, the intestinal mucosa appears thickened, which may be hemorrhagic, and the intestine may contain a large quantity of mucus, which tends to be fetid. Crawley (1922) has reported this worm as killing chickens in Pennsylvania. Rietz (1930) has reported paralysis associated with the presence of this worm. However, the true relationship of leg weakness to this disease is still unknown.

Davainea meleagridis Jones, 1936

Description. Mature specimens up to 5 mm. long, composed of 17 to 22 segments. Suckers armed with 4 to 6 rows of hooklets, the longest about 5μ long; rostellum with a double row of about 100 to 130 hooks, 8 to 10μ long. Genital pores usually regularly alternate, located in extreme anterior point of segment margin. Testes 20 to 26 in number, in posterior half of segment. One egg in each capsule.

This parasite was described from the duodenum of the domestic turkey by Jones (1936b) in the vicinity of Washington, D.C., and from the wild turkey by Gardiner and Wehr (1949) in Maryland.

Life history. Unknown.

Pathology. Unknown.

Raillietina cesticillus (Molin, 1858)

Synonyms. Taenia cesticillus Molin, 1858; Raillietina cesticillus (Molin, 1858) Joyeux, 1923.

Description. Mature worms may attain a length of as much as 12 cm. Suckers unarmed; rostellum armed with two rows of hooks, about 300 to 500 in number (Fig. 35.5 A and B). Genital pores irregularly alternate, located anterior to middle of segment margin. Testes 16 to 30 in number, in posterior part of segment (Fig. 35.5C). Uterus divided into egg capsules, each capsule containing a single egg.

The most distinctive feature of this tapeworm is the unusually broad and flattened rostellum, with 2 rows of hooks near its base.

This fowl cestode is probably one of the most common species occurring in poultry. It is a rather large species, and its habitat is the duodenal and jejunal regions. Southwell (1930) reported R. cesticillus from Gallus sonnerati, the gray jungle fowl, in the Zoological Gardens of Calcutta.

Life history. Birds become infected with

FIG. 35.5 — Raillietina cesticillus. (A) Head, Original. (B) Hook from rostellum. (C) Mature segment. (From Ransom, 1905.)

R. cesticillus after being fed various infected ground beetles and dung beetles. Cysticercoids have been observed in such beetles as *Anisotarsus* spp., *Amara* spp., *Anaferonia* spp., *Harpalus* spp., *Pterostichus* spp., and other ground and dung beetles after they have been given experimental feedings of gravid segments of *R. cesticillus*, and also have been observed in natural infections in some of these beetles. Larva in beetles apparently requires from 2 to 4 weeks to develop to a stage infective for chickens. Adult worms in primary host usually require from 2 to 3 weeks to develop to maturity.

Pathology. This worm has been reported to cause degenerations and inflammations of the villi of the intestine at the point of attachment by the rostellum. Heavy infections in young birds may cause emaciation. However, Stoddard (1931) noted no serious inflammation of the intestinal walls, nor was stoppage of the intestines found to result from the presence of the worms in quail. Ackert and Reid (1937) and Ackert (1932) demonstrated experimentally that chickens 2½ to 5 months of age are more resistant to infection with this species of tapeworm than younger birds, and that a reduction in the blood sugar and hemoglobin contents of the blood resulted from such infections Harwood and Luttermoser (1938) reported that the growth rates of Rhode Island Red and White Leghorn chicks

were retarded by infections with *R. cesticillus*.

Raillietina echinobothrida (Megnin, 1881)

Synonyms. *Taenia echinobothrida* Megnin, 1881; *Raillietina echinobothrida* (Megnin, 1881) Fuhrmann, 1924.

Description. Mature specimens measure up to 25 cm. long. Suckers armed with 8 to 15 rows of hooks, 5 to 15μ long; rostellum armed with 2 rows of 200 to 240 hooks, 10 to 14μ long (Fig. 35.6 A and C). Genital pores almost unilateral, or definitely irregularly alternate, located at middle or, usually, posterior to middle of segment margin (Fig. 35.6B). Testes 20 to 30, occasionally as many as 45 in number. Uterus ultimately forming egg capsules, each capsule usually containing a single egg. Posterior segments of strobila frequently becoming constricted longitudinally through median line to form windows in the center of the segments. However, this appearance of the gravid segments is not constant in all specimens.

Raillietina echinobothrida is apparently widely distributed among poultry.

Life history. Jones and Horsfall (1935) reported that the ants *Tetramorium caespitum* and *Pheidole vinelandica* naturally harbored bladder worms or cysticercoids of *R. echinobothrida* and also those of another closely related species, *Raillietina tetragona*. The cysticercoids of the
FIG. 35.6 – Raillietina echinobothrida. (A) Scolex. Original. (B) Section through region of genital pore showing cirrus pouch and part of vagina. (From Long, 1929.) (C) Hooks from suckers.

two species were fed to laboratory-reared chickens. Three weeks after feeding the cysticercoids, adults of the two species of tapeworms were recovered post mortem from the experimentally fed birds; the controls were negative. All attempts to produce experimental infections in ants were unsuccessful. Large numbers of undissected ants collected from infected poultry runs were fed to 23 chickens; 19 of the chickens later became infected. Joyeux and Baer (1937) reported finding cysticercoids of *R. echinobothrida* in naturally infected ants, *Tetramorium semileave*, in the region of Marseilles, France.

Pathology. This worm causes the formation of tubercles on the intestinal wall of infected birds (Fig. 35.7). This condition resembles tuberculosis and, therefore, must be differentiated from that disease.

Gage and Opperman (1909) reported losses of 50 per cent in affected flocks in Maryland. They noted emaciation and a mucoid diarrhea as early symptoms, and later listlessness, loss of appetite, and a tendency to huddle; some birds are weak and epileptic. Death comes suddenly, accompanied by convulsions.

Raillietina tetragona (Molin, 1858)

Synonyms. *Taenia tetragona* Molin, 1858; *Raillietina tetragona* (Molin, 1858) Joyeux, 1927.

Description. Worms measure as much as 25 cm. long. Suckers armed with 8 to 12 rows of small hooks, 3 to 8μ long; rostellum armed with about 90 to 130 hooks, 6 to 8μ long, arranged in 1 or 2 rows (Fig. 35.8A). Genital pores usually unilateral, rarely irregularly alternate, located anterior to middle of segment margin. Testes 18 to 35 in number (Fig. 35.8D). Uterus eventually breaking up into egg capsules, 6 to 12 eggs in each capsule (Fig. 35.8B).

This worm is morphologically very similar to *Raillietina echinobothrida*. It is of common occurrence but is rarely associated with the distinct tuberculosis-like lesions produced by the former species.

Life history. See life history of *R. echinobothrida*.

Pathology. Lopez-Neyra (1931) reported a single case in which he found small nodules in the intestine due to this species. In quail, Stoddard (1931) observed that this species may be the principal or only cause of death in cases of heavy in-

FIG 35.7 — Nodular disease of intestine of chicken caused by tapeworms Raillietina echinobothrida. (After Bushnell and Brandly, 1929.)

fections. Of 25 birds, the deaths of which were attributed to infection with this species, the youngest was 17 days old, and the oldest 60 days; the greatest mortality occurred between the ages of 25 and 40 days. Although many birds may recover if they survive to 2 months of age, they are almost certain to be under-sized. Quail heavily infected with specimens of this tapeworm almost invariably have their crops and gizzards filled with food. That portion of the intestine occupied by these tapeworms sometimes becomes so distended that it is reduced to nearly one-half its length, being thrown into ridges of a purplish-red color. The lining of the intestine frequently sloughs off in cases of heavy infections. In several instances Stoddard observed that bobwhites heavily infected with this species moved with difficulty, a partial paralysis being evident.

Raillietina magninumida Jones, 1930

Synonym. Raillietina (Paroniella) magninumida Jones, 1930.

Description. Mature worms about 6 to 15 cm. long. Suckers armed with about 10 rows of hooks, the largest 7 to 8μ long; rostellum armed with 2 rows of about 150 to 170 hooks, 8 to 11μ long (Fig. 35.9A). Genital pores unilateral. Testes 12 to 20 in number (Fig. 35.9B). Egg capsules containing 1 egg each.

This tapeworm is a common parasite of the guinea fowl in the United States. Hudson (1934) considered R. magninumida as a synonym of R. numida (Fuhrmann, 1912). The latter species occurs in the guinea fowl of Africa.

Life history. Guinea fowls become infected with this species by ingesting cysticercoids of this tapeworm. Cysticercoids have been found in beetles both as a result of the experimental feeding to them of gravid tapeworm segments and in natural infections. Approximately 3 weeks are required for the larva to develop to the infective stage in the beetle, and 3 weeks more are necessary for the cysticercoid to develop to the adult form in the guinea fowl.

Pathology. Adult birds seem little af-
FIG. 35.9 — *Raillietina magninumida.* (A) Scolex with rostellum extended. (B) Mature segment (c.p., cirrus pouch; o., ovary; t., testes; v., vagina; v.g., vitelline gland; v.d., vas deferens). Original.

those of the outer row being largest (Fig. 35.11A). Rostellum hemispherical, 200 to 214μ in diameter, armed with double crown of 152 to 156 hooks, larger and smaller hooks alternating (Fig. 35.11B). Genital pores unilateral, in anterior third of segment margin (Fig. 35.11C). Uterus breaking up into 75 to 100 egg capsules, each with 8 to 13 eggs (Fig. 35.11D).

This tapeworm occurs commonly in the wild turkey.

Life history. Unknown.

Pathology. Unknown.

Raillietina georgiensis Reid and Nugara, 1961

Description. Fully developed worms 150 to 380 mm. long. Suckers approximately round, with hooks 8 to 13μ long (Fig. 35.12 C); arranged in 8 to 10 circles. Rostellum armed with 220 to 268 hooks, each 17 to 23 μ long and 12 to 16μ wide (Fig. 35.12B); arranged in 2 rows. Genital pores unilateral, rarely irregularly alternate, situated in middle third of body (Fig. 35.12D). Testes 23 to 29 in number, distributed in two groups, 7 to 9 poral and 16 to 20 aporal; lying between excretory canals. Gravid proglottids longer than broad, each containing 80 to 130 egg capsules, each capsule with 8 to 10 eggs.

This tapeworm is most closely related to *R. williamsi, R. tetragona,* and *R. echinobothrida* from which it is differentiated by the size and number of rostellar hooks and in location of genital pores. It has been reported from the wild turkey in Alabama, Florida, Georgia and Tennessee, and from the domestic turkey in Georgia.

Life history. The ant, *Pheidole vinelandica* has been found naturally infected with cysticercoids (Fig. 35.12F). Domestic turkeys fed cysticercoids recovered from this ant became positive for tapeworms after about 20 days.

Pathology. Reid (1962) reported that a mild enteritis may develop in birds heavily infected with this tapeworm.

Anoplocephalidae

These worms lack both rostellum and hooks. The proglottids are usually wider than long, and each contains one or two sets of reproductive organs. The testes are numerous. The uterus may persist or be replaced by egg capsules, or the eggs may pass into one or more paruterine organs. Eggs contain "pyriform bodies."

Aporina delafondi (Railliet, 1892)

Synonyms. *Taenia delafondi* Railliet, 1892; *Bertiella delafondi* (Railliet, 1892)
FIG. 35.12 – *Raillietina georgiensis*. (A) Scolex. (B) Rostellar hook. (C) Acetabular hook. (D) Mature segment. (E) Gravid segment. (F) Cysticercoid. (From Reid and Nugara, 1961.)

Railliet and Henry, 1909. Yamaguti (1961) transferred this species to the genus *Killigrewia* Meggitt, 1927.

Description. Mature worms 7 to 16.5 cm. long. Suckers unarmed; rostellum absent. Genital pores irregularly alternate, located in anterior third of segment margin. Testes about 100 in number. Eggs not contained in capsules.

This is a common tapeworm of pigeons in several parts of the world. In the United States it has been collected from pigeons in Iowa, Texas, Pennsylvania, and District of Columbia.

Life history. Unknown.

Pathology. Unknown.

Hymenolepididae

The hymenolepid tapeworms have a scolex with rostellum that is armed with 1 row of hooks, rarely with a double row, or unarmed. The number of testes rarely more than 4. The uterus is saclike, rarely reticulate. The eggs are enclosed in 3 envelopes.

Several species of the genus *Hymenolepis* have been transferred to other genera by the Russian helminthologists. The present writer has retained the following species in the genus *Hymenolepis*, pending a wider acceptance of the new classification.

FIG. 35.13 – *Hymenolepis carioca*. (A) Scolex. (B) Mature segment. (After Ransom, 1902.)

Hymenolepis carioca (Magalhães, 1898)

Synonyms. *Davainea carioca* Magalhães, 1898; *Weinlandia carioca* Mayhew, 1925.

This species has been placed in the genus *Echinolepis* Spassiky and Spasskaja, 1954.

Description. Mature specimens 3 to 8 cm. long, composed of many hundreds of segments; segments 3 to 5 times broader than long. Suckers and rostellum unarmed (Fig. 35.13A). Genital pores unilateral, located anterior to middle of segment margin. Testes 3 in number, usually in a more or less straight row across the segment (Fig. 35.13B).

This tapeworm is readily recognizable by its very slender and threadlike form. Complete specimens are very difficult to obtain on account of the fragility of the worm; the head is usually broken off and lost. Several thousands of these worms have been found in a single chicken.

This tapeworm is one of the most common tapeworms of the duodenum of chickens and turkeys in the United States. Stafseth (1940) reported this species of tapeworm as a parasite of quail in Michigan. Ward (1946) listed *H. carioca* as a parasite of the quail in Mississippi.

Life history. Guberlet (1919) observed that chickens became infected with this tapeworm after they had been fed stable flies caught around poultry yards. It has been demonstrated by Jones (1929) and by Cram and Jones (1929) that dung beetles act as intermediate hosts.

Horsfall (1938) successfully grew cysticercoids of this species in *Tribolium castaneum* and *T. confusum*. When flour beetles containing cysticercoids of *H. carioca* were fed to young chickens, the latter became infected with the adults of this worm. Cysticercoids develop in beetles to a stage which is infective for chickens within approximately 3 weeks. Development of the adult worm in the chicken to the time when gravid segments are passed requires from 2 to 4 weeks.

Pathology. This tapeworm sometimes occurs in large numbers in chickens and turkeys; but it has very little, if any, ef-
FIG. 35.14—*Hymenolepis cantaniana*. (A) Developing larvae. (B) Head. Original.

fect on the growth rate of the birds, according to Luttermoser (1940).

Hymenolepis cantaniana (Polonio, 1860)

Synonym. *Taenia cantaniana* Polonio, 1860. This species has been placed in the genus *Staphylepis* Spassky and Oshmarin, 1954.

Description. Mature specimens about 2 cm. long. Rostellum and suckers unarmed (Fig. 35.14B). Genital pores unilateral, anterior to middle of segment margin. Testes 3 in number, usually arranged in a transverse row.

This species has been reported from poultry in the United States, Puerto Rico, Europe, and Asia. It is reported from quail collected in Maryland.

Life history. The development of the cysticercoid of this species of tapeworm is rather unique. As observed by Jones and Alicata (1935), the terminal buds arise

from the many-branched individual and ultimately develop into infective larvae (Fig. 35.14A). Dung beetles serve as intermediate hosts of this tapeworm. From 2 to 3 weeks are required for the bladderworm to develop into the adult tapeworm in the avian host.

Pathology. No definite pathological conditions have been associated with this species.

Hymenolepis tenuirostris (Rudolphi, 1819)

Synonyms. *Taenia tenuirostris* Rudolphi, 1819; *Drepanidotaenia tenuirostris* (Rudolphi, 1819) Railliet, 1893. This species has been placed in the genus *Microsomacanthus* Lopez-Neyra, 1942.

Description. Mature worms 10 to 25 cm. long. Rostellum slender, with about 10 hooks, 20 to 23μ long (Fig. 35.15A). Genital pores unilateral. Testes 3 in number, in a transverse row. Eggs (Fig. 35.15B) not in capsules.

Life history. Unknown.

Pathology. Cram (1928) reported this parasite to be present in large numbers from the goose in Oregon and regarded it as responsible for heavy losses. The affected birds showed symptoms of weakness, emaciation, incoordination, and diarrhea. Gower (1939) lists this tapeworm as a parasite of the duck in North America.

FIG. 35.15 — *Hymenolepis tenuirostris.* (A) Head with rostellar hooks. (B) Egg. (From Krabbe, 1869.) (C) Cysticercoid. (From Hamann, 1889.)

Hymenolepis compressa (Linton, 1892)

Synonym. *Taenia compressa* Linton, 1892. This species has been placed in the genus *Microsomacanthus* Lopez-Neyra, 1942.

Description. Mature worms up to 4 cm. long. Suckers unarmed (Fig. 35.16A), rostellum with 10 hooks, 50 to 58μ long (Figs. 35.16B and D). Testes 3 in number, in a more or less straight row across the segment (Fig. 35.16C).

Sprehn (1932) listed this tapeworm as a parasite of ducks and geese from North America.

Life history. Unknown.

Pathology. Unknown.

Hymenolepis coronula (Dujardin, 1845)

Synonyms. *Taenia coronula* Dujardin, 1845; *Weinlandia coronula* (Dujardin, 1845) Mayhew, 1925. This species has been placed in the genus *Dicranotaenia* Railliet, 1892.

Description. Mature worms 1 to 2 cm. long. Suckers unarmed; rostellum armed with a crown of 18 to 26 hooks, 9 to 18μ long, with short handle and a strong guard which is almost as long as the blade (Fig. 35.17A and B). Testes 3 in number (Fig. 35.17C) Eggs not contained in capsules.

Life history. The eggs of this tapeworm are ingested by small crustaceans, the embryos hatching and developing to cysticercoids in the body cavity of these animals. When these infected crustaceans are swallowed by waterfowl, the cysticercoids develop to adult tapeworms in the intestines of the birds. Joyeux (1920) demonstrated that snails may carry cysticercoids of this species for a time after having eaten infected crustaceans. Birds may become infected by eating snails infected with cysticercoids.

Pathology. Pillers (1928) reported a heavy infection with this species and with *H. megalops* and *Aploparaksis furcigera* as "apparently the cause of 'going light' and deaths" in ducks in England. Kingscote (1932) reported an enzootic in a flock of ducks in Canada caused by this

species, the parasites being present in large numbers. Schofield (1932) reported heavy mortality among ducklings in Canada due to *H. coronula*.

Hymenolepis lanceolata (Bloch, 1782)

Synonym. *Taenia lanceolata* Bloch, 1782. This species has been placed in the genus *Schistocephalus* Creplin, 1829.

Description. Mature worms 3 to 13 cm. long. Segments 20 to 40 times as wide as long. Suckers unarmed; rostellum with 8 hooks, 31 to 35μ long, with handle longer than blade, and guard slightly salient (Fig. 35.18C). Genital pore at anterior corner of segment margin, testes 3 in number, in a transverse row (Fig. 35.18D). Eggs not in capsules.

Quortrup and Shillinger (1941) reported *Hymenolepis* sp. (probably *H. lanceolata*) from the Canadian goose in Utah.

Life history. Ruszkowski (1932) demonstrated that larvae of this species developed to the cysticercoid stage in small crustaceans in about 6 weeks at 9°–12° C. The time required for the development of the adult worm in the primary host has not been determined.

Pathology. Emez (1929) described an epizootic, chiefly among young geese but also in some older birds. Muscular incoordination was the chief symptom. Postmortem examination showed a catarrhal inflammation of the intestinal mucosa.

Hymenolepis megalops Nitzsch, in Creplin, 1829

Synonyms. *Taenia megalops* Nitzsch, in Creplin, 1829; *Weinlandia megalops* (Nitzsch, in Creplin, 1829) Mayhew, 1925. This species has been placed in the genus *Cloacotaenia* Wolffhügel, 1938.

Description. Mature worms 3 to 6 mm. long. Head very large, 1 to 2 mm. wide (Fig. 35.19A). Suckers and rostellum unarmed. Testes 3 in number. Eggs not in capsules.

This tapeworm may be readily distinguished from other species found in poultry by its extraordinarily large head and its preference for the cloaca and bursa Fabricii. It has been found on a number of occasions in wild ducks.

Green et al. (1938) reported this tapeworm from wild ducks in Minnesota. It has been collected on a number of occasions from wild ducks in Montana by Wehr.

Life history. Unknown.

Pathology. Pillers (1923) reported a heavy infection with this worm and with *H. coronula* and *Aploparaksis furcigera* as "apparently the cause of 'going light' and of deaths in ducks in England."

Hymenolepis tritesticulata Fuhrmann, 1906

Synonym. *Weinlandia tritesticulata* (Fuhrmann, 1906). This species has been placed in the genus *Microsomacanthus* Lopez-Neyra, 1954.

Description. Mature worms 25 cm. long. Suckers unarmed; rostellum with 10 hooks, 32μ long (Fig. 35.20B). Testes 3 in number. Eggs not in capsules.

This species of tapeworm has been reported by Linton (1927) as occurring in wild ducks of North America.

Life history. Unknown.

Pathology. Unknown.

Hymenolepis introversa (Mayhew, 1925)

This species has been placed in the genus *Dicranotaenia* Railliet, 1892.

Description. Mature worms 5 to 8 cm. long. Suckers unarmed (Fig. 35.21A); rostellum armed with 20 hooks, 17 to 20μ long (Fig. 35.21B). Genital pores in anterior region of right segment margins. Testes 3 in number, irregularly lobed.

This species of tapeworm has been reported by Mayhew (1925) as occurring in the duck from Illinois.

Life history. Unknown.

Pathology. Unknown.

Fimbriaria fasciolaris (Pallas, 1781)

Synonyms. *Taenia laevis* Bloch, 1782; *Diploposthe laevis* (Bloch, 1782) Jacobi, 1896.

Description. Mature worms 10 to 50 cm.
FIG. 35.18 – Hymenolepis lanceolata. (A) Head. (B) Egg. (C) Hook. (D) Proglottids in early and late stages of development. (From Potemkinot, 1938.)

(From Yamaguti, 1940.)
FIG 35.20 — Hymenolepis tristiculata. (A) Ovary and vitelline gland. (B) Rostellar hook. (C) Penal region showing part of cirrus pouch with internal sacculus accessorius. (From Fuhrmann, 1907.)

long by 3 to 9 mm. wide. Scolex small, provided with 10 hooks 16 to 21μ long, with long handle and very short guard and blade; suckers unarmed. Anterior part of body forms a folded expansion or "pseudoscolex." Genital pores unilateral. Testes 3 in number. Uterus continuous throughout strobila, breaking up posteriorly into tubules, each containing several eggs.

This tapeworm has been reported by Todd (1946) as occurring in chickens in Tennessee. It has also been recorded as a parasite of wild ducks on several occasions in this country.

Life history. The water flea, *Diaptomus vulgaris*, has been reported as harboring the cysticercoid of this tapeworm.

Pathology. Unknown.

SYMPTOMS

Everything else being equal, the severity of the symptoms resulting from tapeworm infections apparently depends to some extent on the number of worms present, on the diet, and on the age of the birds. Few, if any, clinical symptoms are observed in lightly infected birds. Heavily infected birds sometimes show marked retardation in growth rate.

Harwood and Luttermoser (1938) demonstrated experimentally that the growth rates of 2- to 4-week-old chicks fed an adequate diet and having infections at necropsy ranging in numbers from 15 to 155 *Raillietina cesticillus* were definitely retarded. Ackert and Case (1938) reported weight retardation and reduced sugar and hemoglobin content of the blood in 3- to 4-month-old birds each having at necropsy infections of 4 to 25 *Raillietina cesticillus*. Levine (1938) found that the difference between the mean weights of chickens experimentally infected with *Davainea proglottina* when 7 weeks of age and held under observation for 13 weeks was 12 per cent less than the controls. Alicata (1940) experimentally determined that birds receiving animal-protein supplements (fish meal and dry skim milk) had, at necropsy, an average of 14 tapeworms (*Hymenolepis exigua*), while a similar number of birds receiving plant-protein supplements (yeast, sesame meal, peanut oil, and soybean meal) had an average of 66 tapeworms. In contrast to the above observations, Luttermoser (1940) reported that the growth rates of twenty-two 4-week-old Rhode Island Red chickens experimentally fed 1,000 cysticercoids of *Hymenolepis carioca* were practically the same as those of an equal number of controls held under similar conditions.

Birds of all ages harbor tapeworms. However, Ackert and Reid (1937) have demonstrated that concomitant with an increase in age of the bird there is a corresponding increase in resistance to tapeworm infection.

A number of clinical symptoms have been inadvertently ascribed to tapeworm infections. At the present time there is not sufficient experimental evidence to show that such clinical symptoms as cyanosis, lameness, poor feathering, and failure to come into or stay in production are due solely to the presence of these parasites.

DIAGNOSIS

Diagnosis of tapeworm infection by examination of the fresh droppings for
FIG. 35.21 — Hymenolepis Introversa. (A) Head. (B) Hook. (C) Proglottids. (D) Cirrus sac. (E) Reproductive organs. (From Mayhew, 1925.)

the presence of eggs or segments is unreliable. Even in cases of heavy infection, segments or eggs are sometimes absent. It has been shown by Harwood (1938) that segment production in the tapeworm *Raillietina cesticillus* occurs in cycles, segment production being marked at first by a period of intense segment elimination, alternating with periods in which no segments, or only a relatively few segments, were eliminated.

The diagnosis of poultry taeniasis is best made at necropsy. The intestine of the supposedly infected bird is slit open with an enterotome, spread out flat on the bottom of a suitable container, and examined carefully for the white ribbon-like worms. If this method of examination reveals no worms, a small amount of water may be added to the container. The water will cause the worms, if present, to float to the surface, or they may be seen swaying back and forth in the water above the opened intestine. In infections involving tapeworms of the smaller species, the individual worms are often so small that they are overlooked. Therefore, examination of the intestinal scrapings under the binocular microscope is frequently necessary to detect such small species as *Davainea proglottina* and *Amoebotaenia sphenoides*.

CONTROL OF POULTRY TAPEWORMS

Prevention. When one considers the number of tapeworms infecting poultry and their various intermediate hosts, the task of prevention of tapeworm infection in birds raised under natural conditions seems impossible. Investigations have shown that many intermediate hosts of varying habits may serve experimentally as intermediate hosts of a single species of tapeworm. To prevent birds eating the many species of invertebrates, such as insects, snails, and slugs, is an inconceivable

task. However, intermediate hosts of these parasites may be reduced in numbers by the application of certain insecticides to the poultry manure, *as shown* by Kartman *et al.* (1950). Laboratory tests conducted by these investigators showed that parathion, benzene hexachloride, chlordane, and DDT gave sufficiently satisfactory *results to warrant their use under field conditions.*

House flies may also be controlled by a spray containing 1 pint diazinon, 2 pints malathion, and 12 pounds of granulated sugar. These ingredients are mixed with enough water to make 27 gallons and should be applied lightly. One pound of technical malathion (emulsifiable concentrate) and 20 pounds of sugar give good control of both adult flies and maggots when applied to droppings, cages, and supports A commercially prepared bait containing metaldehyde will control slugs and snails. It is best to apply bait in late afternoon or evening. Ground beetles are difficult to control. These, as well as slugs and snails, tend to collect under loose boards and other protected places where it is moist. Prompt removal of these mechanical protections and elimination of moist feed wastes from poultry yards will discourage their presence in such places. Grasshoppers are controlled by spraying with the proper insecticides, poison baits, and, to some extent, by agricultural practices. The controls for stable flies, as well as house flies, are directed toward their breeding places. Moisture is necessary for the development of the fly larvae. Therefore, the prompt removal of moist feed wastes, weed piles, and other vegetation which has accumulated in piles is essential. Loose piled strawstacks, if allowed to become wet, are important breeding places of the stable fly. Hence, straw should not be allowed to become wet and decayed before removal. Ants may be controlled by the use of approved ant poisons. Malathion and Sevin may prove useful. The first step in the control of ants is to find the nests. if possible. Then an insecticide is applied to the nests and to the surfaces over which

the ants crawl. The number of earthworms may be reduced considerably by keeping the yards dry and well drained, and by avoiding the accumulation of manure.

The proper disposal of the droppings is unquestionably the most important single preventive measure for the control of tapeworm infection. The droppings of infected birds are the source from which the intermediate hosts become infected. Therefore, care in removing the droppings frequently and disposing of them in such manner as to prevent the intermediate hosts from picking up the tapeworm eggs or gravid segments passed in the droppings is of primary importance. The body wastes from farm flocks can usually be disposed of by hauling them to the field and spreading thinly over the land. The action of the sun and wind will quickly dry out the droppings and destroy all parasitic material that may be present in them, since prolonged desiccation is fatal to the infective stages of the parasites. This practice of disposing of poultry droppings not only serves to destroy parasitic material but also adds tremendously to the value of the land for growing crops. Poultry manure, when handled in this way, is said to be an excellent fertilizer for garden and field crops.

The body wastes from backyard flocks usually must necessarily be handled in some other way, as accumulations from such flocks usually exceed the demands of the owner. In communities where large numbers of poultry raisers are within a short distance of each other, the droppings from their birds are sometimes hauled to one or more centrally located storage sheds and retailed to the public at a reasonable price. In order that the fertilizing value of poultry manure may not be lost, it must be stored in a suitable screened-in shed which has been provided with a cement floor and with a roof to keep out the rain and snow. The screens exclude the flying and crawling insects which may serve as intermediate hosts of poultry parasites. This practice naturally

raises the question as to how safe this manure is if used on land where other poultry are likely to run. Limited experimentation seems to indicate that much destruction of the tapeworm eggs may result from the self-sterilization process which takes place in stored manure.

TREATMENT

Medication has served to reduce appreciably parasitism in many groups of livestock, but its applicability in the control of poultry parasites in general is limited.

A drug, in order to be a satisfactory poultry remedial agent, must be inexpensive, highly effective, nontoxic, and easy to administer. It is highly essential that a drug designed for the purpose of removing parasites from poultry possess the above qualifications, since the unit value of the domestic fowl is usually quite low.

A large number of drugs have been recommended for the removal of tapeworms from poultry. Guthrie and Harwood (1941) reported that mixtures of 0.3 to 1.0 gm. of stannous (tin) tartrate and 0.07 to 0.2 gm. of synthetic pelleterine hydrochloride removed 86.8 per cent of *Raillietina cesticillus* and 95.0 per cent of *Hymenolepis carioca* from experimentally infected chickens. However, when used by themselves, the tin compounds possessed only slight value for the removal of *R. cesticillus*. By adding small amounts of synthetic pelleterine hydrochloride to any of the various tin compounds, a synergistic action was obtained, thus increasing the effectiveness of the mixture. The above authors (1944) found that a freshly prepared mixture of tin oleate and triethanolamine effectively removed a large percentage of the *R. cesticillus* from experimentally infected birds in some tests and only a small percentage of these worms in others. Kerr (1948) demonstrated that hexachlorophene (2,2'-dihydroxy-3,3', 5, 5', 6, 6'-hexachloro-diphenylmethane) at doses of 25–50 mg. per kg. body weight possesses a high efficacy in removing *Raillietina cesticillus* from chickens. However, when used at the therapeutic level

this drug seriously affects egg production.

Kerr (1952) presented data to show that butynorate was an effective and safe drug for the removal of *Raillietina cesticillus* from chickens. When administered as a single dose by capsule, a dose of 75 to 150 mg. per kilogram of body weight gave efficacies ranging from 86 to 100 per cent. Edgar (1956) reported the above compound to be highly effective in removing six species of tapeworms, *R. cesticillus, R. tetragona, Hymenolepis carioca, Choanotaenia infundibulum, Davainea proglottina,* and *Amoebotaenia sphenoides,* from field-infected chickens when administered in the feed at the rate of 500 mg. per kilogram of feed for 2 to 6 days, or by capsule at the rate of 125 mg. per bird, or in combination with nicotine and phenothiazine. A temporary drop in egg production, which persisted from the third through the tenth day after treatment, resulted from the use of the combination.

Nugara and Reid (1962) tested Trithiadol in the feed at the rate of 3 pounds per ton for 5 days, dibutyltin dilaurate (butynorate) in the feed at a 0.07 per cent level for 5 days, and dibutyltin oxide via capsule at 65 mg. and 125 mg. doses per bird against the turkey tapeworm, *Raillietina georgiensis.* They reported the latter to be the most efficacious, removing 100 per cent of the worms at the lower level and 90 per cent at the higher level.

Reid (1940) found that starvation of birds infected with the cestode *Raillietina cesticillus* for 20 to 48 hours, including the overnight feeding intervals of the chicken, resulted in the loss of the strobilae (minus the head) of the worms. The loss of the tapeworm strobilae was apparently directly due to the partial starvation of the parasite, as it was determined that the glycogen store in worms from chickens starved 20 hours was lowered to less than one-twelfth of that found in tapeworms taken from nonstarved birds. However, he (Reid, 1942) demonstrated that the tapeworm head was not affected by the long period of starvation. When normal

feeding habits of the fowl were restored, new strobilae or segments were regenerated by the unaffected heads, and gravid segments appeared later in the feces of the birds. Therefore, it is obvious that the practice of starving tapeworm-infected birds has the effect of breaking off the

strobilae and leaving the heads attached to the mucosa. Because of its harmful effects on the health and growth of the birds and the rapid regeneration of new segments following the starvation period, such a procedure is not practical.

Trematodes of Poultry

The trematodes, or flukes, are parasitic flatworms that as adults are devoid of cilia or other locomotor appendages, but are provided with adhesive organs in the form of suckers or other specialized structures.

The class TREMATODA is usually divided into two subclasses, namely, the MONOGENEA and the DIGENEA. Some systematists recognize a third subclass, ASPIDOGASTREA, which comprises a peculiar group of flukes usually parasitic in bivalve mollusks. The MONOGENEA are parasites of cold-blooded animals, as a rule, and usually live on the exterior of the body; they are peculiar forms having elaborate adhesive organs and direct life histories. The DIGENEA are almost exclusively endoparasitic and, for the most part, are provided with adhesive organs in the form of suckers; the life histories are complex, involving alternation of generations and of hosts.

The digenetic trematodes are customarily divided into two orders, GASTEROSTOMATA and PROSOSTOMATA. The GASTEROSTOMATA is a relatively small group consisting of several genera characterized by having a single, saclike digestive tract communicating with the exterior through a mouth located near the middle of the ventral surface of the body. The gasterostomes are parasites of fishes. The PROSOSTOMATA is the order to which all of the poultry flukes belong. Members of this group are characterized by having the mouth located at or near the anterior end of the body. The mouth is usually surrounded by a sucker; a second sucker is usually present on the ventral surface near the middle or, more rarely, at the posterior end of the body.

General morphology. In general the body of the adult fluke is leaflike, occasionally cylindrical, and frequently covered with scalelike spines. Except for the blood flukes (Schistosomatidae), all trematodes of poultry are hermaphroditic, that is,

both the male and female organ systems are present in a single individual. The male reproductive system usually consists of two testes, vasa efferentia, a vas deferens which enlarges to form a seminal vesicle, and a copulatory organ or cirrus surrounded by a saclike structure known as the cirrus pouch. The female system consists of an ovary, vitelline or yolk glands, an ootype or chamber in which the ovum and yolk cells are surrounded by shell material, and a long slender uterus, the terminal portion of which is modified to form a vagina or metraterm. Both the male and female ducts usually open into a cavity or genital sinus which communicates with the exterior through the genital pore. In most flukes the genital pore is situated ventrally in the anterior part of the body. The digestive system is simple, and consists of a mouth, a short tube or prepharynx, a muscular bulb or pharynx, and a slender esophagus of varying length which branches to form the intestine; the intestinal branches are usually simple blind sacs or ceca, but in some forms the two branches are fused posteriorly (Cyclo-coelidae) or united and terminating in a common cecum (Schistosomatidae). The nervous system consists of ganglia located in the pharyngeal region and of anteriorly and posteriorly directed nerves. The excretory system consists of an excretory pore that is located at the posterior end of the body, a bladder, two principal collecting ducts, and collecting tubules which ramify and terminate in flame cells.

Development. The developmental cycles of the trematodes of poultry are very complex. The eggs that are passed by the mature flukes customarily reach the exterior in the feces. On reaching water the eggs undergo embryonation and, in the course of time, hatch. The embryo or *miracidium* thus liberated swims about in search of a snail intermediate host. In some instances, as in the Cyclocoelidae and Schistosomatidae, the egg contains a fully formed miracidium at the time it is laid, and hatching takes place soon after

it reaches water. In other instances, as in the Opisthorchiidae and Brachylaemidae, the egg contains, at the time of deposition, a fully formed miracidium which is not liberated until the egg is ingested by the snail host. On reaching a suitable location in the snail's tissues, the miracidium is transformed into a *sporocyst*. When fully developed, the sporocyst may give rise to a larva provided with a mouth and gut, which is known as a *redia*, and to *cercariae* (Echinostomatidae and Paramphistomidae), or it may give rise to *daughter sporocysts* and cercariae (Schistosomatidae and Strigeidae). The cercaria consists of a body, which becomes the mature fluke, and a tail which enables it to swim about. In some instances the cercaria may become encysted in the water or on various objects (Paramphistomidae and Notocotylidae) or penetrate into secondary intermediate hosts, such as snails, tadpoles, and fishes (Echinostomatidae, Opisthorchiidae, and Strigeidae), and become encysted. The encysted cercaria is known as a *metacercaria*. When the young encysted fluke, or metacercaria, is eaten by the final or definitive host, the cyst wall is digested, and the young fluke is liberated and grows to maturity. In the Schistosomatidae the metacercarial stage is omitted; the cercaria penetrates the skin of the definitive host and on reaching the circulatory system develops into the adult fluke.

Importance of flukes as parasites of poultry. In comparison with the nematodes or roundworms of poultry, the flukes are of much less importance. In spite of the fact that a large number of trematodes are known from poultry — about 50 species from the chicken, 12 from the turkey, 8 from the guinea fowl, 2 from the peafowl, 28 from the pigeon, 75 from the duck, and 24 from the goose — only a few have been reported as causing serious injury. Many of the flukes of poultry have disease-producing potentialities, and serious losses may result if infections are sufficiently large. In the case of the trematodes, as with

other parasites, the amount of damage produced depends largely on the number of individuals harbored and to a lesser degree on the organs affected. In this chapter consideration is given mainly to those trematodes occurring in the United States which are actually or potentially capable of causing serious loss.

The species of flukes parasitizing poultry belong to 18 families, the more important of which may be distinguished by the following key:

1. Sexes separate; parasites of the circulatory system . . . Schistosomatidae
   Hermaphroditic; not parasites of the circulatory system 2

2. Body fleshy, rounded or hemispherical; in cysts of skin
   . . . . Troglotrematidae
   Body elongated, usually flattened; not in cysts 3

3. Intestinal branches united posteriorly; parasites of respiratory system . . . . Cyclocoelidae
   Intestinal branches not united posteriorly 4

4. With oral sucker only 5
   With both oral and ventral suckers 6

5. Pharynx absent; uterus pretesticular; parasites of intestine and ceca . . . . Notocotylidae
   Pharynx present; uterus largely post-testicular; parasites of kidney . . . . Eucotylidae

6. Acetabulum or ventral sucker located at posterior end of body . . . . Paramphistomidae
   Acetabulum or ventral sucker in middle, or anterior to middle, of body 7

7. Uterus passing between testes, reaching posterior end of body . . . . Plagiorchiidae
   Uterus pretesticular 8

8. Cirrus pouch absent; parasites of bile ducts . . . . Opisthorchiidae
   Cirrus pouch present; not parasites of bile ducts 9

9. Body divided by constriction into a cup-shaped anterior portion and a cylindrical posterior portion . . . . . . Strigeidae
   Body not divided as above 10

10. Gonads in posterior fourth of body; ovary between testes . . . . Brachylaemidae
    Gonads in middle, or posterior to middle of body; ovary in front of testes 11

11. Oral sucker surrounded by an adoral disc armed with relatively large spines . . . . Echinostomatidae
    Oral sucker not surrounded by an adoral disc 12

12. Vitellaria tubular; eggs containing eye-spotted miracidia when deposited; parasites of the conjunctival sac . . . . Philophthalmidae
    Vitellaria follicular; eggs not containing eye-spotted miracidia when deposited; parasites of digestive tract . . . . . Psilostomidae

TREMATODES OF THE SKIN

The skin fluke belongs to the Troglotrematidae. Members of this family have more or less plump, spiny bodies and frequently occur in cysts, usually in pairs.

Collyriclum faba (Bremser, 1831)

Synonym. *Collyriclum colei* Ward, 1917.

Description. Body hemispherical, 4.2 to 8.6 mm. long by 4.5 to 5.5 mm wide (Fig. 36 1). Oral sucker subterminal; acetabulum absent. Testes variable in shape, ovary T shaped, with each of the branches divided into several lobes Vitellaria in anterior part of body, somewhat asymmetrical, consisting of 6 to 9 groups of follicles on each side. Uterus greatly coiled, in posterior part of body. Eggs 19 to 21μ long by 9 to 11μ wide.

This parasite occurs encysted in the skin of chickens and turkeys and of a number of passerine birds. The cysts are 4 to 6 mm. in diameter, and each contains two flukes, one usually smaller than the other An opening is present at the summit of the cyst through which the eggs of the flukes escape. In the United States this fluke has been reported from poultry in Minnesota where it was found in young chickens and turkeys by Riley and Kernkamp (1924). This parasite has also been reported by Marotel (1926) as parasitizing turkey poults in southeastern France.

Life history. The life history of this fluke is unknown. Like other members of the Troglotrematidae, this fluke undoubtedly

FIG. 36.1 — Collyriclum faba. Ventral view. (From Kossack, 1911.)

requires a snail primary intermediate host and a secondary intermediate host, which is probably an arthropod. The theory of Jegen (1917) that infection is direct, since he reported that the eggs contained two embryos which were not miracidia but young flukes, is disproved by Tyzzer (1918), Riley and Kernkamp (1924), and Riley (1931) who observed miracidia escaping from the eggs, as in the case of other flukes. Riley is of the opinion that dragonfly larvae may serve as secondary intermediate hosts because the outbreaks of infection among chickens and turkeys which he was able to observe occurred in birds having access to wet or marshy places at a time in early summer when the dragonfly nymphs were emerging. Riley also "recovered from these nymphs metacercariae which suggest closely the characteristics of the adult Collyriclum."

Pathology. The encysted flukes are found mainly around the vent, but may occur elsewhere on the body of the affected bird (Fig. 36 2). In the cases studied in the United States there were no striking symptoms, but there is little doubt that extremely heavy infections in young birds would prove fatal. In poultry of marketable age the presence of Collyriclum cysts would greatly decrease the value of the birds.

TREMATODES OF THE EYE

The eye flukes belong to the family Philophthalmidae. They are relatively small trematodes with well-developed suckers and without spines; the gonads are in the posterior end of the body, the ovary being in front of the testes; the yolk glands or vitellaria are tubular.

Philophthalmus gralli Mathis and Léger, 1910

Description. Body lanceolate, 3 to 6 mm. long by 0.9 to 1.7 mm. wide, yellowish and transparent. Oral sucker 0.285 mm. wide; acetabulum about 0.588 mm. in diameter, about one-fourth of body length from anterior end. Genital aperture about midway between oral sucker and
FIG. 36.2 — View of abdomen of turkey showing cysts of Collyiclum faba. (Kernkamp, Univ. of Minn.)

acetabulum. Cirrus pouch slender, its base slightly distal to acetabulum. Testes oval, tandem, in posterior fourth of body. Ovary median, pretesticular. Uterus with numerous transverse loops, filling greater part of body from level of anterior margin of testicular zone to base of cirrus pouch; metraterm slender, as long as, and paralleling, cirrus pouch. Vitellaria tubular, more or less obscured by uterus. Eggs in uterus 85 to 120μ long by 39 to 55μ wide, containing fully developed miracidia.

Life history. The life cycle (Fig. 36.3) has been ascertained by Alicata and Noda (1960) and Alicata (1962) in Hawaii, and by West (1961) in Indiana. The egg when laid contains a fully developed miracidium in which is found a mother redia. Hatching takes place almost immediately on reaching water. Upon coming in contact with a suitable snail (*Tarebia granifera mauiensis* and *Melanoides newcombi* in Hawaii, and *Goniobasis* spp. and *Pleurocerca acuta* in Indiana) the miracidium penetrates and the mother redia escapes into the heart. According to Alicata, two subsequent generations of redia develop in the heart and digestive gland, the final generation giving rise to cercariae. The

time required for development from mother redia to cercaria is 3 months or longer. Upon emergence from the snail host, the cercariae soon encyst on any solid object, including the shells of snails and exoskeletons of crayfish. When eaten by
FIG. 36.3 — Philophthalmus gralli. (1) Egg. (2) Cercaria. (3) Encysted metacercaria. (4) Adult. (From Alicata and Noda, 1960.)

a bird host, the encysted cercaria (meta-cercaria) excysts in the mouth and crop, the young flukes migrate to the conjunctival sac through the naso-lacrimal duct; from 1 to 5 days are required for the excysted metacercariae to reach the eye where they become mature in about a month.

Pathology. The attachment of the worms by their suckers to the conjunctiva causes congestion and erosion of the membrane. The conjunctival fluid contains blood, fluke eggs, and active miracidia.

Philophthalmus gralli has been reported in natural infections of the chicken, peafowl, turkey, duck, and goose in Indo-China and Formosa, and in experimental infections of chicks in the United States (Hawaii and Indiana). Several other species have been reported from domestic poultry as follows: *P anatinus* Sugimoto from the duck in China, *P mnraschkinzcwi* Tretiakowa from the duck in Russia, and *P. problematicus* Tubangui from the chicken and *P. rizalensis* Tubangui from the duck in the Philippines. Recently Penner and Fried (1961) and Fried (1962) reported experimental infections of chicks with an unnamed species of Philophthalmus obtained from a marine snail, *Batillaria minima*, from Florida. In spite of successful experimental infections with this species, the fact that a marine snail is involved in the life cycle makes it improbable that domestic poultry would be found infected under natural conditions

TREMATODES OF THE RESPIRATORY SYSTEM

Several species of the family Cyclocoelidae occur in domestic fowl. These flukes are relatively large and have flattened oval or lancet-shaped bodies. The oral sucker is weakly developed or absent, and the acetabulum or ventral sucker is absent or rudimentary. The digestive tract is continuous posteriorly. The gonads are in the posterior end of the body with the ovary variously arranged with respect to the testes.

Typhlocoelum cucumerinum (Rudolphi, 1809)

Synonyms. *Typhlocoelum flavum* (Mehlis, 1831); *T. obovale* Neumann, 1909.

Description. Body oval, 6 to 15 mm. long by 2 to 7 mm. wide, yellow in color. Mouth terminal, not surrounded by an oral sucker; acetabulum absent. Intestinal tract continuous posteriorly and provided with median diverticula. Ovary and testes in posterior part of body, the latter deeply lobed. Uterus greatly convoluted, in median field. Eggs 151 to 180μ long by 85 to 90μ wide.

This fluke occurs in the trachea of wild waterfowl in the United States and in Europe; it has been reported from the domestic duck in South America.

Life history. Incompletely known, probably similar to that of *T. cymbium*.

Pathology. This fluke has been reported by Magalhães (1899) in Brazil as the cause of suffocation promptly resulting in death of some domestic ducks; the flukes were present in large numbers in the trachea and bronchi.

Typhlocoelum cymbium (Diesing, 1850)

Synonym. *Tracheophilus sisowi* Skrjabin, 1913.

Description. Body oval, 6 to 12 mm. long by 3 to 6 mm. wide (Fig. 36.4) and similar in appearance to *T. cucumerinum*, except that the testes are rounded instead of lobed. Eggs 122 to 154μ long by 63 to 81μ wide, containing miracidia at time of oviposition.

This species is not uncommon in wild waterfowl in various parts of the world, including the United States, and has been reported from the duck and goose. It occurs in the trachea, bronchi, air sacs, and infraorbital sinus.

Life history. The life history of this fluke has been ascertained by Szidat (1932) and by Stunkard (1934). The eggs, which contain miracidia when deposited, hatch on reaching water. The miracidium swims about and, on coming in contact with
FIG. 36.4 — Typhlocoelum cymblum (= Tracheophilus sisowi). Ventral view. (From Skrjabin, 1913.)

suitable snails (*Menetus planorbis*, *Helisoma trivolvis*, *Planorbis corneus*, *Lymnaea palustris*, or *L. ovata*), penetrates the tissues and liberates a redia which is present in the body of the miracidium. The redia increases in size and gives rise to tailless cercariae which escape and become encysted in the vicinity of the redia. Birds become infected by eating the snails harboring the encysted cercariae.

Pathology. The presence of large numbers of these flukes in the larynx and trachea of birds causes death by suffocation. Light infections may cause little or no injury.

Several other cyclocoelids have been reported as parasites of poultry, namely, *Cyclocoelum mutabile* (Zeder) from the goose and turkey in Europe, Asia, and South America; *C. japonicus* Kurisu from the chicken in Japan; and *Hyptiasmus tumidus* Kossack from the goose in Europe.

In addition to flukes of the family Cyclocoelidae, Price (1937) reported *Clinostomum attenuatum* Cort (Clinostomidae), normally a parasite of bitterns, from the trachea of a chicken in Nebraska. This was apparently a case of accidental parasitism acquired through the ingestion of a tadpole or young frog containing the larval fluke.

TREMATODES OF THE DIGESTIVE SYSTEM

The digestive tract is a favorite location for flukes, and a large number of species representing many families have been reported from this organ system. Only a few of the more important of these species are discussed here.

Echinostomatidae

Flukes of this family are characterized by having a kidney-shaped collar or adoral disc armed with one or two rows of spines.

Echinostoma revolutum (Froelich, 1802)

Synonyms. *Echinostoma echinatum* (Zeder, 1803); *E. columbae* Zunker, 1925; *E. paraulum* Dietz, 1909; *E. miyagawai* Ishii, 1932; *E. cinetorchis* Ando and Ozaki, 1923.

Description. Body elongated, up to 22 mm. long (Fig. 36.5). Oral sucker surrounded by an adoral disc bearing 37 spines, 27 marginal and 5 on each ventral lobe. Acetabulum strongly developed, situated a short distance posterior to oral sucker. Testes variable in shape, one behind the other; ovary pretesticular; uterus preoraral. Eggs 94 to 126μ long by 59 to 71μ wide.

This trematode occurs in the intestine, ceca, and cloaca of a wide variety of hosts, including the chicken, duck, goose, swan, turkey, pigeon, wild waterfowl, and some mammals. It has been reported under a variety of names from practically all parts of the world.

Life history. The life cycle of *Echinostoma revolutum* has been ascertained by Johnson (1920) and by Beaver (1937). The larval stages develop in freshwater mollusks of the genera Planorbis, Helisoma, Lymnaea, Stagnicola, and Pseudosuccinea. The cercariae, which are formed in rediae and are provided with an adoral disc armed with spines as in the adult, escape and usually encyst in snails and tadpoles. The final hosts become infected through ingestion of

FIG. 36.5 — Echinostoma revolutum. Ventral view. (From Dietz, 1910.)

the infected secondary intermediate hosts.

Pathology. In most instances and in light infections, this fluke causes little injury. Heavy infections in pigeons have been reported from Europe by Zunker (1925), Krause (1925), Bolle (1925), and van Heelsbergen (1927b), and in these cases losses have resulted. Zunker stated that the small intestine of the affected birds showed hemorrhagic inflammation, and similar findings were reported by Bolle. Krause collected about 5,000 echinostomes, apparently E. revolutum, from eight pi-

geons at Rostock; the more heavily parasitized birds died, while the more lightly infected ones recovered after sickness lasting several weeks. In the cases studied by Bolle, there was a hemorrhagic diarrhea, and some of the pigeons died in an emaciated condition after being sick for 4 days. Krause reported as early symptoms the refusal of food, increased thirst, weakness in flight, and pronounced diarrhea; death occurred in 8 to 10 days following increased weakness. Van Heelsbergen in Holland also reported a severe enteritis in pigeons infected with an echinostome which appears to be E. revolutum. The birds showed atrophy of the pectoral muscles, engorged liver, and intestinal congestion, with the lumen of the gut filled with a hemorrhagic catarrhal secretion containing numerous flukes, 1,550 specimens being present in one pigeon. In the United States, Beaver (1937) reported a case of experimental infection of a pigeon which developed a bloody diarrhea 10 days after infection. At necropsy 621 flukes were recovered, the majority being in the lower duodenum and upper ileum.

Hypoderaeum conoideum (Bloch, 1782)

Synonyms. Echinostoma oxycephalum (Rudolphi, 1819); Opisthorchis pianae Galli-Valerio, 1898; Psilochasmus lecithosus Otte, 1926.

Description. Similar in size and appearance to Echinostoma revolutum (Fig. 36.6). Adoral disc poorly developed, bearing a double row of 49 short spines. Eggs 95 to 108μ long by 61 to 68μ wide.

This species occurs in the small intestine of numerous wild waterfowl and has been found in the chicken, goose, and pigeon. It has been reported from the domestic duck in the United States by Stunkard and Dunihue (1931).

Life history. Similar to that of E. revolutum, snails of the genera Lymnaea, Stagnicola, and Planorbis serving as primary intermediate hosts, and Planorbis and tadpoles serving as secondary intermediate hosts.

Pathology. Not well known. In a duck

FIG. 36.6 — Hypoderaeum conoideum. Ventral view. (From Dietz, 1910.)

FIG. 36.7 — Echinoparyphium recurvatum. (A) Entire worm. Ventral view. (B) Anterior end, (C) Encysted cercaria. (From Bittner, 1925.)

experimentally infected with 40 of these flukes, Vevers (1923) found a localized inflammation of the infected portion of the intestine, and the bird had been weak before death.

Echinoparyphium recurvatum (Linstow, 1873)

Description. Body (Fig. 36.7A) 0.7 to 4.5 mm. long, with the anterior part strongly recurved ventrally. Adoral disc (Fig. 36.7B) armed with 45 spines in a double row. General organization similar to that of Echinostoma revolutum. Eggs 108 to 120μ long by 64 to 84μ wide.

This parasite is widely distributed, having been reported from Europe, Asia, Africa, and North America. It occurs in various wild waterfowl and has been found in the duck, chicken, and pigeon in Europe, in turkey poults and chickens in the United States, and in the chicken in Mexico.

Life history. Similar to that of Echinostoma revolutum. The larval stages develop in fresh-water snails of the genera Lymnaea, Planorbis, and Viviparus. The cercariae encyst (Fig. 36.7C) in snails and tadpoles. After ingestion of infected snails and tadpoles, the flukes become mature in the small intestine of the final host, and eggs appear in the feces in 5 to 7 days.

Pathology. Van Heelsbergen (1927a) reported that in Holland infected chickens showed a severe enteritis. The parasitized birds were emaciated, anemic, and developed weakness of the legs. Annereaux (1940) in California observed in a 10-week-old turkey with 267 adult flukes in the upper portion of the small intestine a "severe inflammation of the intestinal mucosa with cecal involvements consisting of a pasty, cheeselike mass which greatly distended the organs."

Psilostomidae

Flukes of this family resemble, in general morphology, species of the Echino-

stomatidae but are not provided with a spine-bearing adoral disc.

Ribeiroia ondatrae (Price, 1931)

Synonym. *Psilostomum ondatrae* Price, 1931; *Cercaria marini* Faust and Hoffman, 1934.

Description. Elongate oval flukes measuring 1.6 to 3 mm. in length (Fig. 36.8), cuticle spiny. Oral sucker and acetabulum well developed. Esophagus with lateral diverticula. Testes in posterior end of body, ovary pretesticular. Vitellaria consisting of relatively large follicles extend ing from level of esophagus to posterior end of body. Uterus between ovary and acetabulum. Eggs 82 to 90μ long by 45 to 48μ wide

This fluke, which was originally described from the muskrat in Canada by Price (1931a), occurs in the proventriculus of several fish-eating birds, including California gull, green heron, osprey, and Cooper's hawk. It has also been reported in natural infection in the chicken in Colorado by Newsom and Stout (1933), in domestic geese in Canada by Kingscote (1951), in experimental infections in the chicken, duck, pigeon, and canary by Beaver (1939), and parakeet and pigeon by Riggin (1956).

Life history. Similar to that of the echinostomes. According to Beaver, the primary intermediate host is a fresh-water snail, *Helisoma antrosum percarinatum*, and the secondary intermediate hosts are fishes, including perch (*Perca flavescens*), rock bass (*Ambloplites rupestris*), small-mouth black bass (*Micropterus dolomieu*), pumpkin seed (*Eupomotis gibbosus*), bluegill (*Lepomis pallidus*), and bullhead (*Ameiurus*). Riggin reported the snail host in Puerto Rico to be *Australorbis glabratus* and experimental hosts for the metacercariae to be the guppy (*Lebistes reticulatus*), minnow (*Poecilia vivipara*), and tadpoles. The cercariae become encysted principally in the lateral line canal of fishes and in the cloaca of tadpoles. In the final host the flukes reach maturity in 6 to 7 days.

FIG. 36.8 – *Ribeiroia ondatrae*. Ventral view. (Newsom, Colo. St. Coll.)

Pathology. Newsom and Stout reported outbreaks of proventriculitis in two flocks of chickens in Colorado. The birds lost their appetite, stood around with their eyes closed, and gradually wasted away. Gross examination "showed a very noticeable enlargement of the proventriculus. On opening this organ there seemed to be a deep reddening around the orifices of the glands. In the more extreme cases there appeared to be a grayish exudate on the surface, simulating ulceration" (Fig. 36.9). Microscopic examination "showed that the surface of the mucous membrane was covered with a fibrinous exudate, the outer portion of which had become necrotic. Below this necrotic area was a thick zone heavily infiltrated with polymorphonuclear leukocytes. Under this, the mucous layer was quite edematous in which were scattered a few polymorphonuclear leukocytes and a few monocytes. In a few places small abscesses had formed in the lower portion of the mucous membrane." Beaver observed in experimental infections in chickens and canaries that this fluke is fairly pathogenic, each worm forming in the proventriculus a separate lesion which is a deeply eroded pit with
FIG. 36.9 — Proventriculus of chicken showing lesions caused by *Ribeiroia ondatrae*. (Newsam, Colo. St. Coll.)

a raised orifice surrounded by a conspicuous reddish to purple area.

Sphaeridiotrema globulus (Rudolphi, 1814)

Description. Body piriform to globular, 0.5 to 0.85 mm. long (Fig. 36.10). Suckers well developed, acetabulum massive. Genital aperture lateral, at level of posterior margin of oral sucker. Testes in posterior end of body, one dorsal to other. Ovary pretesticular; vitellaria consisting of large follicles extending from intestinal bifurcation to level of anterior margins of testes; uterus relatively short, largely preacetabular. Eggs 90 to 105μ long by 60 to 67μ wide.

This fluke occurs in the small intestine of the wild duck in Europe and North America and has been reported from the domestic duck and swan. In the United States this trematode was reported by Price (1934) as causing extensive loss among lesser scaup ducks near Washington, D.C., and it has also been found by Shaw in the domestic duck in Oregon.

Life history. As determined by Szidat (1937) in Germany, the cercaria of this fluke develops from redia in the snail *Bithynia tentaculata*. The cercariae become encysted between the shell and mantle of this snail, and birds acquire the
FIG. 36.10 — *Sphaeridiotrema globulus*, Ventral view. Original.

parasite through ingestion of the infected mollusks, eggs appearing in the feces 5 to 6 days later.

Pathology. This fluke produces in wild ducks a severe ulcerative enteritis. In the cases studied by Price, the small intestine, especially the lower third, showed marked congestion, hemorrhage, and ulceration, the lumen of the involved portion of the gut being filled with a cast composed largely of fibrin. Histologically the serosa, muscular, and mucous layers of the intestine showed evidence of acute hyperemia; the mucous membrane showed pronounced desquamation of epithelium, the villi being entirely denuded in most areas. There was severe ulceration in places, the ulcers frequently extending as deep as the muscularis and containing numerous flukes firmly attached by means of their powerful suckers.

Sphaeridiotrema spinoacetabulum Burns, 1961

Description. Body oval to pyriform 1.08 to 1.10 mm. long by 0.583 to 0.778 mm.
FIG. 36.11—Sphaeridiotrema spinoacetabulum. Ventral view. (From Burns, 1961.)

FIG. 36.12—Cotylurus flabelliformis. (A) Lateral view showing digestive and excretory systems. (B) Female genital system. (C) Male genital system. (From Van Haitsma, 1931.)

wide (36.11). Suckers well developed, acetabulum smaller than in *S. globulus* and armed with spines around its opening. Eggs 100 to 115μ long by 60 to 75μ wide. Other characters similar to those of *S. globulus*.

This species occurs in the ceca of ducks; so far it is known only from Oregon.

Life history. According to Burns (1961), the cercariae develop from rediae in the snail *Fluminicola virens*; they emerge from the anal opening and, upon coming in contact with this snail and *Oxytrema silicula*, encyst between the shell and mantle. About 16 days are required for the flukes to reach maturity after ingestion of encysted metacercariae.

Pathology. In infected ducklings the ceca show intense hyperemia, hemorrhage into the lumen, and marked ulceration of the mucosa. Heavy infections in young ducks may result in death.

Strigeidae

The strigeids are characterized by having the body divided by a constriction into two parts, an anterior cup-shaped portion containing the suckers and a peculiar tongue-shaped adhesive organ, and a cylindrical posterior portion containing the reproductive organs.

Cotylurus flabelliformis (Faust, 1917)

Description. Body 0.56 to 0.85 mm. long, anterior cup-shaped portion 0.20 to 0.28 mm. long, and posterior cylindrical portion 0.36 to 0.57 mm. long (Fig. 36.12). Genital aperture at posterior end of body. Eggs 100 to 112μ long by 68 to 76μ wide.

The fluke occurs in the intestine of a number of wild ducks in the United States and has been reported from the domestic duck; it has also been reared experimentally in chickens.

Life history. The cercarial and precercarial stages occur in snails of the genera Helisoma, Planorbis, Stagnicola, Lymnaea, and Physa. The cercariae, which develop in sporocysts in the snail, are fork-tailed. The cercariae that escape from the primary snail intermediate host penetrate into other snails and develop into tetracotylid larvae. When snails containing the encysted tetracotylids are ingested by a definitive host, the worms mature in 3 to 4 days.

Pathology. According to Van Haitsma (1931), *C. flabelliformis* digests away the epithelium of the intestine of the host and causes a congestion of the subepithelial tissue. The symptoms shown by infected ducks appear to vary greatly. Some of the infected ducks studied by Van Haitsma showed leg weakness, nervous twitchings of the head and wings, dyspnea, diarrhea, and irregular appetite, while others which had been given heavy doses of larvae died within a week without showing definite symptoms.

The only other strigeid reported in natural infections from poultry in the United States is *Strigea falconis meleagris* Harwood (1931). This parasite was found in viscera of turkeys at Houston, Texas, and so far as is known is of little economic importance.

A number of strigeid flukes have been

reported from poultry in other parts of the world and include *Strigea intermedia* Szidat from the duck and goose in Germany and *Cotylurus cornutus* (Rudolphi) from the duck, goose, swan, and pigeon in Europe and South America.

Brachylaemidae

Flukes of this family are characterized mainly by having the gonads in a linear series in the posterior end of the body, the ovary being situated between the testes. The genital pore is in the zone of the gonads.

Postharmostomum gallinum (Witenberg, 1923)

Synonyms: *Harmostomum* (*Postharmostomum*) *horizawai* Ozaki, 1925; *H. annamense* Railliet, 1925; *H.* (*P.*) *hawaiiensis* Guberlet, 1928.

Description. Body linguiform, 3.5 to 7.4 mm. long (Fig. 36.13). Oral sucker and acetabulum relatively well developed, the latter situated about one-third of body

FIG. 36.13—*Postharmostomum gallinum*. Ventral view. (From Skrjabin, 1924.)

length from anterior end. Intestinal ceca with wide serpentine undulations. Ovary between testes, in posterior end of body. Vitellaria lateral, extending anteriorly as far as posterior margin of acetabulum; uterus extending anteriorly as far as intestinal bifurcation. Eggs 29 to 32μ long by 18μ wide.

This trematode occurs in the ceca of the chicken, turkey, guinea fowl, and pigeon in Europe, Asia, and Africa. It has also been reported from the chicken in Hawaii and Puerto Rico.

Life history. According to Alicata (1940), the eggs contain miracidia when oviposited. When these eggs are eaten by the snail *Eulota similaris*, the eggs hatch, and the miracidia enter the liver and develop into sporocysts. The cercariae developing in the sporocysts escape and leave the body of the snail; they may reenter the same snail host or others of the same or a different species where they become encysted in the pericardial cavity. Another land snail, *Subulina octona*, has been shown to harbor the metacercariae, but it has not been determined whether this snail may also serve as a primary intermediate host. In the Orient, *Euhadra peliomphala*, *Philomycus bilineatus*, and *Eulota sieboldiana minor* have been reported as capable of serving as secondary intermediate hosts.

Pathology. So far as known, these flukes cause little or no injury to their bird hosts. It is possible that in extreme cases of heavy infection, some irritation or inflammation of the ceca might result from the presence of the worms.

Notocotylidae

The notocotylids are small to medium-sized monostomes. The ventral surface is usually provided with rows of glands or ridges (absent in *Paramonostomum*). There is no pharynx, and the tips of the intestinal ceca pass between the testes, which are located in the posterior part of the body. The eggs are small and are provided with a long slender filament at each pole.

Notocotylus imbricatus (Looss, 1893)

Synonyms. *Notocotylus seineti* Fuhrmann, 1919; *N. urbanensis* Harrah, 1922, in part; *N. intestinalis* Tubangui, 1932.

Description. Body elongate, oval, 2 to 4 mm. long (Fig. 36.14A and B). Ventral surface with 3 linear rows of glands, 12 to 16 in median row and 12 to 17 in each lateral row. Eggs (Fig. 36.14C) 17 to 20μ long by 9 to 12μ wide.

This species is perhaps the widest distributed of the notocotylids and occurs in Europe, Asia, and North America. It has been reported from ducks and numerous wild waterfowl and has been reared experimentally in the chicken. According to Harwood (1939), this fluke has been collected from domestic ducks in Oregon and New York.

Life history. The larval stages develop in the livers of snails of the genera Bithynia, Lymnaea, and Physa. When the cercariae escape from the intermediate host, they encyst on the shell of the snail or on other objects. When the cysts are ingested by suitable bird hosts, the young flukes are liberated and develop to maturity in the rectum and ceca.

Pathology. Flukes of this genus produce little injury to their hosts. It is possible that if present in large numbers they may cause some inflammation of the rectum and ceca.

Other species of Notocotylus reported from poultry are *N. attenuatus* (Rudolphi) from the duck, goose, turkey, and chicken in Europe and Asia; *N. ephemera* (Nitzsch) from the chicken and duck in Europe; *N. chionis* Baylis from the goose in Europe; and *N. aegyptiacus* Odhner from the duck in Africa (Egypt).

Catatropis verrucosa (Froelich), a notocotylid having a glandular keel or ridge instead of a median row of glands, occurs in the duck, goose, and chicken in Europe, and chicken in the United States. *Paramonostomum alveatum* (Mehlis) and *P. parvum* Stunkard and Dunihue, species without ventral glands, occur in domestic ducks in Europe and North America, respectively.

Paramphistomidae

This family comprises flukes having the acetabulum or ventral sucker situated at the posterior end of the body. Only one species occurs in poultry.

Zygocotyle lunata (Diesing, 1836)

Synonym. *Zygocotyle ceratosa* Stunkard, 1916.

Description. Body ovate, up to 9 mm. long (Fig. 36.15). Oral sucker subventral, provided with two evaginations or pouches. Acetabulum terminal, large, with its posterior margin provided with a flap terminating on each side in a conclike projection. Eggs 124 to 153μ long by 72 to 96μ wide.

This fluke occurs in the ceca of a number of wild waterfowl and has been reported by Price (1928) from the goose in the United States and by Caballero (1941) from the chicken in Mexico; it has also been reared experimentally in domestic ducks by Willey (1941).

Life history. The life history of this form
FIG. 36.14 — Notocotylus imbricatus (= N. seineti). (A) Ventral view, showing glands. (B) Dorsal view, showing internal organization. (C) Egg. (From Fuhrmann, 1919.)

FIG. 36.15 — Zygocotyle lunata. Ventral view.
(Willey, New York Univ.)

has been studied in detail by Willey. The larval stages develop in the snail *Helisoma antrosum*. The cercariae which develop in rediae escape from the snail intermediate host and encyst on such objects as pond weeds and the shells of snails; infection of the final or definitive host occurs when the cysts are eaten. The flukes mature and give off eggs in about 6 weeks.

Pathology. So far as known, these flukes produce no appreciable injury to their bird hosts.

TREMATODES OF THE LIVER

The trematodes of the liver of poultry belong for the most part to the family Opisthorchiidae. They are semitransparent, usually elongate flukes, and occur in the bile ducts. Only one opisthorchiid has been reported as a parasite of poultry in the United States. This form, *Amphimerus* sp., was recorded by Price (1931b) from a turkey from North Dakota. The liver of this bird showed marked distention of the bile ducts and extensive pressure atrophy of the liver parenchyma.

Several opisthorchiids have been reported from ducks in various parts of the

world and include *Opisthorchis simulans* (Looss) from Europe; *O. longissimus* (Linstow) from Russia; and *Amphimerus anatis* (Yamaguti) from Japan. Closely related flukes of the genus Metorchis occur in ducks in Europe and elsewhere.

TREMATODES OF THE URINARY SYSTEM

The trematodes occurring in the kidneys of poultry belong to the family Eucotylidae. These flukes lack a ventral sucker and a cirrus pouch and have a long tortuous uterus filling the greater part of the pre- and post-testicular fields.

Tamerlania bragai dos Santos, 1934

Description. Body elongate, flat, up to 3 mm. long (Fig. 36.16). Oral sucker subterminal, acetabulum present, minute, according to Stunkard (1945). Pharynx relatively large; esophagus absent; intestinal ceca extending to and uniting near posterior end of body. Testes side by side in middle of body; ovary more or less triangular, immediately pretesticular. Vitel-
FIG. 36.16 — Tamerlania bragai. Ventral view.
(From dos Santos, 1934.)

laria lateral, extending from level of pharynx to about one-fourth of body length from posterior end. Uterus convoluted, pre- and post-testicular. Eggs 31μ long by 13μ wide.

This fluke is found in the kidneys and ureters of pigeons in Brazil, Puerto Rico, and the Philippine Islands; it has also been reported from the chicken in Brazil

Life history. Maldonado (1945) reported that the intermediate host is a land snail, Subulina octona; the larval cycle is completed in about a month. Birds become infected upon ingestion of infected snails containing encysted metacercariae Eggs are recoverable in the urine and excreta 23 days after infection.

Pathology. According to dos Santos (1931), the presence of the flukes in the kidney caused distention of the collecting tubules and a thickening of their walls, the lumen of the tubules being filled with amorphous and crystallized detritus. The parenchyma of the kidney showed extensive cellular infiltration, but the cortex was rarely involved. Maldonado and Hoffman (1911) noted similar changes in pigeons in Puerto Rico but were of the opinion that the parasites caused no ill effect, since birds that were kept in cages for several months appeared unaffected by the parasites.

TREMATODES OF THE REPRODUCTIVE SYSTEM

The flukes of the reproductive system belong to the Plagiorchiidae, a family which is characterized by having the ascending and descending limbs of the uterus passing between the testes. Several representatives of this family occur in American poultry, the most important of which is discussed below.

Prosthogonimus macrorchis Macy, 1934

Description. Body piriform in outline, 5.26 to 7.56 mm. long (Fig. 36 17); cuticula spiny. Intestinal ceca simple, extending to near posterior end of body. Genital pore at anterior end of body, slightly to left of oral sucker; testes oval,

FIG 36 17 – Prosthogonimus macrorchis. Complete worm from oviduct of chicken. (Macy, College of St Thomas, St. Paul, Minn.)

opposite each other and about one-third of body length from posterior end. Ovary greatly lobulated, immediately posterior to acetabulum, vitellaria lateral, extending from acetabulum to testes; uterus with numerous coils in post testicular part of the body Eggs 28μ long by 16μ wide, with spine of variable shape and length at antopercular pole.

This fluke occurs in the bursa Fabricii and oviduct of the duck, chicken, and other birds in the United States; it is particularly common in the lake region of Michigan and Minnesota.

Life history. According to Macy (1934), "The sporocyst, found in the 'liver' of Amnicola limosa porata, produces the cercaria directly, there being no redia stage. The cercaria swims away from the snail host, and, if it is drawn into the anal opening of a suitable species of dragonfly naiad by the breathing movements of such a host, the tail of the cercaria is lost and the metacercaria thus formed makes its way to the muscle of the naiad, where it increases to about five times its original size. A thick wall with an outer radially-striated and an inner homo-
FIG. 36.18 — Section through metacercaria of *Prosthogonimus macrochis* from abdomen of a dragonfly. (Macy, College of St. Thomas, St. Paul, Minn.)

geneous layer (Fig. 36.18) now forms about the metacercaria, and the cyst usually comes to lie in the body cavity of the host. In the event the infected dragonfly naiad or adult is eaten by a suitable avian definitive host, the wall is digested off the cyst as it passes down the digestive tract of the bird. The worm then makes its way down the intestine to the cloaca and then to the bursa Fabricii or to the oviduct, where it develops into the mature trematode. Embryonated eggs produced by the fluke leave the host by way of the cloacal opening, and if they reach a lake inhabited by *Amnicola limosa* the latter become infected and sporocysts and cercariae develop. The important dragonfly hosts of *P. macrochis* belong to the genera *Leucorrhinia*, *Tetragoneuria*, and *Epicordulia*.

Pathology. The lesions and symptoms caused by species of *Prosthogonimus* in Europe have been described by Hieronymi and Szidat (1921). Reinhardt (1922), Seifried (1923), de Blieck and van Heelsbergen (1922), and others, and in the United States by Kotlán and Chandler (1925) and Macy (1934). The disease in American fowl caused by *Prosthogonimus macrochis* is essentially the same as that in Europe caused by *P. pellucidus*. Af-

fected birds lose their normal activity and appetite, and there is a pronounced dropping off in egg production. The eggs that are produced frequently have very thin shells or no shells. On necropsy there may be extreme emaciation and anemia, and an adhesive peritonitis. The intestines may show pronounced hyperemia and be covered with a fibrinous exudate. The oviduct may show similar changes, be distended, and contain considerable exudate and egg material. In some cases there may be a rupture of the oviduct with the secretions, albumen and yolk material, present in the body cavity. Flukes are present in the oviduct and in the egg material, as well as in the abdominal cavity in the case of oviduct rupture. In some instances the peritonitis may be so pronounced as to be detected in the dead and unopened birds by the bluish-red color of the abdominal wall. These lesions, as well as the laying of thin-shelled eggs or of eggs with no shells, may be due to other causes, but it seems to be an established fact that the flukes may be a contributory cause, if not the actual cause, of this condition in many instances. At any rate, if such conditions are encountered in areas where dragonflies are breeding, such as in the lake regions of the country, prosthogonimiasis should be suspected.

TREMATODES OF THE CIRCULATORY SYSTEM

All of the trematodes living in the circulatory system of birds belong to the family Schistosomatidae and are characterized by having the sexes separate. Several species, namely, *Bilharziella polonica* (Kowalewski), *Pseudobilharziella yokogawai* (Oiso), *Dendritobilharzia pulverulenta* (Braun), *Trichobilharzia ocellata* (La Valette), and *Gigantobilharzia monocotylea* Szidat occur in domestic waterfowl in Europe and elsewhere; but none of this group is known to occur in this country. Several schistosomes are known from wild waterfowl in North America, and some of them will probably be found

capable of infecting poultry. In spite of the fact that the blood flukes are serious parasites of man, those infecting poultry do not seem to cause comparable injury to their bird hosts. Szidat (1929) reported that, in infections with *Bilharziella polonica*, the eggs of the fluke in the intestinal wall caused slight connective tissue proliferation and some leukocytic infiltration; in infections with *P. yokogawai*, Oiso (1927) noted pathological changes in the liver and intestine and arrested growth of the bird host.

TREATMENT OF POULTRY TREMATODIASES

Owing to the fact that trematode infections of poultry are rarely diagnosed ante mortem, practically nothing is known concerning effective treatment for their removal. Medicinal treatment would appear to be of no value for the removal of the skin fluke, *Collyriclum faba*, surgical incision and mechanical removal of the worms seeming to be the rational procedure in such infections.

Flukes occurring in the respiratory system, particularly of the nasal passages, trachea, and bronchi, might possibly be removed by inhalations of powdered drugs having vermicidal properties. The most promising of such drugs is barium antimonyl tartrate, which is highly effective against the poultry gapeworm. The method of administration of this drug is discussed on page 996.

For trematodes occurring in the digestive tract, carbon tetrachloride in doses of 1 to 3 cc., depending on the kind and size of the bird, might be tried. In case the flukes are in the proventriculus or in the upper part of the intestine, the drug may be introduced directly into the former organ by means of a syringe and rubber catheter. For flukes in the lower part of the intestine or in the ceca, 2 to 5 cc. of carbon tetrachloride in three to four times its volume of a bland oil, such as mineral oil or cottonseed oil, administered by rectal injection, would probably prove effective.

In infections with the oviduct fluke Prosthogonimus, carbon tetrachloride is again the most promising treatment. Schmid (1930) reported the administration to a hen of 1.5 cc. of this drug in an equal amount of flour paste. On the following day the bird received 1 cc. of the drug in 8 cc. of the paste, and on the third day 1.7 cc. of the drug in the same amount of the paste. At this time no more Prosthogonimus eggs could be found in the feces. On the day following the last treatment, a mass of egg yolk containing nine of the flukes was found in the cage. The bird was then killed, and in the oviduct were found two small egg concretions in which several flukes were lying, and other flukes were imbedded in collections of mucus; all of the flukes apparently were dead. Other birds in the flock were treated, but the results were inconclusive.

No drug treatment of value is known for the destruction of fluke parasites of the excretory and circulatory systems.

CONTROL OF POULTRY TREMATODES

In view of the fact that all of the trematode parasites of poultry require at least one snail intermediate host, measures for the prevention of fluke infections must be directed toward control or eradication of these mollusks, or to keeping poultry away from areas where the parasites may be acquired. The latter is the easier and perhaps the most certain method of preventing the birds from acquiring trematode infections, and consists of selecting areas for poultry raising that are as far removed as possible from streams or swampy places, or by fencing to keep the birds from ranging over such areas.

The control of the snail intermediate hosts may be accomplished either by draining the low, marshy places or by the use of chemicals that are toxic to the snails. In the case of swampy areas, drainage, either by means of open ditches or by the

use of agricultural tile, will lower the water table to a point where there is insufficient surface moisture to enable the snails to propagate. If drainage should be too expensive or otherwise impractical, the snails may be destroyed by dusting the area with powdered copper sulfate or bluestone. The copper sulfate should be mixed with a carrier, such as fine sand or land plaster in the proportion of 1 part of the chemical to 4 to 8 parts of the carrier, and spread either by broadcasting by hand or by the use of hand or power dusters. For destroying snails in ponds and small lakes, the powdered copper sulfate may be used as in the case of marshes. The chemical should be spread along the banks and in the water near the shore, as most of the snails will be found in these locations.

For destroying snails in streams, burlap sacks containing large crystals of copper sulfate may be placed in the streams at the uppermost part of the section to be treated in an amount sufficient to give a concentration of 1 part of the chemical to about 500,000 parts of water. The amount of the chemical necessary may be determined by ascertaining the cross-section area of the stream and multiplying by the velocity in order to get the flow in cubic feet per second. This result multiplied by 12, which is the amount in pounds of copper sulfate necessary to give a concentration of the chemical of 1 to 500,000 for a 24-hour period, equals the amount of copper sulfate needed for the treatment. For example, if a stream is 3 feet wide and 1 foot deep and the velocity is 2 feet per second, the flow is 6 cubic feet per second; this result times 12 equals 72, or the number of pounds of copper sulfate necessary for one treatment. This concentration of the chemical will kill most snails but is not injurious to livestock; it may kill some fish and will destroy algae and moss.

In some instances, especially with Prosthogonimus, where the fluke is acquired through the ingestion of dragonflies, keeping poultry away from the shores of ponds or lakes in the mornings when these insects are inactive is recommended.

Protozoa

COCCIDIOSIS OF THE CHICKEN

Coccidiosis is a general term applied to infection with one or more of the many species belonging to the Coccidia, a subdivision of the great protozoan class SPOROZOA, all of whose representatives are parasitic and devoid of specialized organelles of locomotion in the vegetative stages. There are, however, as Tyzzer (1932) has emphasized, as many kinds of coccidiosis as there are species of coccidia, each with its characteristic symptoms. All known types in chickens involve the digestive tract, whose cells are penetrated by the parasites. While coccidiosis is cosmopolitan and occurs in practically all kinds of birds, the problem is simplified somewhat by the fact that the parasites are host-specific; that is, each species occurs in a single species of host or limited group of

closely related hosts. In the latter case, one particular species seems to be the optimum host for the parasite. However, a particular bird host may harbor more than one species of coccidia. Thus, while the problem of identifying species of coccidia is simplified by the host limitations of these parasites, it is, on the other hand, complicated by the possibility of occurrence of multiple species in a single host species.

As a group, the coccidioses of chickens are of more economic importance than those of any other domesticated bird. Brackett and Bliznick (1950) have documented morbidity and mortality data for the species of Eimeria parasitizing chickens and have submitted evidence that losses are more far-reaching than generally recognized. Turkeys, ducks, and guinea fowls suffer less than do chickens from coccidial infection, though under certain conditions the infection may become serious in these birds. There are also on record disastrous outbreaks of renal coccidiosis in geese.

Pheasants and quail, when raised in captivity, frequently suffer serious losses.

Taxonomic relationships. Of the many known genera of the Coccidia there are but two of importance: Eimeria and Isospora. They are readily distinguished on the basis of the development of their terminal stages, the oocysts, subsequent to passage by the host. The freshly passed oocysts of both genera consist of little more than a compound wall and a rounded mass of nucleated protoplasm separated by a jelly-like material. In the presence of moisture and oxygen there characteristically develop, from the protoplasmic mass of Eimeria, four spores, or sporocysts, each containing two more or less banana-shaped sporozoites (Fig. 37.1). The matured cyst of Isospora contains but two spores, each holding four sporozoites. The net result in the case of both genera is the production of eight sporozoites inside each oocyst. Incidentally, sporozoite formation is considered to represent the final phase of the life cycle.

The distribution of the two genera among the orders of birds has been worked out by Boughton (1937a), Boughton, Boughton, and Volk (1938), Boughton and Volk (1938), and Becker (1956) who along with later workers report the occurrence of species of Eimeria in twelve orders of birds. Species of Isospora have been located in eleven orders of birds. It is likely that when sufficient numbers of hosts have been examined, species of Eimeria and/or Isospora will be found in birds of most orders. Our interest is limited mostly to the genus Eimeria, which commonly occurs in barnyard fowls and pigeons.

The life cycle. When a viable matured or sporulated oocyst of the genus Eimeria is ingested by a bird of a suitable species, eight sporozoites, whose development has been previously discussed, escape from the enclosing spore and oocyst in the intestine of the new host and invade epithelial cells of the mucosa. Ordinarily the infective stages are ingested with food or drink, and the excystation process is facilitated by the

1—Micropyle.
2—Polar inclusion.
3—Oocyst jelly.
4—Endomembrane of cyst wall.
5—Middle or "granular layer" of cyst wall.

body temperature of the bird and the action of digestive juices. Pratt (1937) and Goodrich (1944) working with *E tenella*, Itagaki (1954) with a mixture of oocysts principally *E. tenella*, Doran and Farr (1962) with *E. acervulina*, and Farr and Doran (1962) with *E. acervulina* and *E. tenella* of chickens and *E. meleagrimitis* and *E. gallopavonis* of turkeys observed excystation as indicated by liberated sporocysts and sporozoites in the digestive tracts of birds inoculated *per os*. They all concluded that the oocyst walls were ruptured before the sporozoites escaped from the sporocysts. Pratt (1937) and Itagaki (1954) observed free spores and sporozoites in the crop of chicks. Doran and Farr (1962) and Farr and Doran (1962) reported that oocysts were apparently unchanged in the crop, that a high percentage were broken in the gizzard and the liberated sporocysts passed on into the intestine, where in the presence of bile and pancreatic juice the sporozoites were activated to escape.

That other factors may be operating was demonstrated by Sharma and Reid (1962) and Davies and Joyner (1962) who succeeded in producing infection in appropriate portions of the intestinal tract following subcutaneous, intravenous and intraperitoneal inoculation of sporulated oocysts of *E. tenella* and other species of chicken coccidia. These infections were usually much lighter than those following oral inoculation but according to Davies and Joyner (1962) some were severe enough to cause death. (See also Horton Smith and Long, 1963.)

Levine (1942) and Ikeda (1955) failed to obtain infections in chickens fed sporulated oocysts when the pancreatic ducts were ligated. Ikeda (1955) demonstrated that infection could be produced if trypsin was fed along with the oocysts.

Gill and Ray (1954b) and Ikeda (1960) reported *in vitro* excystation from intact *E. tenella* oocysts using preparations of trypsin or pancreatin. On the other hand all attempts by Pratt (1937), Goodrich (1944), Itagaki and Tsubokura (1953),

Itagaki (1954), and Doran and Farr (1962) to excyst sporozoites *in vitro* from intact oocysts of chicken coccidia, using various tissue extracts, trypsin, and other commercial preparations, were unsuccessful. Itagaki (1954) reported that excystation was solely due to mechanical rupture of oocysts and sporocysts. Goodrich (1944) obtained excystation of sporozoites from liberated sporocysts using artificial mixtures containing trypsin. Doran and Farr (1962) found that low percentages of sporozoites could be excysted from free sporozoites when placed in various pancreatic preparations. In the presence of bile or bile salts the action of these preparations was greatly increased. Bile alone had no effect. These authors showed that trypsin was one of the enzymes involved, but that it was not the only one.

The presence of a sporozoite in the epithelial cell, or of the first generation trophozoite developing from it, is betrayed by an eosinophilic globule (an inclusion typical of sporozoites) observable in thin, stained sections. The young trophozoite, or schizont, is usually an ovoid or rounded body enclosing a nucleus in addition to the aforementioned globule. Growth of the schizont is accompanied by repeated binary divisions of the nuclear material so that it comes to possess a considerable number of nuclei by the time growth ceases (Fig. 37.2). The cytoplasm segments about the nuclei so that there are produced about as many first-generation merozoites as there were nuclei. Merozoites usually become sickle- or banana-shaped. Before their release from the host cell they are recognizable as a clump with the individuals lying more or less parallel like the sections of an orange. The process just described, wherein a considerable number of merozoites are produced through asexual reproduction, is known as schizogony. In most species of coccidia, as many of the first crop of merozoites as can do so enter other epithelial cells, and the process is repeated in a general way. So far as is now definitely known, the different generations of schizonts within any one species are

EIMERIA TENELLA

FIG. 37.2 — Life cycle of E. tenella. (After Levine, 1961.)

characteristic. They differ in size, shape, number of merozoites produced, and in their effect upon the form, location, and activities of the parasitized host cell.

After several repetitions of the process of schizogony, there appears a generation of merozoites that enter epithelial cells to develop into sexual phases, or gametocytes. The latter are, in their younger stages, rounded bodies, but as growth proceeds it becomes evident that they are of two sorts: (1) males, or microgametocytes, in which growth is accompanied by many nuclear divisions, and (2) females, or macrogametocytes, which also grow but retain a single nucleus. From the microgametocyte there may develop as many microgametes as nuclei, each of which is a minute flagel-

lated body Fertilization is accomplished by the penetration of the microgamete into the macrogamete (a matured macrogametocyte) through a micropyle. The resulting zygote secretes a wall about itself, a process in which certain cytoplasmic granules are involved, and it is known as an oocyst (Pattillo and Becker, 1955).

After the oocysts are discharged in the feces of the bird the zygote divides into four sporoblasts. Each sporoblast transforms itself into a sporocyst containing two sporozoites and, usually, an intraresidual body. The time required for completion of sporulation is dependent upon temperature and oxygen supply. Edgar (1954, 1955a) reported that the optimum temperature for rapid sporulation of *E tenella* and five other species of chicken coccidia varied between 28° and 29° C Sporulation *E. tenella* was slow and poor at 8° and 37° C. According to Duncan (1959) oocysts of the pigeon coccidium *E labbeana* sporulated slowly under anaerobic conditions Wilson and Fairbairn (1961) stated that sporulation of *E. acervulina* oocysts did not occur anaerobically. (See also Ellis, 1938b, Itagaki, 1952; Long, 1959; Smith and Herrick, 1944; Schwalbach, 1961b)

Periodicity. Boughton in 1933 discovered diurnal gametic periodicity in infections of the English sparrow with Isospora. The oocysts appeared in the bird's droppings from 3 P.M. to 8 P.M each day. They commenced to appear in small numbers at the beginning of this period, reached a peak, and declined again to small numbers at the end of the period. It was concluded that the periodicity of oocyst production was affected, at least to a certain extent, by the metabolism of the host, as it was regulated by the responses of the bird to light and darkness. (Cf. Schwalbach, 1960, 1961a and b). Levine (1942a) studied the periodicity of oocyst discharge in *E. necatrix*, *E. hagani*, *E. maxima*, *E. mitis*, and *E. praecox* infections of chickens. In all cases except *E. necatrix* there was a tendency for the peak of oocyst discharge to occur during the 6 hours from 3 P.M. to 9 P.M., while in necatrix infections the highest

oocyst elimination took place between 9 P.M. and 9 A.M. The latter phenomena may be due to the fact that necatrix oocysts develop in the ceca, which do not discharge their content regularly.

Etiology. There are eight valid species of coccidia of the genus Eimeria known to occur naturally in chickens. Wenyonella was found in chickens by Ray (1945) (see page 1070). Since it is practically impossible to present anything like a complete description of the nine species without involving the effect on the host, it is recommended that the section on pathogenicity be read in connection with this one.

Table 37.1 shows that the oocysts of the eight species of Eimeria differ in respect to size, shape, and sporulation time (see Johnson, 1938; Tyzzer, 1929; Becker, Zimmermann, and Pattillo, 1955; Becker, Jessen, Pattillo, and Van Doorninck, 1956; Becker, Zimmermann, Pattillo, and Farmer, 1956). Nevertheless, it is most difficult to distinguish the species on the basis of oocyst characteristics alone, save that those of *E. maxima* can usually be readily identified by their larger size, together with their egg shape and rough walls. The minimal times that intervene between the feeding of sporulated oocysts and recovery of the next generation of oocysts in the feces are, according to Edgar (1955a), about 97 hours for *Eimeria acervulina*, 99 hours for *E. mitis*, 120 hours for *E. brunetti*, 123 hours for *E. maxima*, and 138 hours for *E. tenella*, *E. necatrix*, and *E. hagani*. Numbers discharged are scanty at first appearance but increase rapidly during the subsequent day or two until they reach a peak, after which they decline rapidly. The region of the intestine parasitized, the position of the parasites in the intestinal mucosa, the macroscopic lesions, and the clinical type are also important characters that help in the identification of species. Tyzzer and Levine have also used the cross-immunity test to advantage.

Ordinarily it is difficult to identify the species on the basis of the morphology of the asexual stages in the intestinal wall

TABLE 37.1

CHARACTERS FOR THE SEPARATION OF THE EIGHT SPECIES OF EIMERIA OCCURRING IN CHICKENS*

Characters	E. tenella	E. mitis	E. acervulina	E. maxima	E. necatrix	E. praecox	E. hagani	E. brunetti
Size in μ (Oocyst)	14.2-31.2X 9.5-24.8: av. 22.9X19.1	10.8-19.8X 9.2-17.3: av. 15.8X13.4	11.7-52.7X 9.2-21.1: av. 16.4X13	26.9-35.4X 17.7-29.8: av. 31.8X22.7	12.1-28.9X 10.1-18.8: av. 19.7X16.7	19.8-24.7X 15.7-19.8: av. 21.3X17.1	15.8-20.9X 14.3-19.5: av. 19.1X17.6	13.8-33.7X 12.1-26.2: av. 23.1X19.7
Shape	broad ovoid	Subspherical	Egg-shaped	Egg-shaped	Oblong ovoidal	Ovoidal	Broadly ovoid	Egg-shaped
Sporulation time	48 hr.* (18 hr.*)	48 b* (18 hr.*)	21 hr. (17 hr.)	48 hr. (30 hr.)	48 hr. (18 hr.)	48 hr.	36 hr. (16 hr.)	24-48 hr.
Prepatent period	6 days	4-5 days	4 days	5-6 days	6 days	4 days	6 days	5 days
Region of intestine chiefly parasitized	Schizonts and oocysts in ceca	Anterior small intestine	Anterior small intestine	Middle, anterior to posterior small intestine	Schizonts in small intestine, oocysts in ceca	Upper third of small intestine	Anterior half of small intestine	First generation schizonts throughout small intestine, later stages in ileum and posteriorly
Portion of parasites in tissue	Second generation schizonts subepithelial	Schizonts generally above and gametocytes generally below nuclei of epithelial cells	Above nuclei of epithelial cells	Schizonts above nuclei. Gametocytes deep in epithelium	Similar to E. tenella	Below nuclei of epithelial cells	?	Oocysts in all parts of cecal mucosa
Macroscopic lesions	Hemorrhagic ceca	None	Intestinal mucosa streaked transversely with whitish opacities composed of oocysts. Catarrhal exudate	Exudate or flecks of blood on mucosa; intestinal wall thick	Whitish opacities and hemorrhage and exudate in small intestine	None, except mucous cast of intestine	None	Catarrhal enteritis with blood-tinged exudate
Degree of pathogenicity	++++	+	++	++	++++	+	+	++++

*Sporulation times in patentheria are minimal at 29° C. reported by Edgar (1955a). See text for I. mavih. Edgar and Seibold (1964).

when pathology and other characteristics are disregarded, but in the case of the *E tenella* and *E. necatrix* there are certain stages that are indubitably peculiar to them. The second generation schizont of *E. tenella* commences its development in an epithelial cell of the cecal epithelium but soon the parasitized cell grows, becomes rounded, and migrates into the underlying connective tissue. These large schizonts, measuring up to 54_μ by 40_μ and subepithelial in position in the cecal wall, are peculiar to *E. tenella*. *E. necatrix* produces second-generation schizonts similar to those of *E. tenella*, often even larger, but they are located in the subepithelial tissues of the small intestine.

Transmission. The only accepted natural method of transmission has been ingestion of the viable sporulated oocysts by a susceptible host. However, several workers have succeeded experimentally in the transmission of infection by means of merozoites.

Krijgsman (1929b) states that Nöller succeeded in experimental transmission of coccidiosis to chicks through rectal injection of merozoite-containing material. Although Tyzzer (1929) had consistently failed to infect chicks with *Eimeria tenella* by cloacal injection of merozoites, Levine (1940c) accomplished this and also infected with merozoites injected directly into the small intestine through a catheter. He likewise succeeded in attempted merozoite infections of the crop and intestine of chicks with *Eimeria maxima, E. praecox, E. necatrix,* and *E. hagani.* These successes encouraged Levine to express the opinion that under favorable conditions merozoite infection occurs in the field.

Most infections have their incipiency in oocysts admitted into the digestive tract with food and drink or by fouling of the beak while scratching litter or preening In most poultry houses and runs where no special preventive measures are taken, there is ample opportunity for fecal material to lodge in wet drinking or feeding vessels and on damp litter or soil until sporulation has occurred. Under such con-

ditions the whole flock is likely to become infected sooner or later, with the probability that certain birds will acquire much more massive infections than others.

Dissemination of the oocysts is often more indirect. The hands, feet, and utensils of the attendants undoubtedly serve mechanically to convey infection from one building or pen to another. Flies have also been incriminated as mechanical vectors (Allen, 1932; Krijgsman, 1929a and b; Baker, 1933; and Wellman, 1954). Metelkin (1935) tested various species of wild and laboratory-bred muscoid flies and found them all capable of ingesting oocysts, which remained unaltered and viable in the insect gut up to 24 hours and in discharges until they dried. Delaplane and Stuart (1933) found that oocysts of avian coccidia in maggots were destroyed or eliminated in the process of development of larvae into adult flies. Less has been said about beetles, cockroaches, ants, and other invertebrates, but these are also suspected as mechanical vectors.

Birds and mammals visiting poultry runs probably carry oocysts about on their feet, but definite proof is lacking. There is, however, definite proof that oocysts, particularly the unsporulated, can pass through the intestines of certain animals and remain viable. Pérard (1933), for example, proved that dogs fed upon infected rabbit liver later egest the oocysts in such condition that they are capable of sporulating and infecting susceptible rabbits. Rats and mice may pass viable oocysts originating from other animals (Krijgsman, 1929b; Yakimoff and Iwanoff-Gobzem, 1931; Pérard, 1933; Bejšovec, 1960).

It is sometimes stated that both diseased and resistant recovered animals may act as contact carriers of coccidia. The statement is true, in a sense, but it is probably also true that a chick may be very severely stricken with bloody cecal coccidiosis on the fourth or fifth day of the infection and die before elimination of oocysts has commenced.

In *Eimeria tenella* infection, oocyst elimination commences late on the sixth day,

and sometimes becomes so intense on the seventh or eighth day that the cecal portions of the droppings consist of little else than oocysts and a small amount of fluid. Usually the numbers passed decline rapidly thereafter, until after a week or two they are difficult to find in the droppings at all. If, however, as often occurs in heavy infections, the cecal content commences to caseate on the sixth or seventh day, there may be practically no oocysts passed until days or weeks later when the cheesy core commences to liquefy.

Herrick, Ott, and Holmes (1936b) made a study of the length of time chickens may serve as carriers of *Eimeria tenella* during a single infection. Oocysts capable of sporulation and producing infections were found enmeshed in the cecal wall from 1½ to 7½ months following the infection date. In general, however, the longer the infection persisted the fewer were the number of oocysts found, and the higher was the percentage of them showing unmistakable signs of degeneration.

Warner (1933) found soil previously seeded with the oocysts of chicken coccidia infective for 197 days, but not 217 and 231 days. Delaplane and Stuart (1935), working in Rhode Island, demonstrated that the oocysts of avian coccidia survived in soil from experimental ranges for four to nine months following the removal of chickens. In soil from a wooded range the oocysts remained viable at 15 and 18 months. Farr and Wehr (1949) working in Maryland found that on shaded soil *E. acervulina*, *E. tenella*, and *E. maxima* oocysts remained infective for 602, 336, and 287 days respectively. (See also Koutz, 1950; and Kogan, 1959, 1960.)

A number of years ago the suggestion was frequently made that eggs become contaminated by excreta containing coccidia as they are being laid, and that young chicks can become infected by ingesting shell during the hatching process. Johnson (1923) early minimized the importance of this proposed method of transmission on the basis of the susceptibility of oocysts to drying and certain other fac-

tors. Tyzzer, Theiler, and Jones (1932) actually smeared eggs with fecal material and potassium dichromate solution containing *Eimeria necatrix* and *E. praecox* oocysts and incubated them. When the chicks began to pip the shell the fecal material was removed from the eggs and fed to susceptible chicks, but infection did not follow. Warner (1933) found that eggs dipped in suspensions of viable oocysts of poultry coccidia were not infective after 10 to 14 days of incubation at 40–70 per cent relative humidity and 38–40° C. temperature. Ellis (1938a), who made a more detailed study of *E. tenella*, found no viable sporulated oocysts on paper strips when they were kept at 45–70 per cent relative humidity and 100–104° F. for between 1 and 2 days, but at 91–93 per cent relative humidity and 100–104° F. they survived 3 and 4 days. Under conditions approximating those of normal egg incubation, sporulated oocysts did not live on the egg shell for more than a day or two.

The presence of a few oocysts in mash or in the feces of chickens does not necessarily mean that chicken coccidia are present. The junior author, while running a routine flotation on chicken feces, recovered along with a number of grain mites a few oocysts of a species of Barrouxia. Some of these oocysts were also found within the body of one of the grain mites. These oocysts, elliptical in shape and ranging in size between 22.5μ–26.2μ by 15.2μ–17μ, contained 10 to 15 spindle-shaped bivalve sporocysts and an oocystic residual body. Within each sporocyst was a single sporozoite.

Host-specificity. It is generally acknowledged that coccidia, particularly those of the common genus *Eimeria*, exhibit a marked degree of host-specificity. Evidence to support this will be found in many papers, some of the most pertinent of which are the following: Becker (1933), Corcuff (1928), Crooks (1934), Yakimoff and Ivanoff-Gobzem (1931), Yakimoff, Ivanoff-Gobzem, and Buewitsch (1932) ff and Gouseff (1933), Yakimoff, obzem, and Matschoulsky (19... (1962).

The experiments reported in these papers involved many Eimeria species of both mammalian and avian origin and many mammalian and avian hosts, but few indeed were successful intraspecific cross-infections, some of which should be discussed

Tyzzer and Jones (see Tyzzer, 1929) transferred *E. dispersa* from quail (bobwhite) to turkeys and occasionally to chickens, and *E. dispersa* from pheasants to quail, but second transfers in chickens and turkeys did not succeed. Hawkins (1952) transferred *E. dispersa* from turkeys to Hungarian partridges (*Perdix perdix*). Farr (1953) succeeded in transferring three species of Eimeria from Canada geese (*Branta canadensis*) to domestic geese (*Anser anser*). *E. meleagridis* of turkeys was passed to chickens and from chickens back to turkeys by Steward (1947) Gill (1954a) reported that three species of turkey coccidia, *E. meleagridis*, *E. meleagrimitis*, and *E. gallopavonis* were transmissible to chickens. It is to be noted that all of these successful attempts at cross-infection were between rather closely related groups.

The genus *Isospora* seems to show some laxity of host-specificity. One species, *Isospora lacazei*, has been reported from a number of unrelated passerine birds. Both Scholtyseck (1954, 1956) and Schwalbach (1959, 1960, 1961a), who have carried out experimental and taxonomic investigations on species of Isospora occurring in wild birds, suggested that *I. lacazei* may consist of two or more species. However, they have reported that, in many cases, a given species of Isospora has been found in many different species of birds.

There have been also certain claims of successful interspecific infections that are open to serious question in view of lack of subsequent confirmation. Henry's (1931) claims for successful passages of *E. tenella*, *E. acervulina*, and an *E. mitis*-like coccidium (all taken originally from two species of California quail) to baby chicks, have been severely questioned by Tyzzer, Theiler, and Jones (1932) on the basis of certain possible deficiencies in her procedure. Tyzzer (1929) had failed to infect twelve

chickens with *E. dispersa* from the quail, and Venard (1933) claims to have transmitted *E. tenella* of quail (bobwhite) origin to the chicken, although Patterson (1933) failed in infecting quail with *E. tenella*, *E. mitis*, *E. acervulina*, and *E. maxima* of chickens. Haase (1939) reported that he found *E. tenella* in quail (*Perdix perdix*). Thus host limitations of quail and chicken species require further investigation.

Many years ago wild birds, particularly the English sparrow, were blamed for the transmission of coccidiosis to fowls. Hadley (1910) discussed the English sparrow in terms that virtually condemned it as the source and disseminating agent in coccidiosis menacing the poultry-raising industry in all parts of the United States. Smith and Smillie (1917) and Johnson (1923), however, pointed out that only two spores appeared in the developing sparrow coccidium, while there were four in those from domesticated fowls.

Thus, the observed facts make it clear that, in general, coccidiosis in any particular species of bird or mammal is a problem more or less peculiar to it, and that "animal reservoirs" can usually be safely ruled out of consideration. It is not to be implied, however, that animals which frequent poultry runs, such as rats, mice, and sparrows, cannot act as passive disseminators.

Immunity. Flocks may almost imperceptibly develop more or less protective immunity to coccidiosis by repeatedly picking up small amounts of infective material. It has been emphasized time and again that the ideal type of environmental control of coccidiosis is one which permits this immunizing process to proceed, rather than to attempt to maintain the flock coccidia-free. In the latter event a severe outbreak would follow accidental introduction of the infection. Immunity resulting from previous infections is one reason older birds are more resistant to coccidiosis than younger ones. Immunization has also been produced by artificial inoculation with sporulated oocysts (Farr, 1943; Dickinson,

Babcock, and Osebold, 1951; Babcock and Dickinson, 1954; Pierce, Long, and Horton-Smith, 1962; Rose and Long, 1962). (Cf. Becker, 1934, pp. 11–13, 40; Jankiewicz and Scofield, 1934.) Herrick (1934) found that chicks displayed a natural resistance, and that certain chicks raised from parents that were particularly resistant to *E. tenella* were approximately 100 per cent more resistant than unselected chicks. (See also Champion, 1954; Edgar, King, and Johnson, 1951; and Rosenberg, Alicata, and Palafox, 1954.)

Various attempts have been made to attenuate the virulence of *Eimeria tenella* by treatment of the oocysts so as to effect immunity with a minimum of injury to the host. Jankiewicz and Scofield (1934) found that oocysts heated at 46° C. for 15 minutes before segmentation, and then fed to chickens after sporulation, conferred resistance to later inoculation with unheated oocysts and a minimum of injury to the host. Waxler (1941b) X-rayed the oocysts with 9,000r. Such oocysts, when fed to 35-day-old chicks, caused some drop in hemoglobin concentration but no deaths. The mild infection conferred almost as much resistance as a severe attack resulting from untreated oocysts. Uricchio (1953) fed oocysts kept frozen at −5° C. for 5 days to chicks 12 and 15 days old, with the result that they developed a marked protective immunity.

Until recently all attempts to determine the mechanism of immunity to coccidiosis have been unsuccessful. The evidence obtained by challenging previously infected birds with large doses of oocysts has suggested that the immunity might be restricted to the invaded tissue. In their experiments with ligated or isolated ceca Burns and Challey (1959) and Horton-Smith, Beattie, and Long (1961) showed that there was a more or less generalized response on the part of the chicken. Resistance to *E. tenella* acquired by infection of one cecum was transferred to the uninfected isolated cecum. Efforts to immunize birds or mammals with nonliving antigenic derivatives have been uniformly unsuccessful. (Cf. Pierce, Long, and Horton-Smith, 1963.) Becker and Zimmermann (1953) reported that chicks infected with *Eimeria tenella* and injected intravenously with an alcoholic extract of horse kidney discharged fewer oocysts during the infection than the untreated infected controls, though the reason remains obscure. Likewise, efforts to demonstrate antibodies in the circulating blood have generally been fruitless until McDermott and Stauber (1954) demonstrated agglutination of merozoites of *E. tenella* by means of sera from rabbits and roosters immunized with formalinized merozoite suspensions. They also demonstrated the agglutinins in the sera of experimentally infected chickens. Using the agar-gel diffusion technique, Pierce, Long, and Horton-Smith (1962) detected precipitating antibodies in the sera of chickens immunized with doses of *E. tenella* oocysts. Although these precipitins could usually be demonstrated during immunization, their presence was not essential for complete resistance. Rose and Long (1962) found that "serum precipitins were produced in infections with *E. maxima, E. acervulina, E. tenella* and *E. necatrix*. A first challenge of immune fowls with the immunizing species produced some increase in precipitation in agar whereas a second challenge had no such effect."

Although these investigations have shown that resistance is tied in with humoral mechanisms, the factors responsible for the immunity of chickens are yet to be elucidated.

Pathogenicity. Tyzzer, Theiler, and Jones (1932) state that in common poultry certain species of coccidia are practically innocuous, while others are capable of producing serious, destructive outbreaks of disease. *Eimeria mitis* and *E. praecox* are generally considered to be innocuous and *E. hagani* only slightly pathogenic.

The pre-eminently pathogenic species are *E. tenella*, which so attacks the cecal wall as to produce an acute, hemorrhagic type of disease, *E. necatrix*, which attacks the small intestine so as to produce either an acute initial attack resulting in early

death or a lingering illness characterized by progressive emaciation and general un-thriftiness, and *E. brunetti* which produces a necrotic enteritis in the lower half of the intestinal tract, causing more or less continuous losses in the flock. Of less importance as pathogens are *E. maxima* and *E. acervulina*. Heavy infections with these two species may cause weight losses and some deaths.

Since the life cycles of coccidia of the chicken are limited, and hence indefinite multiplication in the host is precluded, the size of the infective doses of sporulated oocysts bears a definite relation to pathogenicity. It has been found that very light doses may produce no clinically recognizable symptoms, and that up to a certain point morbidity and mortality increase in proportion to the size of the dose. (Cf. Tyzzer, 1929, Horton-Smith, 1947, 1949; Gardiner, 1955.)

Specific pathological peculiarities. E. meria tenella is the cause of so-called cecal or bloody coccidiosis of chicks (Figs. 37.3 and 37.4). Involvement of the ceca rather than of the small intestine is one of its characteristic features. Patillo (1959) and Burns and Challey (1959) reported that the sporozoites penetrate the surface epithelium of the cecal mucosa and migrate independently or are transported within macrophages through the lamina propria toward the muscularis mucosae. Along with the macrophages they enter the epithelium of the glands of Lieberkühn. The remainder of the life cycle is depicted on page 1067. The severity of this type of coccidiosis is attributable to the second generation schizont, which causes infected epithelial cells to increase tremendously in size and assume a migratory habit. Through pressure or otherwise there is produced sufficient degeneration of the blood vessels and surrounding tissues to result in bleeding into the ceca, and the copious bloody discharges from the ceca. The discharges usually commence to appear bloody sometime before the end of the fifth day after infection, but a certain wateriness of the droppings is sometimes noted much earlier.

The presence of thromboplastin in the cecal content of infected birds after the fourth day (i.e., after the hemorrhage occurs) has been demonstrated by the production of intravascular coagulation when such cecal content was injected intravenously into chickens (Bradford, Herrick, and Wolfe, 1947). The presence of the thromboplastin in the cecal content is explained by the disintegration of the cecal mucosa on the fifth day of the infection.

Levine and Herrick (1954) have shown by means of experiments in which gastrocnemius muscles of White Leghorns infected with *E. tenella* (fifth or sixth day) and of normal birds were electrically stimulated either through the sciatic nerve or directly, that the ability of that muscle to do work became greatly impaired during the infection and fatigued earlier and more severely. Since the same authors (1957) found that the muscles of infected White Leghorns did more work per contraction per gram than did those of Plymouth Rocks when stimulated directly, but not when stimulated through the nerve, the suggestion was made that the mechanism for the difference might be an effect of the end-plates or allied structures. A 50 per cent decrease in erythrocyte count and hematocrit value and a consequent decrease in blood volume entirely attributable to loss of erythrocytes were noted by Natt and Herrick (1955, 1956) on the fifth and sixth days of severe cecal coccidiosis. (See also Joyner and Davies, 1960; and Natt, 1959.) Bertke and Herrick (1954) noted petechial hemorrhages in the kidney parenchyma reaching maximum size by the end of the fourth day of the infection and accompanied by certain other alterations of the kidney structure. Schildt and Herrick (1955) noted that the motility of the crop and cecal pouches was seriously disturbed during *E. tenella* infection.

In their studies of bacterial populations in ceca of chickens infected with *E. tenella*, Johansson and Sarles (1948) reported that coliform organisms, primarily *Escherichia* species, did not decrease in numbers during the course of coccidiosis whereas lactic acid

(All after Tyzzer, reproduced with permission of the Am. Jour. Hyg.)

producing bacteria almost disappeared. Conditions in the ceca were altered so as to favor proliferation of *Clostridium perfringens*. The authors suggested that *C. perfringens* and coliform organisms might be involved in the etiology of cecal coccidiosis. On the other hand Clark, Smith, and Dardas (1962) reported that, except for

delayed release of second generation merozoites, the course of *E. tenella* infection in bacteria-free chicks was the same as that of conventional chicks. The gross and microscopic lesions also appeared identical in gnotobiotic and conventional chicks.

Oocysts appear in the droppings commencing on the sixth day. Their dis-
FIG. 37.4 – Diagram illustrating the situation of different species of coccidia in the intestine of fowls and the reaction of the parasitized epithelium. 1, Cryptosporidium parvum. 2, Eimeria acervulina. 3, E. mitis. 4, E. maxima. 5, E. tenella. 6, E. phasioni (in the pheasant). charge continues more or less continuously over a considerable period. Herrick, Ott, and Holmes (1936b) found them in the droppings of chickens to 7½ months after the infection date. Their study showed that following infection the oocysts are enmeshed in the tissue of the ceca where they remain viable for at least 7½ months.

Eimeria necatrix attacks the small intestine, with the maximum involvement near the middle. According to Van Doorninck and Becker (1957), the sporozoites penetrate the epithelium of the villi and migrate through the lamina propria toward the muscularis mucosae. En route most of them are engulfed by macrophages which transport them into the epithelium of the fundi of the intestinal glands. The invaded

epithelial cells hypertrophy and migrate to the lumen of the gland fundus, meanwhile the parasites become first generation schizonts. The second generation schizonts are similar in form and behavior to those of *E. tenella*, and like them produce the injurious effects. On the fourth and fifth days aggregations of these schizonts appear as small whitish opacities. Later, punctate hemorrhages appear in the center of the whitish areas and may become so extensive as to obscure them altogether. As Tyzzer and collaborators state, "The unopened intestine thus presents a spotted appearance, the small whitish areas being intermingled with rounded, bright or dull red blotches of various sizes while transversely extending reddish streaks represent hemorrhages along the superficial vessels." There is profuse hemorrhage into the intestinal lumen. Joyner and Davies (1960) reported that the packed erythrocyte volume dropped 5 per cent within seven days after inoculation of oocysts.

Disease produced by *E. necatrix* may be of two types — acute or chronic. The former may result in the death of the bird 5 to 7 days after infection, while in the latter case the bird may linger on for a long time with a wasting illness. During the acute attack blood may be observed in the droppings.

In the case of *Eimeria necatrix* the first two generations of schizonts develop in the small intestine, the merozoites generated by the second generation schizonts migrate to the ceca where they invade the epithelium and develop, some into further generations of schizonts and some directly into oocysts. The ceca are little altered by the growth of the gametocytes and third generation schizonts. Blood drained from the small intestine may discolor the cecal contents.

Oocysts appear in the droppings on the seventh day after infection, and ordinarily require 2 days to sporulate. Tyzzer found that far more of them are produced in light infections than in heavy ones. An infected bird may discharge oocysts over a prolonged period. (See also Davies, 1956.)

Eimeria brunetti is the third of the definitely pathogenic species of the chicken.

Levine (1942c) indicated that the various stages of the parasite are distributed throughout the mucosa of the posterior half of the small intestine, rectum, ceca, and cloaca, and also the upper portion of the small intestine in heavy infections. In moderate infections there is a thickening of the gut wall, a pinkish or blood-tinged catarrhal exudate, and there also may be in the mucosa short, transverse red streaks, a millimeter or so in length, arranged in ladderlike fashion in long rows down the lower intestine and rectum. In severe infections there is an extensive coagulation necrosis and sloughing throughout the entire intestinal mucosa. Caseous cores may be found plugging the narrow portion of the ceca, but the dilated portions of the cecal wall are only moderately affected. According to Boles and Becker (1954) the first generation of schizonts develops in the epithelium of the entire small intestine and ceca. Later stages are usually concentrated in the lower digestive tract. Davies (1963) stated that *E. brunetti* "does not produce characteristic lesions in the intestine but infection is suggested by the presence of white caseous material in the lower intestine and rectum." (See also Pellérdy, 1961; Reid, Sharma, and Keener, 1961; Wiley, 1956; Zimmermann, 1957.)

Eimeria maxima, the fourth of the pathogenic species in the chicken, is far less lethal than the other three. Clinically, the recognition signs are dilation of the small intestine and thickening of the wall. The serous surface may show faint hemorrhages. The content is not bloody but takes the form of viscid mucus, grayish, brownish, or pinkish in color. In some instances the portion of the feces from the small intestine may show flecks of blood. Infections sometimes terminate fatally, but in general, large doses of oocysts produce temporary loss of weight, diarrhea, and a temporary reduction in egg production. (Cf. Johnson, 1931; Brackett and Bliznik, 1950; Long, 1959; Scholtyseck, 1959.)

Oocysts appear in the droppings on the sixth day after infection and continue for only a few days. After oocyst elimination ceases, the bird usually possesses a high de-

gree of immunity to reinfection. According to Long (1962) this resistance is short-lived. Chickens that showed marked resistance to reinfection 4 weeks after their first infection were highly susceptible when reinoculated 10 weeks later. The oocysts of this species are quite characteristic, being the largest of all occurring in chickens (about 29.3μ by 22.6μ on an average) and having a slightly roughened wall.

Eimeria acervulina is, fortunately, not a severe pathogen, though it is perhaps the commonest of all the poultry coccidia. It is characterized clinically by numerous gray or whitish patches in the upper half of the small intestine, visible through the serous surface. These patches are caused by forming oocysts.

That the species is not very pathogenic is quite likely a fair statement of the situation. Heavy doses, however, result in considerable morbidity and mortality (Gill, 1954b; Moynihan, 1950; Gill and Lall, 1961; Horton-Smith and Long, 1959a and b; Morehouse and McGuire, 1956).

In the northwestern part of the United States this species has a serious effect on pullets three or four weeks after housing. (See Peterson, 1949; Peterson and Munro, 1949; Dickinson, 1939, 1941, 1949.) The symptoms noted were shriveled combs, weight loss, and cessation of egg production. Flock culling at this time results in loss of about a fourth of the birds. Egg production is renewed after the disease has run its course. The affected birds reveal at necropsy the lesions of *E. acervulina* throughout the upper portion of the small intestine and great numbers of oocysts within the gut lumen. Thus it appears that under certain conditions *E. acervulina* is not the almost innocuous parasite that it appears to be under usual conditions.

Eimeria mitis grows in the small intestine throughout its entire length, but is most concentrated in the upper half. It is definitely not a serious pathogen. The oocysts are small, with a tendency to be spherical, and usually are not abundant in the droppings. Joyner (1958) reported that large doses of oocysts caused (1) weight retardation and limited mortality in very young chicks, and (2) a reduction in weight gain in chicks 17 to 26 days old. He found no evidence of hemorrhage and no gross lesions in any infected chicken.

Eimeria praecox develops in the upper third of the small intestine. Tyzzer, Theiler, and Jones (1932) stated that this species "elicits no appreciable inflammatory reaction even in heavy infections, so it may be regarded as practically innocuous as far as direct injury to the tissue is concerned." Johnson (1931) found that feeding of large doses of oocysts to mature, highly susceptible White Leghorn chickens was followed by a slight average decrease in egg production. (See also Levine, 1945.)

Eimeria hagani occurs chiefly in the upper half of the small intestine. Levine (1938) reported that infection produces round hemorrhage spots the size of a pinhead and a severe catarrhal enteritis in the duodenum and upper half of the remainder of the small intestine, and comparatively few such lesions in the lower half. Later Levine (1942a, 1945) concluded that this species is relatively nonpathogenic and that it does not produce any characteristic lesions by which it can be recognized.

Eimeria mivati was established as a new species by Edgar and Seibold (1964). It is said to be moderately pathogenic, producing congestion, petechiae, and whitish opacities principally in the upper third of the small intestine with some spread into the lower small intestine, ceca, and rectum. The schizonts and gametocytes are located above the host cell nuclei in the upper intestine and usually below the nuclei in the lower tract. The oocysts (11.1μ–19.9μ by 10.5μ–16.2μ) are ellipsoid to broadly ovoid. The minimum sporulation time is 12 hours. The prepatent period is 93 hours and the infection lasts from 6 to 12 days. Ray (1945) has described *Wenyonella gallinae* from 4- to 6-week-old chickens in India. Sporulated oocysts of the genus *Wenyonella*, like *Eimeria*, contain four spores, and each of the latter, like *Isospora*, contains four sporozoites. The oval oocysts presented a punctate surface,

rough in optical section, and measured $29.5\mu–33.5\mu$ by $19.8\mu–22.8\mu$. The characteristically flask-shaped sporocysts measured 18.8μ by 8.0μ. At $28°$ C. in 2.5 per cent potassium dichromate solution, sporulation required 4 to 6 days. The infection was characterized by (1) blackish-green, semisolid excreta and intestinal content containing numerous oocysts and (2) pinpoint hemorrhages in the mucosa and thickening and congestion of the terminal part of the intestine. Gill (1954c) reported that 1.7 per cent of fecal samples collected from various parts of India contained oocysts of this species.

Scholtyseck (1954) found, in feces of three hens, unsporulated oocysts whose zygote almost filled the space enclosed by the wall. The oocysts, oval in shape and without a micropyle, ranged in approximate size between $19\mu–27\mu$ by $15.5\mu–23\mu$. When sporulated they possessed two pyriform sporocysts each containing four sporozoites. No transmissions were reported. The species was named *Isospora gallinae*. The validity of this species is questionable.

Tyzzer (1929) found a species of *Cryptosporidium* growing in the cuticular layer of the cecal epithelium in a few chickens. He tentatively identified the parasite as *C. parvum* Tyzzer, 1912, a species originally described from the house mouse. Levine (1961), doubting the accuracy of Tyzzer's identification, gave the chicken form "a name of its own," *C. tyzzeri*. According to Levine the oocyst measures $4\mu–5\mu$ by 3μ and contains four free sporozoites and an oocystic residual body.

Histopathology. We are indebted largely to Tyzzer (1929); Tyzzer, Theiler, and Jones (1932); and Mayhew (1937) for knowledge concerning the histopathology in coccidiosis of the chicken. *E. tenella* is probably by far the most important of the severe pathogens.

According to Pattillo (1959), penetration by groups of *E. tenella* sporozoites produced damaging passageways or "penetration tubes" in the epithelium of villi tips.

After transportation through the tunica propria and into the base of an epithelial cell of a cecal gland, the sporozoite rounds up and grows into a large schizont. The schizont develops about 900 merozoites and moves out through the distal end of the cell into the lumen of the gland, pushing the host cell nucleus before it. The merozoites escape from the schizont, penetrate adjacent epithelial cells and start to grow, causing the host cells to round up and assume wandering habits. The host cells migrate into the mucosa and submucosa where they and their parasites increase in size to such an extent that by virtue of volume and numbers the cecal wall becomes congested, blood vessels become disrupted, and leakage of blood ensues. Thus is explained the hemorrhage that sometimes commences late on the fourth day of a heavy attack and persists through the sixth day. According to Tyzzer, the bird may literally bleed to death.

Mayhew (1937) found that in light attacks severe damage to the tissue is but local and any destroyed epithelial or underlying tissues are regenerated. If there has been severe bleeding, a core will form in the lumen. In heavy attacks, on the other hand, a considerable area of the mucosa and submucosa may become congested, and the developing parasites may cause such disintegration of the tissue elements that the layers of the mucosa and submucosa lose their identity. There is such profuse discharge of blood cells, lymph, parasites, and tissue cells into the lumen of the cecum as to form a clot or core fitting the form of the ceca. The core to the cecal wall is adherent at first, but in a few days the surface liquefies so as to free it. It may be passed with the feces in the course of time, though sometimes the cores are retained. Allen (1934) and Mayhew (1937) have discussed the latter condition. As the birds recover from the severe form of the disease, the epithelium in the glands and the tunica propria are restored, but in the most severely afflicted birds the surface epithelium between the glands is not renewed. (See also Gill and Ray, 1957; Greven, 1953; Inagaki and Tsubokura, 1954; and Scholtyseck, 1953.)

Histochemical studies have been made on the life cycle stages and lesions of several of the chicken species of Eimeria. For a detailed discussion of cytochemical work on both chicken and rabbit coccidia see Horton-Smith and Long (1963). (See also Gill and Ray, 1954a, b; Long and Rootes, 1959; Monné and Honig, 1954; Pattillo and Becker, 1955; Pattillo, 1957; Ray and Gill, 1954, 1955; Tsunoda and Itakawa, 1955; and Wilson and Fairbairn, 1961.)

Seasonal incidence. Under ordinary farm conditions, most outbreaks of coccidiosis occur during the months of May, June, July, and August. This is clearly shown by Durant and McDougle (1939) in a graph of 838 necropsied chickens in Missouri. Krassner (1963) observed that yields of E. acervulina oocysts from birds of comparable ages were higher in winter than in summer. In broiler raising, however, chicks are reared throughout the year, and outbreaks may occur at any time.

Age factor. Cecal coccidiosis occurs principally in young chicks, but seldom in those less than 10 or 11 days old. Edgar (1955e, 1962) stated that when chickens were inoculated with numbers of E. tenella oocysts in proportion to body weight, there was significantly less mortality in those inoculated at three days of age than among those inoculated when older. The greatest mortality was among chicks inoculated at four weeks of age. Nonexposed chickens were highly susceptible at one year of age (See also Gordeuk, Bressler, and Glantz, 1951.) Many of the worst outbreaks occur at the age of six to eight weeks. Herrick, Ott, and Holmes (1936a) in their study of experimental infections in chickens of different ages found that the heaviest mortality (72 per cent) and the greatest decrease in erythrocytes (60 per cent decrease) occurred in chicks one month old. Mortality and red cell decrease were also heavy in one-half-month- and two-month-old chicks, whereas in older birds (three to ten months) mortality was low or lacking, though the drop in red cell counts ranged from 29 per cent to 46.8 per cent. Gardiner

(1955), who employed dosages of 50,000, 100,000, and 200,000 sporulated oocysts, infected young chickens in age groups of 1, 2, 3, 4, 5, and 6 weeks. Those in the 4-week group were, in agreement with the findings of Herrick, Ott, and Holmes, die most severely affected, and those in die 2-week group the least. Brackett and Bliznick (1952b) and Davies (1956) found that with equal doses of oocysts, E. necatrix was more pathogenic for young chickens than for older ones. However, Brackett and Bliznick (1952b) noted that when the size of the dose of oocysts was in proportion to the body weight, the older birds might be more severely affected than younger birds. Long (1959) working with E. maxima and Krassner (1963) with E. acervulina concluded that on the basis of oocyst output older birds were more susceptible to these species than younger ones. Levine (1940a), in a study of subclinical coccidial infection in pullets at least eight months old, reported that these older birds were serving as abundant sources of E. mitis, E. acervulina, E. praecox, E. maxima, E. necatrix, and E. tenella, although only 8 per cent showed gross lesions of coccidiosis.

Effect on development and egg production. Mayhew (1932a, b; 1934b) has found that birds inoculated during the seventh or thirteenth and fourteenth weeks were definitely handicapped in that they do not regain the weight lost during an attack in the following three months; i.e., as compared with the uninfected controls. In a later study he showed that hens developed from chicks inoculated at the age of six to eight weeks laid 19.25 per cent fewer eggs than the controls, and did not attain normal weight (as determined by controls) until five or six months after the attack. Johnson (1931) found that inoculation of mature S.C. White Leghorns with large doses of either E. acervulina, E. maxima, or E. tenella oocysts resulted in complete temporary cessation of egg production. Dickinson (1941) reported that pullets receiving massive doses of E. acervulina oocysts lost weight temporarily and ceased laying for 7 to 12 days. Within a

month they had returned to normal. According to Berg, Hamilton, and Bearse (1951) a small dose of *E. maxima* oocysts had a similar effect on the egg production of White Leghorn pullets. (See also Bressler and Gordeuk, 1951; Edgar, 1960.)

Physiological effects. Severe cecal coccidiosis, with loss of blood, causes a rise in blood sugar during the fifth, sixth, and seventh days of the infection. Artificial bleeding produces the same effect, while starvation does not (Pratt, 1940). Pratt (1941) later found that on the sixth day of the infection the glycogen content of the bird's muscle was less than half of that in normal birds starved 19 hours, while the liver glycogen was slightly higher, though more variable than normal. Daugherty and Herrick (1952) suggested that the increased blood sugar level in cecal coccidiosis is due not so much to bleeding as to possible interference with carbohydrate metabolism; they were able to demonstrate, in support of the hypothesis, interference with phosphorylative carbohydrate dissimilation by homogenates of tissues by an unidentified material present in the cecum of infected fowls. Also, they reported that the R.Q. (respiratory quotient) values of muscle tissue from infected fowls were lower than the normal on the fifth and sixth days.

Challey (1960) observed that both acute cecal coccidiosis and artificial hemorrhage caused a marked increase in ascorbic acid in the adrenals of chickens. He suggested that the adrenal ascorbic acid elevation might be due to blood loss alone. Challey (1962) reported that adrenal corticosterone concentrations were also elevated in chicks during the early hemorrhagic phase of cecal coccidiosis.

Waxler (1911a) has demonstrated that feeding concentrated physiological salt solution to birds during the hemorrhagic phase of the disease effects a lesser rise in blood sugar than when no salt is fed. In addition, the mortality was three times greater in the untreated birds than in the salt-fed. However, he was not able to positively attribute the beneficial effects of salt

feeding to the lower rise in blood sugar.

Prevention. The ideal control of poultry coccidioses would seem to consist simply of preventing the ingestion of viable sporulated oocysts by susceptible hosts. The difficulties lie in perfecting methods of achieving this desideratum. One difficulty is that the oocysts of most of the species occurring in chickens will survive in soil for as long as a year and more.

While extremely low temperatures, such as −12° C. for seven days (Edgar, 1954), will kill the oocysts of *Eimeria tenella*, Horton-Smith (1957b) thinks it is the moderately low winter temperatures, preventing the fresh oocysts from sporulating or reducing the rate at which sporulation proceeds, that are most important in the epidemiology of coccidiosis. Other environmental factors that unfavorably affect the survival of oocysts are dryness, direct sunlight, heat, lack of oxygen, and bacterial and fungal action.

The findings of Andrews and Tsuchiya (1931) showed that on a poultry farm the greatest concentrations of oocysts are built up in places where the birds spend the most of their time. Devices to prevent contact of the birds with their droppings in such areas should, and in actual practice do, reduce losses from coccidiosis, as Van Es and Olney (1940) indicated.

The frequent removal and replacement of the litter is recommended also, but despite all these precautions, the problem often remains unsolved.

The thorough cleansing of the floor and equipment in a brooder house between each group of chicks brooded is helpful. After the thorough removal of filth, floor and utensils should be thoroughly scrubbed with hot lye water. Sawyer and Hamilton (1935) recommended 1 pound of lye to 20 gallons of water. Afterwards floor and equipment should be thoroughly dried for, as Pérard (1925) has demonstrated, drying is probably one of the most potent natural forces in the destruction of oocysts.

Of all the fumigation methods that

have been proposed, ammonia fumigation seems the most practicable. Horton-Smith, Taylor, and Turtle (1940) obtained complete killing of the oocysts of *E. tenella* with a 1.0 per cent solution of 0.83 per cent ammonia in 24 hours, with a 5.0 per cent solution in 2 hours, and with a 10 per cent solution in 45 minutes.

It is important that the attendant takes care that he does not track fecal material from one house or pen to another.

The form of range management advocated is the three-year rotation plan, wherein the range is used for chicks but one year and planted to a cereal crop and grass the next two years. Under this plan the brooder houses are of the movable type. Each house is thoroughly cleaned before it is transported into the clean range.

The "deep litter method" of controlling poultry coccidiosis was tested by Boughton (1939). It consists of the use of a deep layer of sawdust or shavings, stirred daily, over the entire period of brooding, i.e., ten or twelve weeks. The litter is renewed just before the advent of the new brood of chicks. Boughton's preliminary study did show that such litter, when dry, does reduce the potential number of sporulated oocysts through drying.

Improvements in the deep and built-up litter methods consist of better insulation and ventilation of the poultry house, which favor dryness of the litter, and the use of hydrated lime in the litter. Kennard and Chamberlin (1947) have adopted the following procedure for combining the built-up litter and hydrated lime practices in the brooder houses: At intervals of 2 to 4 weeks hydrated lime is scattered over the litter at the rate of 10 to 15 lb. per 100 square feet of floor space, and carefully mixed with the litter at time of distribution in order to avoid caustic effects on the feet of the birds. The litter is stirred and redistributed every 2 or 3 days during the first 8 weeks and daily after that. Litter and lime may be added at any time as needed, but lime is seldom needed after the first 4 or 5 weeks. Such litter will remain dry and fresh for 8 to 16 weeks. Particular care should be taken to redistribute the litter about the water fountains and feed boxes. The Ohio Station had no coccidiosis in a brooder house in a season during which five successive broods, totaling 10,000 chicks, occupied the structure. Koutz (1918) doubted the value of liming deep litter, though his investigation proved the value of deep litter, properly managed, in helping the birds to build up protective resistance to *E. tenella* with minimal losses from the disease. In this and later work Koutz (1952a, b) showed that many oocysts of *E. tenella* and other coccidia, as well as ova of parasitic nematodes, remain alive, so that continuously used litter develops a high and dangerous concentration of them. For these reasons, and also because of increased amounts of dust and ammonia fumes, there are certain hazards to the life and health of successive groups of birds reared under the so-called continuous, built-up, deep litter method. Horton-Smith (1954) has pointed out similar dangers inherent in built-up litter when its depth is not maintained, but has noted that proper management of deep litter would reduce the number of viable oocysts, presumably largely through the toxic action of the ammonia produced. (See also Davies and Joyner, 1955; Long and Binstead, 1959.)

Treatment. The advent of the sulfonamides marked a new era in suppressive and therapeutic drug treatment of coccidiosis. Levine (1939) made the interesting discovery that sulfanilamide suppressed the normal development of *E. mitis*, *E. hagani*, *E. pmecox*, *E. acervulina*, and *E. maxima*, so that oocysts did not appear at the anticipated date, though a reduced number of the terminal stages appeared a few days after treatment was discontinued. There was no effect of this drug upon *E. tenella* and *E. necatrix*, the two most pathogenic species which, incidentally, produce schi-

zonts deep in the submucosa. Sulfapyri-
dine's action almost paralleled that of sul-
fanilamide (Levine, 1940b).

Sulfaguanidine, however, when mixed
with the ration at the ½ per cent level,
prevented discharge of oocysts from chick-
ens inoculated with *E. praecox, E. mitis, E.
maxima,* and *E. hagani,* according to Le-
vine (1941a). At the 1 per cent level it
markedly reduced the severity of symp-
toms and lesions due to *E. tenella,* while
a 1½ per cent concentration was effective
against *E. necatrix.* Farr and Allen (1942),
Horton-Smith (1942), and Allen and Farr
(1943) have attested to the prophylactic
value of sulfaguanidine against cecal coc-
cidiosis in mash containing 1 or 2 per cent
of the drug, providing the treatment is in-
stituted several days before ingestion of
infective oocysts and continued for more
than a week thereafter. It would seem
from the work of Waletzky and Hughes
(1946) that 0.75 per cent might be the mini-
mal requirement for marked prophylactic
value.

Horton-Smith and Taylor (1942, 1943,
1945) obtained beneficial results with
sulfamerazine (=sulfamethazine) and
sulfadiazine in the food or drinking water
after establishment of the cecal infection
in chicks through induced epizootics.
Treatment reduced mortality by 50 to 73
per cent of that in the controls. Hawkins
(1943) confirmed this work in general,
and noted inhibition of the cecal coccid-
iosis by substituting a saturated solution
of sulfamethazine for drinking water 96
hours after infection. Hawkins and Kline
(1945) found that 0.4 to 1.0 per cent in
the feed, started 4 days after infection,
gave more constant results than solutions
in drinking water. Farr and Wehr (1947)
and Wehr and Farr (1947) attributed the
beneficial effects of sulfamethazine in *E.
tenella* infection to the susceptibility of
the second generation schizonts to the
toxic effects of the drug.

Swales (1914, 1946a) confirmed Horton-
Smith's work on sulfamethazine (=sulfa-
methazine), and showed that related

compounds, sulfamerazine and its sodium
salt, were highly coccidiostatic and would
check the disease when treatment was
started at the first sign of bloody drop-
pings in the flock. The levels found satis-
factory were 2 gm. of sulfamerazine per
pound of dry mash or 2 gm. of its soluble
sodium salt per liter of drinking water.
There was no advantage in continuing the
treatment for more than 3 days. (See also
Hawkins and Rausch, 1946; Gardiner,
1957a.) Horton-Smith and Boyland
(1946) have effectively treated *E. tenella*
infections with 0.2 per cent sodium sul-
famezathine or 0.1 per cent sodium sulfa-
pyrazine in the drinking water. Asplin,
Boyland, and Horton-Smith (1946) have
issued the warning, however, that because
of the dangers involved in long-continued
administration, sulfamezathine treatment
should not exceed one week.

Horton-Smith (1957a) showed the rela-
tive effects of sulfanilamide, sulfapyridine,
sulfathiazol, sulfaguanidine, sulfadiazine,
sulfamerazine, sulfamezathine, and sulfa-
pyrazine on the second generation schizonts
of *Eimeria tenella* and on mortality when
administered 48 hours before infection and
48 hours afterwards.

The action of sulfonamides in coccidial
infection is antagonized by para-amino-
benzoic acid (cf. Horton-Smith and Boy-
land, 1946; Waletzky and Hughes, 1946),
a phenomenon which might indicate that
the coccidiostatic effect of the sulfon-
amides is upon the PAB-folic acid meta-
bolic sequence. Continuing the work
along this line in search of more potent
inhibitors, Lux (1954) not only found
certain diaminopyrimidines and dihydro-
triazenes that played this role effectively,
but he discovered synergism between 2,4-
diamino compounds and certain sulfon-
amides. Even sulfanilamide, which at 0.5
per cent level in the ration permitted 89
per cent mortality with the dosage of *E.
tenella* employed, when fed at the 0.025
per cent level together with 2-4-diamino-5-
p-chlorophenyl-6-ethylpyrimidine at the
0.005 per cent level, prevented mortality

altogether. The potentiation of otherwise ineffective doses of sulfadimidine, sulfaquinoxaline, and sulfaguanidine by pyrimethamine has been reported by Joyner and Kendall (1955) and Kendall and Joyner (1956). (See also Arundel, 1959; and Joyner, 1960.) Another seeming synergism is that between aureomycin and sulamethazine (Gardiner, 1957b, 1959). Levels of these chemicals, which by themselves were ineffective in preventing mortality and promoting growth under conditions of exposure to cecal coccidiosis, when combined in the mash reduced the pathological changes identified with cecal coccidiosis.

Other forms of drug prophylaxis or therapy in cecal coccidiosis are: (1) certain halogenated arsenic acids and their sodium salts at the proper concentrations in feed or water (Morehouse, 1946; Morehouse and Mayfield, 1946; and Goble, 1949;) (2) nitrofurans such as 5-nitro-2-furaldehyde semicarbazone ("nitrofurazone") in the mash (Harwood and Stunz, 1949a, 1949b, 1950; Horton-Smith and Long, 1952; Gardiner and Farr, 1954); furazolidone (about .006 per cent in the feed) (Harwood and Stunz, 1954; Wolfgang, et al., 1957; Harwood, et al., 1957); and Bifuran—a mixture of nitrofurazone and furazolidone (Horton-Smith and Long, 1959a and b; and McLoughlin and Chester, 1959); (3) m,m'-dinitrodiphenyl disulfide ("nitrophenide," "Megasul") in the mash (Waletzky and Hughes, 1946; Waletzky et al., 1949; Brackett and Bliznick, 1949; Swales, 1950; Dickinson et al., 1951; Gardiner et al., 1952); (4) sulfaquinoxaline in an all-mash ration (Delaplane et al., 1947; Delaplane and Higgins, 1948; Grumbles and Delaplane, 1948; Grumbles et al., 1948; Grumbles et al., 1949; Peterson, 1948; Junghern and Winn, 1949; Brackett and Bliznick, 1949); (5) bisphenols ("K6606," "K6605," "K1409," etc.) in the feed (Johnson et al., 1949; Hawkins and Dunlap, 1949); (6) nicarbazin (0.0125 per cent) in the ration (Guckler et al., 1955; Guckler et al., 1956; Guckler and Malanga, 1956; Rubin et al., 1956; McLoughlin et al., 1957; (7) Trithiadol—a combination of bithionol and methiotriazamine (Mc-

Loughlin and Chester, 1959; McLoughlin et al., 1960; Stuart et al., 1963); (8) Glycarbylamide (Horton-Smith and Long, 1959a and b; McLoughlin et al., 1960); (9) Amprolium (Cuckler et al., 1960; McLoughlin and Gardiner, 1962a and b); (10) Zoalene (Peterson, 1960); (11) Unistat (Morehouse and McGuire; 1959); (12) vitamin K (Baldwin et al., 1911; Couch, 1951; Harms and Tugwell, 1956; Otto et al., 1958).

Nitrophenide and sulfaquinoxaline are claimed to be effective against both Eimeria tenella and E. necatrix (Waletzky, et al., 1949). Peterson and Munro (1949) have found sulfaquinoxaline to be of value in preventing coccidiosis with E. acervulina in recently housed pullets, and Dickinson (1949) showed it to be an effective coccidiostat against artificial infection with E. acervulina in laying pullets without affecting body weight or egg production at the levels fed. Factors in the evaluation of coccidiostats in poultry have been discussed by Cuckler et al., (1957), with a bias toward nicarbazin.

Tyzzer (1929), Johnson (1932), and others of the early workers have pointed out the possible value of small doses of sporulated oocysts either fortuitously picked up or intentionally administered in the mash as a means of establishing in young chickens a considerable resistance against infection resulting from heavier doses of the infective microorganisms acquired later in life.

With the advent of drug prophylaxis there has become evident the desire of experimenters to show that various drug coccidiostats, while preventing serious disease, do not interfere with the natural development of immunity to coccidial infections acquired while the birds are under treatment. Ripsom and Herrick (1945) showed that sulfadiazine in the mash at the 1.0 per cent level, for 24 hours commencing the sixth day of an experimental E. tenella infection, protected the test birds and did not interfere with the development of immunity. The potential value of sulfaguanidine for establishing

resistance to infective oocysts of *Eimeria tenella* was demonstrated by Allen and Farr (1943) and Seeger and Tomhave (1946). Swales (1946a and b) found that feeding sulfamerazine in the mash early in the infection did not interfere with the development of immunity to *Eimeria tenella*. (For the effect of other sulfonamides see Horton-Smith, 1948.) Dickinson *et al.* (1951) reported that chicks were inoculated at 15 days of age with a "mild clinical dosage" of *Eimeria tenella, E. necatrix, E. maxima, E. praecox,* and *E. acervulina.* Commencing 48 hours after the coccidial inoculation, they were fed, for 14 days, mash containing 0.025 per cent sulfaquinoxaline and were almost as well protected against heavier challenging doses administered at the age of 57 days as were those in the immunized untreated group. Another group, treated the same except that it received nitrophenide in the mash at the 0.05 per cent level, suffered from the challenging doses of infected oocysts almost as much as the nonimmunized, untreated controls. That nitrofurazone, fed to chicks at levels for efficient coccidiostatic action, did not interfere with the development of resistance to *E. tenella* is suggested by the works of Horton-Smith and Long (1952) and Gardiner and Farr (1954). The latter actually felt that when this drug was fed at levels to provide only partial protection, the development of resistance was actually enhanced. Cuckler and Malanga (1956) found that nicarbazin did not adversely affect the immunizing process, although it significantly reduced the pathological effects of avian coccidiosis as well as the numbers of oocysts eliminated. (See also McLoughlin *et al.*, 1957.) Studies on the tissue phases of *E. tenella* have shown that drugs which effectively reduce the pathological effects of the organism while not affecting the immunizing process act chiefly on the second generation schizonts. (See also Horton-Smith, 1957a.)

Success in developing anticoccidial drugs has been attended with the revelation of toxic properties. All of them are toxic

when fed in the mash or drinking water at levels in excess of the manufacturers' recommendations. Lack of knowledge of this fact and of the proper equipment for uniform mixing render it inadvisable for other than the feed manufacturer to add the drug supplements to the ration. Even when fed at or near the recommended levels, unfavorable effects may become manifest. Considerable attention has been paid to blemished or mottled egg yolks, reduced egg size, egg production, and bleached shells when nicarbazin is fed to laying hens (Ott, *et al.*, 1955; Sherwood *et al.*, 1956; Polin *et al.*, 1956 and 1957; McLary, 1955; Newberne and Buck, 1957; Weiss, 1957; Baker *et al.*, 1956 and 1957). Other toxicological studies of note have been made on the following anticoccidial drugs: sulfaquinoxaline, Cuckler and Ott (1955), Newberne and Buck (1956); Megasul, Newberne and McDougle (1956); nitrofurazone, Newberne and McEuen (1957), Peterson and Hymas (1950), Francis and Shaffner (1956); furazolidone, Berg *et al.* (1956), Francis and Shaffner (1956). It has been pointed out that dependence on drugs in raising poultry should not be substituted for sanitary practices, and that medication of any sort should accompany efficient management (see Horton-Smith, 1957a). Anticoccidial drugs have their proper place in poultry management, especially so in preventing losses from cecal coccidiosis in the broiler industry.

The development of drug resistance by coccidia seems first to have been investigated by Harwood and Stunz (1953), who found none in infections with three cultures of *Eimeria tenella* from strains that had long been exposed to drug treatment with either nitrofurazone or sulfaquinoxaline. On the other hand, Cuckler and Malanga (1955) noted loss of sensitivity to a therapeutically ineffective concentration of sulfaquinoxaline by one strain of *E. acervulina* after 10 serial passages and by two strains of *E. tenella* after 5 to 10 passages; but one strain of *E. tenella* did not become less sensitive to suboptimal

doses of nitrophenide, nitrofurazone, or nicarbazin for 15 serial passages. In addition, their studies on 40 field strains of allegedly resistant coccidia revealed 43 per cent were resistant to nitrophenide, 45 per cent to sulfaquinoxaline, and 57 per cent to nitrofurazone. It was not determined whether drug resistance in coccidia is attributable to selective drug action among different strains of the microorganism possessing different degrees of innate susceptibility (See also McLoughlin and Gardiner, 1961, 1962a and b; Gardiner and McLoughlin, 1963.)

Swales's (1947a) "System C" for controlling coccidiosis provides that battery-raised susceptible 3- or 4-week-old chicks be placed in an "immunizing pen" whose floor has previously been contaminated with the droppings of heavily infected chicks, and be given preventive treatment of such drugs as sulfamerazine, sodium sulfamerazine, sulfamezathine, or sodium sulfamezathine for 6 to 10 days. The birds are then placed in clean dry pens for development to broilers or layers.

Edgar (1955b, 1956, 1962) has developed a vaccine for intestinal and cecal coccidiosis which is claimed to achieve regulated immunization of chicks on a commercial scale. Under his plan, 3-day-old chicks are starved for about three hours and then fed a feed freshly mixed with a commercially prepared culture of sporulated oocysts of *E. tenella* and three to five other species of chicken coccidia. The chicks develop mild infections and seed the litter with oocysts which undergo sporulation and in turn become infective. These infective oocysts are picked up by the birds on the newly contaminated litter, and reinfections result. To prevent serious disease, a low level of a coccidiostat is administered until the birds are 5 to 6 weeks old. The chicks are supposed to have acquired enough partial immunity during this period to withstand further exposures. Levine (1961) stated that although this system has often worked well, there have been too many failures to justify recommending its general use.

turkey poults. Hawkins (1952) considered it to be the cause of the most serious coccidial infection of turkeys. With a dose of 50,000 oocysts he was able to produce up to 100 per cent mortality in poults two to three weeks of age. He mentioned that there was some evidence of age resistance. Clarkson and Gentles (1958) confirmed this observation and stated that "although age resistance develops early, reduction in weight gains occurs in previously uninfected birds of all ages and can cause severe economic loss."

There are no symptoms characteristic of this infection. According to Hawkins (1952) and Clarkson and Gentles (1958) the birds appear normal until the end of the fourth day after infection when they begin to cheep and huddle together with drooping wings and ruffled feathers. The feces become fluid and contain some flecks of blood. Hawkins (1952) stated that cylindrical pellets, two to three centimeters long, appear in the feces on the fifth and sixth days after infection, whereas Clarkson and Gentles (1958) reported that on the sixth day, the feces consist "of a foul-smelling, dark brown liquid material containing small streaks of dark blood." Deaths usually occur on the fifth, sixth, and seventh days after infection.

The following description of the life cycle is based on the work of Clarkson (1959a). Both asexual and sexual generations occur in the upper small intestine with some spread of the latter into the lower intestinal tract. All stages, except the first generation schizont, develop both above and below the host cell nucleus with the majority occurring above. The sporozoite invades the tip of the villus and, like the sporozoite of *E. necatrix*, passes through the lamina propria into the base of a cell in the glandular epithelium where it grows into the first generation schizont containing 80–100 merozoites. These merozoites invade adjacent epithelial cells and develop into second generation schizonts with 8–16 merozoites. Third generation schizonts are somewhat similar to second but are restricted to villus epithelium; and

merozoites formed within them penetrate surface epithelium particularly at the tips of the villi, where they develop into gametocytes. According to Tyzzer (1929) and Hawkins (1952) the prepatent period is six days whereas Clarkson (1959a) reported it to be 114–118 hours.

Gill (1954) reported success in infecting week-old chickens with this species of turkey origin, but confirmation would seem to be required.

Eimeria dispersa Tyzzer, 1929, of quail origin was transmitted to three turkeys by Tyzzer (1929). The second transfer, however, did not succeed, suggesting an imperfect adaptation to the turkey, but the transfer of the same organism from the turkey back to the quail was successful. Hawkins (1952) found numerous infections in turkeys and he succeeded in transmitting it from the turkey to bobwhite and Hungarian partridges *(Perdix perdix)*. Moore and Brown (1952) also accomplished infection of both quail and turkeys with this species, but, according to Moore (1954), they were unable to infect pheasants with it.

According to Hawkins (1952) the parasites develop mainly in the epithelial cells of the villi of the upper part of the small intestine of turkeys, superficially to the nucleus of the host cell. The main gross lesions are dilation of the small intestine and creamy, sticky mucoid material in the lumen of its anterior half. The tips of the villi show necrosis on the fourth day. No marked clinical symptoms are noted except the tendency to produce liquid feces and slight depression in weight gains.

Eimeria gallopavonis was first mentioned by Hawkins (1950a) as a parasite of turkeys and the Hungarian partridge. The first published description of the species, however, was by Moore and Brown (1951) (see Table 37.2), who attributed its name to Hawkins (1950a). As used by Hawkins, however, *gallopavonis* is a *nomen nudum*. Hawkins (1952) published a complete description and stated that further study would be required to determine its pathogenicity. According to Farr *et al.* (1961) and Wehr *et al.* (1962) experimental

TABLE 37-2

Characteristics of Eimeria Affecting Turkeys*

Species	Hosts	Site of Infection	Measurements in Microns	Sporulation Time	Prepatent Period	Refractile Body	Pathogenicity
E. meleagrimitis Tyzzer (1929)	Turkey	Jejunum, Tips of villi affected (Mainly jejunum, but upper small intestine ("Glands as well as villi")	15.8–26.9 × 13.1–21.9 Av 19.1 X 16.2 (20.1 = 19.5 × 17.3 = 17) Ovad	48 hr	6 days (116 hr)	Yes	Pathogenic
E. dispersa Tyzzer (1929)	Quail Turkey Hungarian partridge Pheasant	Duodenum, also small intestine and ceca near bifurcation	21.8–31.1 × 17.7–23.9 Av 26.9 X 21.0 Broadly ovoid	48 hr	6 days	No	Relatively nonpathogenic
E. meleagridis Tyzzer (1927)	Turkey	Ceca Tips of villi involved (1st stage 15.4–20.6 remainder ceca, deep glands as well as villi)	20.3–30.8 × 15.4–20.6 Av 24.4 X 18.1 (18.2–28.1 × 13.0–20.7 Av 22.5 X 16.2) Ellipsoidal	24 hr	5 days (110 hr)	Yes	Nonpathogenic
E. gallopavonis Hawkins (1950)	Turkey Hungarian partridge	Ileum and rectum Schizonts not numerous in ileum and ceca. Residual mass present Tips of villi affected	22.2–32.7 × 15.2–19.4 Av 27.1 X 17.2 Ellipsoidal	24 hr	6 days	Yes	Pathogenic
E. adenoeides Moore & Brown (1951)	Turkey	Lower ileum, ceca, rectum. Deep glands as well as tips affected	18.9–30.2 × 12.6–20.9 Av 25.6 X 16.5 (21.5–30 × 13.5–19.5) Ellipsoidal	24 hr.	112 hr. approx. (114–132 hr.)	Yes	Pathogenic
E. innocua Moore & Brown (1952)	Turkey	Villi of small intestine	18.57–25.86 L. 17.34–24.54 W. 22.41 × 20.86 Subspherical	48 hr.	114 hr. approx.	No	Nonpathogenic
E. subrotunda Moore, Brown, and Carter (1954)	Turkey	Duodenum, Jejunum, and upper ileum. Tips of villi	16.48–26.42 L. 14.21–24.44 W. 21.77 × 19.81 Subspherical	48 hr.	95 hr.	No	Nonpathogenic

* Modified from E. N. Moore, J. A. Brown, R. D. Carter, Ohio Agr. Exper. Sta. Bars in parentheses from Clarkson (1958, 1959 a and b).

infections of *E. gallopavonis* were highly pathogenic for 3- to 6-week-old poults and caused marked symptoms and some mortality in 11-week-old poults. Except for a reduction in feed consumption and slight weight losses among heavily infected birds on the fifth day after infection the poults usually appeared normal until the sixth day when they ate little or nothing, became somnolent, and discharged fluid, blood-tinged droppings. Many poults lost weight and a few died on the sixth day. Death occurred in greatest numbers on the seventh, eighth, and ninth days and continued in diminishing numbers through the twelfth day. In severe infections the entire mucosa of the lower small intestine, the rectum, and the proximal portions of the ceca contained marked inflammatory changes. On the seventh and eighth days a milky-white exudate, composed principally of oocysts, was present throughout these areas.

According to Hawkins (1952) development occurs principally in the epithelial cells of the rectum, and, to a lesser extent, of the ileum and ceca. Marked edema, sloughing, and lymphocytic infiltration were noted in sections of the affected tissues.

Transmission of this species from the turkey to week-old chickens is claimed by Gill (1954), but it requires confirmation.

Eimeria adenoeides Moore and Brown, 1951, causes a severe enteritis in the lower small intestine, ceca, and large intestine resulting in up to 100 per cent mortality in young poults and diarrhea and reduced weight gains in poults 9 to 11 weeks of age (Clarkson and Gentles, 1958; Clarkson, 1958). According to Moore and Brown (1951), "there were no marked differences in gross pathology to distinguish this species from others affecting turkeys, other than the site of the infection." The affected regions were dilated, slightly edematous, and whitish in color owing to the presence of a caseous exudate containing enormous numbers of oocysts.

Symptoms have been described by Moore and Brown (1951), Clarkson and Gentles

(1958), and Clarkson (1958). The birds behave normally until the fourth day after infection when they eat less food and huddle together. Their feces become fluid and contain mucus and small amounts of blood. On the sixth and seventh days the feces are composed almost entirely of yellow cheesy casts and subsequently become normal. Deaths occur late on the fifth and continue to the seventh day or a little later.

In his description of the life cycle Clarkson (1958) stated that the first asexual stage is localized mainly in the terminal inch of the small intestine and "neck" of the ceca whereas later stages tend to spread into adjacent regions of the lower intestinal tract. The sporozoites penetrate epithelium on the tips or less often on the sides of the villi, rarely in the glands. They undergo nuclear division and grow into large first generation schizonts containing about 700 small merozoites. These merozoites invade both surface and glandular epithelium and develop into small second generation schizonts with 12–24 large merozoites. Generation two merozoites penetrate epithelial cells on the sides and tips of the villi and in the glands where they grow into gametocytes. Moore and Brown (1951) reported that the prepatent period was about 112 hours whereas Clarkson (1958) stated that it ranged between 114–132 hours.

Eimeria innocua Moore and Brown, 1952, seems to be appropriately named, because massive infections produced no macroscopic lesions and no signs of illness. Moore and Brown (1952) mentioned that preliminary trials suggested a slight retardation in weight gain during the first two weeks of infection. Neither chickens nor quail have proved to be susceptible to infection with this species.

Eimeria subrotunda Moore, Brown, and Carter, 1954, becomes established in the upper portion of the digestive tract to within two inches of the yolk stalk. The epithelial cells most heavily parasitized were those near the tips of the villi. Young poults infected with massive doses of

oocysts failed to exhibit symptoms or lesions. It was established that chicks, guinea fowl, ringnecked pheasants, and bobwhite quail are not susceptible to this species.

Svanbaev (1955) found unsporulated oocysts and an occasional oocyst containing two sporoblasts in feces of young turkey poults in Kazakhstan S.S.R. The oocysts were round or short oval, 21.6μ–32.8μ by 24.6μ–32.8μ, with a mean of 30.5μ by 29.8μ, and a shape index of .98. The double-contoured, smooth, greenish oocyst wall was 1.5μ to 1.7μ thick. Sporulation was completed in 16–20 hours at 20° to 25° C. A polar granule was present. The two sporocysts, 14.9μ by 10.1μ, were rounded at one end and pointed at the other and each contained 4 oval sporozoites, 7.2μ–9.0μ by 4.5μ–5.4μ. Oocystic and sporocystic residual bodies were absent. The species was named *Isospora heissini*. Svanbaev (1955) did not mention any attempt to infect other turkeys with this organism.

Slavin (1955) described and provisionally named *Cryptosporidium meleagridis*, a coccidium parasitic on the "villus epithelium" of the terminal third of the small intestine of young turkey poults from a farm in Scotland. All stages in the life cycle, except sporulated oocysts and liberated sporozoites, were observed. The oocysts were oval, 4.5μ by 4.0μ, with an eccentric nucleus. Slavin considered that the parasite was responsible for diarrhea and low mortality in 10- to 14-day-old poults.

Treatment. As testing of anticoccidial drugs proceeds, it is becoming more and more apparent that the sulfonamide drugs which are effective in chickens affect also the coccidia of turkeys (Moore, 1949; Morehouse, 1949b; Peterson, 1919; Boyer and Brown, 1953; Cuckler et al., 1956; Horton-Smith and Long, 1959). For a concise discussion of investigations on treatment of turkey coccidiosis through 1959, see Levine (1961).

Cuckler et al. (1961) reported that prophylactic feeding of .003–.025 per cent amprolium (1-[4-amino-2-n-propyl-5-pyrimidinylmethyl]-2-picolinium chloride hydrochloride) afforded complete protection from coccidiosis mortality due to E. adenoeides, E. gallopavonis, and E. meleagrimitis. Ball and Warren (1963) demonstrated that either amprolium or sulfaquinoxaline at .0125 per cent in the feed for one day before and fourteen days after infection with either E. adenoeides or E. meleagrimitis prevented much of the weight loss and all mortality. However, poults previously protected with amprolium were less resistant to severe challenge infection than were those which had received sulfaquinoxaline. These workers suggested that the two compounds differed in their action on stages in the life cycle of both E. adenoeides and E. meleagrimitis.

Horton-Smith and Long (1961) found that sulfaquinoxaline and, to a lesser extent, sulfadimidine inhibit the development of the three schizont generations of E. meleagrimitis, but have little effect on the gametocytes. They stated that the mechanism by which sulfaquinoxaline inhibits schizogony is probably associated with the PABA-folic acid sequence.

COCCIDIOSIS OF THE GOOSE

More is known concerning coccidiosis of geese than of ducks, but our information is still meager, particularly regarding the intestinal forms. The goose alone of domestic poultry is afflicted with renal coccidiosis caused by *Eimeria truncata*. The intestinal species *E. anseris* and *E. nocens* are rarely found, but may be pathogenic in severe infections. The three species described by Farr (1953) from the Canada goose (*Branta canadensis*) which she was able to transfer successfully to the common goose—*E. hermani, E. striata,* and *E. fulva* —will not be further discussed here.

Eimeria truncata Railliet and Lucet, 1891, a highly pathogenic parasite of young geese, causes destruction of kidney tissue, particularly the epithelium of the uriniferous tubules. The disease is very acute, lasting but 2 or 3 days, and is almost always fatal. Usually the mortality in a flock is very high. The clinical signs are extreme weakness and emaciation. The kidneys are enlarged and studded with poorly circumscribed, small, yellowish-white streaks and spots. The tubules are dilatated by masses of oocysts and urates.

Opinions differ as to the morphology of this species. The oocysts, $11.7\mu-21.6\mu$ by $14.4\mu-27\mu$, are ovoid, elliptical, or round with one end drawn out a little and sharply cut off. At the truncated pole is a more or less prominent micropyle surmounted,

in some cases, by a membranous cap. The oocyst wall is smooth, colorless, and delicate. At the completion of sporulation, which requires 1–5 days, an oocystie residual body is sometimes found among the sporocysts. According to Lerche (1925) the sporocysts, 7.8μ by 5.5μ, contain two comma-shaped sporozoites and a finely granular sporocytic residuum. (See also McGregor, 1952; Ridala, 1936; and Spiegl, 1921.)

This disease was known only in Europe until McNutt (1929) reported an outbreak in Iowa. The reports and reviews by Levine *et al.* (1950) and Lindquist *et al.* (1951) indicate the prevalence of this parasite in Illinois, Maryland, Michigan, District of Columbia, New York, Washington, Quebec, and Ontario.

E. truncata was reported from goslings of the graylag (*Anser cinereus*) by Christiansen and Madsen (1948) and Christiansen (1952). The last-named author also found in the kidneys of young swans (*Cygnus olor*) oocysts resembling *E. truncata*, but smaller. He also found in the kidneys of common eiders (*Somateria mollissima*) oocysts of a small variant of *E. truncata*. Waldén (1965), believing that the small form from kidneys of *Cygnus olor* was not *E. truncata*, gave it the name *E. christianseni*. He also stated that Christiansen's small form of *E. truncata* from eiders was probably specifically distinct. Pavlov (1942) seems to have found *E. truncata* in the kidney of the domestic duck.

The following descriptions of goose coccidia are based mainly on the work of Kotlán (1933). (See also Cerná, 1956; and Hanson, Levine, and Ivens, 1957.) *Eimeria parvula* Kotlán, 1933, a common harmless parasite was found chiefly in the epithelium of the terminal small intestine. The round or round-elliptical oocysts, 10μ–15μ by 10μ–14μ, had a colorless, delicate wall without a micropyle.

Eimeria nocens Kotlán, 1933 developed within and under the epithelium of the tips of the villi in the posterior small intestine. The brownish oocysts, 25μ–33μ by 17μ–24μ, were egg-shaped with a more or less truncated pole containing a micropyle. *E. nocens* was an uncommon parasite, found principally in young geese with intestinal disturbances. Kotlán (1933) believed that further investigations would be required to determine its pathogenicity.

Stages in the life cycle of *E. anseris* Kotlán, 1932 occurred under and within the epithelium of the posterior small intestine. Experimental infection was apparently harmless for 2½- to 3-month-old geese. The colorless oocysts, 16μ–23μ by 13μ–18μ, were pear-shaped with an evident micropyle at the tapered pole. According to Hanson *et al.* (1957) *E. anseris* oocysts from *Anser c. caerulescens* measured 16μ–19μ by 20μ–21μ. The smooth colorless wall of the oocyst was sharply incised at the narrow pole to form a plate across the micropyle. Below the plate was an amorphous oocystic residuum. The sporocysts, 7μ–9μ by 10μ–12μ, were ovoid in shape and contained two sporozoites and a large residuum. Bajard (1962) stated that symptoms of intestinal coccidiosis due (presumably) to *E. anseris* and *E. nocens* were anorexia and constipation followed by diarrhea. In severe cases death came quickly. Otherwise the geese improved after two or three days of diarrhea.

Tyzzeria anseris Nieschulz, 1947. The description of this species was based on the morphology of oocysts found in feces of a domestic goose in Netherlands. The elliptical oocysts, 12.0μ–16.0μ by 10.0μ–12.5μ, had a thick colorless wall without a micropyle. Upon sporulation they contained 8 free sporozoites and an eccentric oocystic residual body. Nieschulz could not infect a duck with *Tyzzeria anseris*. For a discussion of the problem of the identity of *T. anseris* and of other species of *Tyzzeria* reported from ducks and wild geese and swans see Hanson *et al.* (1957); and Levine (1961). Farr and Wehr (1952) found the same species in two goslings from Maryland.

COCCIDIOSIS OF DUCKS

A number of accounts of losses in domestic ducks have been attributed to coccidia, but the etiology of these cases has not always been sufficiently elucidated. (See Dougherty, 1952, 1960; Davies, 1957.)

Tiboldy (1933) described oocysts of the genus Eimeria that were oval, elongate oval, or occasionally rounded, possessed a sturdy wall, and measured from 10.8μ–25.0μ by 8μ–12.6μ. A number of species are possibly involved, but the question of specificity has not been cleared up. Scholtyseck (1955) has described *E. anatis* from the European wild duck, *Anas platyrhynchos*, but did not find it in the domesticated varieties. The wall of the ovoid oocyst is smooth, homogeneous, and 0.7μ–1.0μ thick. There is a ringlike thickening about the more pointed end and, after sporulation,

a characteristic roundish thickening on the inside of the wall enclosed by the ring. Residual granules are present among the sporozoites. The oocysts measure 14.4μ–19.2μ by 10.8μ–15.6μ; mean, 16.8μ by 14.1μ. Schizonts and gametocytes were observed in the small intestine. Pavlov (1942) found *E. truncata*, more commonly occurring in geese, in the kidneys of domestic ducks in Bulgaria.

The only other described species from domestic ducks is *Tyzzeria perniciosa* Allen, 1936, from the small intestine of its host. It was described from a six-week-old Pekin duck (*Anas domesticus*) obtained from Rinebeck, New York, U.S.A. The oocysts of this genus are peculiar in that they are asporocystic (without sporocysts) and after development for 24 hours outside the body contain eight sporozoites

and a large residual mass. The content of the freshly passed oocyst, however, consists of coarsely granular protoplasm completely filling the oocyst. The asexual developing stages appear in the mucosa of the small intestine from the gizzard to the ceca. There are three morphologically distinguishable generations of schizonts after which (about 48 hours after inoculation) gametocytes make their appearance. Oocysts were first observed in the tissue by the end of the fifth day and in the droppings on the sixth day.

The species is extremely pathogenic, for Allen lost seven of ten very young ducks which she experimentally infected. The symptoms reported as "loss of appetite and weight, weakness manifested by the inability of the bird to stand for any length of time, and continuous crying as if in distress. The last symptom was especially noticeable in baby ducks."

Macroscopic lesions consisted of inflammatory and hemorrhagic areas throughout the small intestine, especially in the upper half. The intestinal wall was thickened and exhibited rounded white spots on the exterior. In severe cases blood and cheesy exudate, but no core, filled the small intestine.

Tissue sections revealed the penetration of the coccidium into the mucosa and submucosa as far as the muscular layers, and extensive tissue destruction. The possible relationship of *Tyzzeria* species occurring in various ducks and geese is discussed in the previous section. See also Levine (1953).

ENTEROHEPATITIS (BLACKHEAD)[2]

Some phases of blackhead are dealt with in the chapter on diseases of the turkey. This section is concerned mostly with the etiological agent, *Histomonas meleagridis*, and other organisms associated with its transmission.

Histomonas meleagridis (Smith, 1895) Tyzzer, 1920

In 1895 Theobald Smith identified a protozoan, which he called "*Amoeba meleagridis*," as the cause of blackhead. He described from sections of lesions spherical or slightly oval bodies from 6μ–10μ in diameter, with a small spherical nucleus 2μ in diameter, in some cases with a nucleolus. In the original paper Smith did state

that movements characterized as ameboid had not yet been demonstrated, but in 1910 Smith again studied the fresh microorganisms from the liver (which were from 8μ–15μ in diameter) in a warm chamber and noted slight changes of form (Fig. 37.5). He states: "Some of the freed parasites . . . pushed out small finger-like pseudopodia, usually one at a time." The arrangement of the organisms singly or in groups in the tissues and unenclosed by a common membrane suggested that multiplication took place as a simple process of division and not as endogenous segmentation.

Tyzzer (1919) first noted adjacent to the nucleus of the protozoan an "extranuclear body" from which delicate filaments radiated over the surface of the nuclear membrane. Division of the extranuclear body
FIG. 37.5 — Liver from turkey affected with blackhead showing the characteristic parasites. ×920. (Biester, Iowa State University.)

resulted in the formation of a paradesmose which persisted until division of the nucleus had taken place, after which cell division occurred. No flagella had been observed at this time, but amoeboid movement had been encountered frequently. Nevertheless, Tyzzer remarked that "the presence of an extranuclear body resembling the blephroplast of flagellates and a type of nuclear division characteristic of certain flagellates, sets it apart from all known amoebae." But he later concluded "reclassification of the parasite should not be attempted until additional facts have been obtained concerning its life history."

Many of the "additional facts" concerning the life history of the protozoan were slow in coming, but in less than a year Tyzzer (1920b) had succeeded in inducing the organisms to move briskly, and in a variety of ways. One type of movement was so suggestive of flagellar activity that he renamed the organism Histomonas meleagridis, even though the much sought external flagella had not yet been observed.

Free flagellated forms were first seen by Tyzzer and Fabyan (1922b). These were taken from the ceca of experimentally infected turkeys. They state that late in the disease they found in the ceca of turkeys forms of Histomonas meleagridis in a considerable proportion of which one or two short flagella were demonstrable. In 1924 Tyzzer found flagellate forms in the ceca of chickens. Drbohlav (1924) obtained the flagellated forms in cultures from the ceca of diseased birds. Flagellate types show a great variety of ameboid movement and ingest bacteria, cell fragments, and starch grains (Tyzzer, 1924).

Tyzzer (1934) later gave us more light on the nature and behavior of Histomonas. In cecal discharges under optimum conditions it is fairly rounded, but with irregular surface extensions, and exhibits active ameboid movements and rhythmic rotary movements. At the proper high temperature the rhythmic beat becomes frequent, and a flagellum may be seen beating in one direction toward the body, causing it to rotate one-fourth to one-third of a full rotation at each stroke. One form was seen with four flagella.

In cultures the organism usually attains a larger size than in cecal discharges. At times culture forms are spread out into thin sheets and exhibit active ameboid movements; at other times they are more rounded and undergo "rhythmic flagellate motility." When brought into contact with

surfaces, the latter forms may become ameboid while still exercising their flagella. The flagellated phases may measure from 4.5μ–5μ in diameter, and flattened ameboid forms considerably more. The cytoplasm may contain starch and bacteria in considerable quantities. While normally uniflagellate, aflagellate forms are common, and those with two or even four flagella are not infrequently encountered in cultures.

DeVolt and Davis (1936) have confirmed in large part Tyzzer's observations on the behavior and nature of the organism from tissues and in cecal discharges and culture.

Lund (1963) described as a new species a histomonad that does not produce blackhead in either chickens or turkeys, but is transmitted in the same ways as is *Histomonas meleagridis*. This organism, named *H. wenrichi*, inhabits the lumen of the cecum, and apparently does not invade the tissues, nor multiply appreciably therein, if liberated in the mucosa by cecal worm larvae. Its dimensions are about 1.5 times those of *H. meleagridis*. It characteristically has four flagella and it feeds primarily on bacteria. It has thus far failed to grow on any of the artificial media used to cultivate *H. meleagridis*, and cannot, therefore, be likened to the large histomonads occasionally seen in cultures of *H. meleagridis*. Neither can its lack of pathogenicity be attributed to prolonged growth on artificial media (see section on "Immunity and Immunization"). Tyzzer undoubtedly had some of these large, nonpathogenic histomonads mixed with *H. meleagridis* in some of his chickens, and he published the first figures of it (1934, Figs. 26 and 28; also possibly, 1927, Fig. 3). Wenrich (1943) found the organism, apparently in the absence of *H. meleagridis*, in two pheasants, and he described it in considerable detail. However, he did not attempt transmission or cultivation, and concluded that the organism was a variant of *H. meleagridis*. *H. wenrichi* is apparently quite common in chickens, turkeys, and

pheasants, but it thrives best in birds not harboring the more prolific *H. meleagridis*. The diagnostician should distinguish it from the pathogen to avoid recommending the institution of expensive and needless control measures for flocks in which blackhead is not present. To the researcher, the use of the nonpathogenic species may have advantages for certain types of studies (Lund and Burtner, 1957; Lund 1959, 1961).

Transmission in Relation to Life History

Blackhead has been produced experimentally in a variety of ways with varying degrees of success. The results of more than two dozen such efforts have been tabulated by Swales (1950 a and b). Evidence of transmission through the egg of the turkey or chicken is entirely lacking. Consequently, infection as a result of ingestion of Histomonas, alone or with other organisms, remains the only plausible means of acquisition of the protozoon under natural conditions.

1. Direct infection. Smith (1895) assumed that "the microparasite is transmitted from bird to bird" without the intervention of an intermediate host. Moore (1896) appeared to have demonstrated this possibility by feeding viscera and droppings from infected birds. However, most of the early workers had difficulty finding the organism in the discharges from infected turkeys (Tyzzer, 1919, 1920a, and Tyzzer and Fabyan, 1920). Tyzzer (1924) found them in relative abundance in the cecal contents of chickens, and Curtice (1907 a and b) had shown that soil traversed by chickens was particularly hazardous as a source of blackhead infection. It is, of course, now known that turkeys also void histomonads in their cecal droppings at times. But the histomonad was known to be a fragile organism, capable of living only a few hours in cecal discharges (Tyzzer and Collier, 1925, and others), and no cyst or comparably resistant stage could be found. This made it difficult for the early workers to explain

how birds were acquiring blackhead by contact with soil or quarters long unused by poultry. As we shall see presently, the protozoan actually does have other means of dissemination, accompanied by adequate protection.

Nevertheless, direct infection without the intervention of other organisms had occasionally been demonstrated experimentally, but evidence to support the reasons postulated for the many failures was lacking. Horton-Smith and Long (1955, 1956a) found that by raising the pH of the gizzard of chickens from its normal low of 2.9–3.3 to 6.7–7.0 by starvation, or to 7.3–7.6 by giving alkaline solutions, the birds could be infected by oral administration of histomonads in cecal droppings. About the same time Lund (1956) found that turkey poults could be more readily infected with histomonads given orally by using inocula containing very little solid material than by using ones containing material subject to digestion, thereby encouraging retention in the gizzard. Both studies pointed to the same circumstance—the unprotected histomonads could not survive long exposure to the acid of the gizzard. It now became clear that natural infection by the ingestion of Histomonas alone was possible, but that it was unlikely among birds with ready access to clean water and feed. Water that had been grossly contaminated with cecal droppings shortly before a hungry bird came to drink might still constitute a hazard for that bird.

2. The relationship of Heterakis gallinarum to blackhead. The initial demonstration of the role of Heterakis, the nematode worm commonly inhabiting the ceca of chickens, turkeys, and other fowl, was made by Graybill and Smith (1920). First two turkeys were fed feces of adult turkeys and cultures of embryonated Heterakis ova (from chickens) kept in Petri dishes in normal saline solution for 17 days. Both infected turkeys became sick 15 days after ingesting the ova, and both died within a week. Three more turkeys given the same feed

contracted blackhead, as did three which received only the embryonated eggs. Negative results were obtained from feeding turkeys the feces only.

It is apparent that Graybill and Smith were of the opinion that the cecal worms, invading the ceca in large numbers, broke down the resistance of the fowl to the protozoan factor which was already present in the ceca, "probably disseminated when the first spontaneous cases occurred in the stock." They suggested that there might likewise be other agents which, when ingested by the turkeys, would prepare the way for invasion of the tissues by the blackhead organism. In the same year, however, Smith and Graybill showed that the disease could be produced in chickens by feeding incubator-hatched chicks an overdose of the eggs of Heterakis which had been placed in 0.5 per cent solution of bichloride of mercury for 30 seconds, washed, and dried. This time they concluded that the evidence pointed to the presence of Histomonas (=Amoeba) meleagridis in the cultures, but they were disinclined to accept this possibility unreservedly and so maintained that the origin of the protozoan was still undetermined. Tyzzer, Fabyan, and Foot (1921) confirmed in principle the work of Graybill and Smith, and noted likewise that it was not necessary to feed the protozoan with the embryonated eggs in order to produce the disease. Swales (1950) found that blackhead was not transmitted from carrier birds to susceptible poults in the absence of embryonated Heterakis eggs.

That the ovum of Heterakis may actually harbor Histomonas inside its shell has received very strong support from the work of Tyzzer and Fabyan (1922b). Heterakis material treated for 3 days with 1.5 per cent nitric acid, which rendered the medium bacteriologically sterile, was proved capable of transmitting blackhead when fed to incubator-bred turkeys. The discharges of blackhead carriers free from embryonated eggs did not transmit the disease after treatment with 1.5 per cent

nitric acid (Tyzzer, 1926). Swales (1948) showed that the histomonad was present within infective larvae separated from embryonated eggs of Heterakis.

Lund and Burtner (1957), working with a nonpathogenic histomonad, found that fewer than one out of 200 of the worm eggs used in their studies transmitted the protozoan, but recognized that this ratio did not necessarily pertain to pathogenic histomonads. Kendall (1957) observed that it seemed "necessary to give at least 1,000 embryonated" (Heterakis) "eggs to each poult in order to set up disease." Actually, this ratio varies greatly according to the source of the worms (unpublished data from files of senior author).

Tyzzer and Fabyan showed that the disease could be produced in turkeys by feeding hen-yard soil which, presumably, contained embryonated Heterakis eggs. Swales (1948) demonstrated transmission of Histomonas in Heterakis larvae mechanically separated from Heterakis eggs.

For many years the weak link in the chain of circumstances incriminating Heterakis eggs was the failure to demonstrate the protozoan inside their membranes. Glaser (1921) was unable to find histomonads in infective cultures of Heterakis ova, and Tyzzer (1926) was likewise unable to find the organism in the ovum, although he reported that "the invasion of the tissue of the worm has been demonstrated in a number of instances, thus far in half-grown worms from cases of blackhead." He later (1927) published figures showing several histomonads in the intestinal epithelium of heterakids 11 days old.

Niimi (1937) found what he believed to be histomonads not only in the lumen and the wall of the gut of developing cecal worms, but also in the terminal portion of the ovary and uterus of mature worms, and in fertile eggs, some of which had undergone cleavage. Niimi's organisms in the gut and gut wall corresponded in form and size with those figured earlier by Tyzzer, but the bodies assumed to be histomonads in the ovary and the eggs were much

smaller, 1μ–1.4μ in diameter, with nuclei 0.5μ–0.7μ in diameter. Niimi's work may not have received the attention it deserved, for various reasons. The journal in which it appeared seems not to have a wide circulation in this country, and accurate translation of the article is very difficult. Moreover, to some it seemed incredible that an organism could be reduced to less than $\frac{1}{3}$ its usual dimensions, nucleus and all (and, presumably, thus to less than 1/100 its usual mass) by simply migrating from the worm's gut to its ovary.

Recently Gibbs (1962) demonstrated histomonads not only in the eggs of Heterakis and throughout most of the reproductive tract of the female worm, but in the lumen and walls of the gut and in the reproductive tract of male worms also. At all sites, the range in size of the histomonad was comparable to that of the protozoan in the tissues of the bird. Dividing forms were seen in the ovary and in the eggs.

Kendall (1959) figured and described four "Parasites resembling *Histomonas meleagridis*" in a 4-day Heterakis larva. Presumably, these histomonads were present in this larva as the egg containing it was ingested by the host bird. Those viewed by Tyzzer, Niimi, Gibbs and others in larvae of 11 days or more were probably for the most part acquired from the host bird as the larvae fed in the infected ceca. Such histomonads would not initiate infections in new hosts until liberated there by the next generation of worms. Obviously, some Histomonas-bearing larvae of each generation must liberate their protozoa if the avian host is to acquire the Histomonas infection, and some of the developing larvae must acquire histomonads from the bird if the larvae of the next generation are to transmit the protozoan with comparable certainty. This does not, of course, preclude the possibility of Heterakis eggs becoming carriers of the same histomonads that were brought in by larvae that gave rise to those eggs, but such a precarious arrangement would, by itself, hardly insure the continued success of the protozoan. Furthermore, both Niimi and

Lund (1961), the latter working with a nonpathogenic histomonad, have shown that Histomonas-free Heterakis can be made to produce Histomonas-bearing ova by growing both parasites in the same birds simultaneously. The nonpathogenic histomonad was apparently acquired most readily by larvae 9 to 18 days old, and most frequently liberated by larvae 6 to 14 days old. These periods are not so well established for the pathogenic histomonad, but are not identical (senior author's unpublished data). In any event, the periods of liberation and acquisition of the histomonads by the cecal worms are such that worms from a single ingestion of Histomonas-bearing Heterakis ova have reasonable assurance of producing some eggs that also carry histomonads, if the worms survive to maturity. As Tyzzer and Fabyan (1922b) and many others have recognized, an active case of blackhead in a turkey frequently makes the cecum an untenable habitat for the worms.

From the above it is apparent that the cecal worm not only plays a very intimate part in the transmission of blackhead, but that it is admirably adapted to perform its role. Its egg is a sturdy body, well suited to survival under most natural conditions likely to be encountered in environments resembling those to which its hosts are adapted. It resists short periods of desiccation, considerable periods of freezing, and remains viable over relatively long periods under more favorable conditions. Riley and James (1921) observed that "Dry cultures which had attained the coiled embryo stage remained latent for 6 weeks, and promptly became motile on the addition of moisture." They further noted that 50 per cent of the embryonated eggs held 3 days at temperatures between −10° and 0° F., followed by storage for 6 months at 0°–10° F. were capable of segmentation, and many of these completed embryonation "in practically a normal period." Graybill (1921) found that undeveloped ova "survived desiccation at room temperature for a period of 16 days, but not 41 days. Fully developed eggs were alive after

desiccation for 18 days, but not after 49 days. In another instance they were no longer viable after 10 days." He further noted that embryonated eggs kept at room temperature in physiological saline survived during a period of a little over 12 months, while those kept in soil outdoors (New Jersey) contained living embryos after a period of 8 months.

Niimi (1937) stated, "The causative agent of the disease in question [blackhead] may survive in worms' eggs longer than 1 year, perhaps 3 or 4 years." Farr, working in Maryland, (1956, 1961) found that Heterakis ova that had been in experimental plots inaccessible to chickens or turkeys for as long as 210 to 230 weeks were still capable of producing worms in poults. Histomonas was not transmitted after 151 weeks, but the number of worms recovered after feeding eggs older than 3 years was small. Lund (1960), also working in Maryland, reported that worm counts in turkey poults exposed periodically to naturally infected test plots declined 89 per cent after the plots had been vacant for 5 summer months, another 8 per cent after the passage of 7 cool months, and was down to only 0.8 per cent of the original after the second summer. After that, 75 to 96 per cent of the birds (usually 160 to 180 per test) harbored no worms. The incidence of blackhead did not decline at a corresponding rate, falling by 35 per cent, 10 per cent, and 45 per cent after the first summer, the 7 cooler months, and the second summer, respectively. Thereafter, both worm counts and the incidence of histomoniasis declined slowly to very low levels until 52 months had elapsed. After that, both parasites almost disappeared, histomonads having been observed in only one of 167 birds released at 60 months, and in none of 176 released 65 months after the naturally contaminated plot had been vacated for testing. As we shall see presently, it may be virtually impossible to rule out completely the possibility of recontamination of soil which is maintained sufficiently close to its natural state to make results meaningful.

3. The relationship of the chicken to the dissemination of blackhead among turkeys. Only a few years after Cushman (1893) had called attention to blackhead as a specific disease among turkeys, and Smith had found the protozoan responsible for it, Chester and Robin (1901) reported the presence of the disease in chickens. Curtice (1907c) concluded, "that the poultry yards are heavily infected; that chickens, though rarely affected by blackhead disease, may be the most potent factor in its dissemination, and that diseased turkeys are nearly or quite as serious a source of infection as chickens." Milks (1908), however, reported mortality as high as 30 to 50 per cent among young chicks in Louisiana.

Following these studies, blackhead was reported repeatedly in chickens (cf. Higgens, 1915; Tyzzer, 1919 and 1924; Smith and Graybill, 1920; Kaupp, 1922; Eriksen, 1925).

The course of the infection in the common fowl usually runs a much milder course than in the turkey but is otherwise very similar. Smith and Graybill found that in chicks experimentally infected with Heterakis eggs, the initial lesions appeared in the ceca, usually followed by only microscopic focal collections of lymphocytes or yellowish necrotic specks in the liver. The inflammation and thickening of the cecal wall and the subsequent formation of a core resemble somewhat the condition in the turkey disease, but the invasion of the liver lesions bears no comparison in the two birds. Smith and Graybill state that all their chicks would probably have survived had they not been killed, for the processes of repair had been initiated, whereas experimentally infected turkeys usually died.

Reports such as those by Milks, Kaupp, and Eriksen indicate, however, that at times the disease of chickens may run a much more severe course. Kaupp reported the death of 42 out of 43 Silver Spangled Hamburg chicks about five weeks of age. Eriksen necropsied a total of 25 birds from 17 Missouri flocks. The losses ranged from one bird in a flock of 350 to more than 50 per cent in two other flocks. At necropsy cecal and liver lesions were observed, the latter organ occasionally enlarged to several times its normal size and studded with gray and grayish-yellow areas 3 to 8 mm. in diameter which penetrated deeply into the liver tissue. Histomonas was observed in sections of both ceca and liver. The age of the chicks attacked was from seven to ten weeks (cf. observations of Milks). Thus the infection in chickens may assume a serious nature at times, although under ordinary circumstances it appears to be well tolerated by the host.

There are indications that blackhead losses among chickens may have increased in recent years. Ohara and Reid (1961) calculated the frequency with which histomoniasis was recorded in proportion to accessions of diagnostic laboratories in northeastern, southeastern, and midwestern states, and report that "1.2 to 5.5 percent of the chickens in diagnostic laboratories show histomoniasis. There is some evidence of slight increase in this disease in the Midwest area." Their own experiments on age of greatest susceptibility led them to conclude, "When histomoniasis was experimentally induced with eggs of Heterakis gallinae, chickens were more susceptible at 32 days than at 1 day, 46, or 64 days of age. Comparisons with field reports indicate that very young birds and birds three months of age show some natural resistance to the organism." Desowitz (1951) and Madsen (1962) have reported similar experiences. No mortality was induced in test birds used by Ohara and Reid, but blackhead occurring concurrently with cecal coccidiosis resulted in a mortality of 12.5 per cent as compared with 6.3 per cent for cecal coccidiosis alone. Stress factors of many sorts may be expected to contribute to the severity of blackhead in chickens, but interpretation of the findings is sometimes perplexing (Madsen, 1962).

The elimination of cecal worms as a result of histomoniasis in chickens is similar to that for turkeys (Lund, 1958; Ohara and Reid, 1961), but because many more chickens survive the disease than do young

poults, the early observations of Curtice regarding the importance of the chicken as a source of dissemination of the disease are still valid.

4. Other possible factors in the transmission of blackhead. Prior to the discovery of the transmission of blackhead by the cecal worm, many means of transmission were considered and tested, usually without success. Not infrequently control birds that apparently had no access to sources of infection developed blackhead. Knowing the role of the cecal worm clarified much of the confusion, but some of the early reports are still worthy of consideration.

As early as 1907, Curtice produced blackhead in turkeys by feeding earthworms from an infected turkey yard, but not by feeding such worms from clean plots. He concluded (1907b and c), "The earthworms in this instance were probably carriers of infected soil and were not necessarily a second host to the parasite." Ackert (1917) infected chickens with Heterakis gallinarum by feeding earthworms, but blackhead, if present at all, did not come to his attention. Madsen (1962) reported having transmitted Heterakis without blackhead by feeding chickens earthworms from pheasant flight cages, but on another occasion 6 of 10 chickens fed earthworms from a different pheasant farm developed blackhead. Madsen remarks, "Before being fed to the chicks, the worms were thoroughly washed and allowed to empty their intestines as much as possible. Nevertheless a certain amount of contents must have remained, as the group contracted infections with Heterakis gallinarum and blackhead." Lund et al. (1963) presented evidence that earthworms transmit Heterakis, and also blackhead, as true hosts to the cecal worm, and not merely as carriers of embryonated heterakid eggs adhering to the cuticle, or in transit in the intestine. Heterakis larvae, sometimes in considerable numbers, were found in the coelom of some worms. If such larvae can accumulate over extended periods, earthworms may be of considerable importance in the transmission of both Heterakis and Histo-

monas by serving to concentrate infective stages, and by providing a motive for the birds acquiring these stages, sometimes in considerable numbers. Consequently, absolute freedom from contamination of outside soil plots or range can hardly be assured. The earthworms migrate to some extent in the soil, and on the surface, under some conditions. Birds carrying worms to their nests may drop them, thus providing a source of contamination for plots well removed from soil contaminated by infected birds.

Arthropod transmission of blackhead has been considered by many workers. Smith (1895) dismissed the possibility because "certain flocks only are infected." Curtice (1907a) raised poults free of blackhead although "they undoubtedly ate all sorts of insects." Tyzzer and Fabyan (1920) failed to produce blackhead in a turkey fed 185 laboratory-raised blowflies (Calliphora erythrocephala) that had recently been allowed to feed on lesions from experimentally infected birds. Another turkey that ate crickets and grasshoppers in a field adjoining its pen also remained healthy. Tyzzer et al. (1921) also failed to infect any of 3 poults that were permitted to consume large numbers of blowflies that had frequented adjoining poultry yards. However, DeVolt and Davis (1936) had 5 cases of blackhead among 67 poults that consumed trapped houseflies, and Frank (1953) was able to transmit blackhead to poults by feeding houseflies, certain flesh flies (Lucila), and grasshoppers of several species.

The recent studies on the direct transmission of Histomonas in the absence of Heterakis ova indicate that transmission by the ingestion of insects with histomonads, but no heterakids, is unlikely. Presumably, any insect, or any other organism, in contact with the soil and capable of carrying Heterakis ova, externally or internally, could serve as a mechanical carrier of histomonads.

The absence of Histomonas in the peripheral circulation of birds has been taken by most investigators to indicate that

were ingested. The identity of the flagellate cultured with the forms found in blackhead was proved by rectal inoculations into chickens, which showed large numbers of the parasites in the cecal discharges within 3 days and then developed typical blackhead. Tyzzer (1934), DeVolt and Davis (1936), and Bishop (1938) also obtained very successful cultures of *Histomonas meleagridis* using various modifications of the diphasic medium employed by Drbohlav. Bishop was apparently the first to culture organisms from liver lesions. She was also the first to report the continued propagation of Histomonas on a liquid medium, employing that used by Laidlaw et al. (1928) for estimating the toxicity of emetine for *Entamoeba histolytica*. Delappe (1953a, b, c, and d), using Laidlaw's medium, found, among other things, that Histomonas is a facultative anaerobe.

DeVolt (1943) grew *Histomonas meleagridis* in a medium consisting essentially of Locke's solution with glucose reduced to 0.2 gm. per liter, to which had been added 2 per cent turkey or chicken serum, and 2 per cent N/20 NaOH to prevent the precipitation of the serum as the medium was autoclaved.

Various workers have used modifications of DeVolt's medium. Lesser (1960a) omitted the N/20 NaOH of the medium considerably, and added sterile bovine serum after autoclaving. He also showed that cream could replace the serum in the above-mentioned medium, and could also be used in a modification of tissue culture medium "199" (Lesser, 1960b). He later (1961b) reported that certain cholesterol compounds could be used instead of cream. However, the cream had the ability to protect the histomonads from the adverse effects of amphotericin B, whereas the cholesterol compounds did not (1963). Lesser in all instances used antibiotics to kill the bacteria which were added to the Histomonas cultures. He found that he could dispense with the dead bacteria if fresh hamster liver tissue was added to the medium (1961a).

Goedbloed and Bool (1962) grew *Histomonas meleagridis* of liver origin in the culture media of Dobell-Laidlaw and Boeck-Drbohlav to which were added *Escherichia coli*, *Staphylococcus aureus*, or *Klebsnella*. These authors do not specify whether the histomonads could be maintained through successive transfers on media to which single species of bacteria were added, but they did succeed in infecting turkeys by the rectal inoculation of histomonads grown in what was apparently the initial culture in these media.

In general, *Histomonas meleagridis* appears to require something contained in or liberated by one or more species of bacteria, except that under some conditions the presence of fresh tissue may provide the deficient constituents (Lesser 1961a). The results obtained by Doll and Franker (1963) in their attempts to infect young gnotobiotic turkeys with Histomonas transmitted by feeding embryonated eggs of Heterakis appear to suggest the same thing.

Immunity and Immunization

Natural Immunity. As has already been mentioned, not all gallinaceous birds are equally susceptible to blackhead. Some breeds of chickens possess considerable resistance to the disease, whereas turkeys of all breeds seem to be quite susceptible. Curtice (1907b) observed, "No breed of turkeys thus far tested is immune to the blackhead disease, for all of them, at all ages, so far as tried, have died of it." This is still true. However, some turkeys of all ages have sufficient natural immunity to resist infection as a result of usual exposures, or even fairly heavy experimental inoculations (Lund, 1955). Curtice also noted that "older turkeys apparently resist the disease better than those which are very young, since about 20 per cent of the former have been found to die in the course of the year, and about 90 per cent of the latter." This was a common experience during the early decades of this century. Obviously, two explanations are possible: (1) the most susceptible birds had died before reaching maturity; and (2)

older birds had acquired immunity from previous sublethal or subclinical attacks. Both circumstances may have operated.

By 1951, when management practices were greatly improved, but before the selective use of effective drug control became an extremely common practice, a large-scale study (Bergesen, 1952) revealed that blackhead mortality of young turkeys and that of breeders was about equal, on a per capita basis, about 1.8 per cent. One can, of course, never be sure what proportion of the birds saved as breeders had ever acquired blackhead as poults.

Active Acquired Immunity. Early attempts to demonstrate the development of active acquired immunity under experimental conditions gave variable results. Tyzzer et al. (1921) reported that a turkey that had recovered from experimentally induced blackhead resisted infection by subcutaneous inoculation. However, Tyzzer and Fabyan later reported (1922a, b) that "the protection afforded by a single attack is not permanent." Still later, Tyzzer (1932) reported that histomonads of a pathogenic strain lost their pathogenicity after two years of cultivation in vitro, and that chickens inoculated with organisms from such cultures developed no blackhead when inoculated with pathogenic histomonads. Subsequently (1934, 1936) he reported somewhat comparable results after having used his attenuated strains with turkeys, but observed that the immunity lasted longer when reinforced by exposure of the birds to virulent strains while the immunity produced in response to the original inoculum was still high. Furthermore, he reported that after long continued in vitro cultivation, the attenuated histomonads lost their ability to produce a transient immunity. In general, Tyzzer concluded that from the practical standpoint the development of a vaccine for protecting turkeys from the ravages of blackhead was beset with difficulties, and still far in the future.

With the discovery of drugs effective in the control of blackhead, a new stimulus was given to studies on immunity because turkeys could then be given initial inocu-

lations with virulent histomonads, and still be protected against fatal or extremely severe blackhead, thus assuring the survival of the birds for later challenging. However, the results obtained by testing for immunity in drug-treated birds have varied considerably. Sautter et al. (1950) comment that little immunity was obtained from experimental infections if birds recovered as a result of drug therapy. If any immunity was developed at all, the "turkey must be markedly ill, almost to the point of death, and then recover." DeVolt et al. (1954) obtained essentially the same results. Swales (1950), Kendall (1957), and Clarkson (1963) had some turkeys that resisted Histomonas infections after having recovered from blackhead kept under control by the use of drugs. Apparently immunity is absent or negligible if the drug is used in such a way that little tissue invasion occurs as a result of the initial ("immunizing") infection or infections, but is significant if the drug is not employed until the histomonads are plentiful in the tissues.

Clarkson has demonstrated the presence of serum precipitins as early as seven days after the antigen could be detected in the cecal content, but by this time there was extensive proliferation of histomonads in the cecal mucosa, and the cecal content contained large numbers of organisms. He makes the following pertinent statement: "It is not suggested that the precipitating antibodies demonstrated in turkeys and fowls are a measure of the resistance of the bird to histomoniasis, but, like the protective immune response, serum precipitins are connected with the infection of the cecal mucosa and persist in both turkeys and fowls for a considerable length of time."

Passive Immunization. Attempts to obtain passive immunization by the injection of whole blood from immunized birds (Sautter et al., 1950) or serum from birds showing precipitating antibodies (Clarkson, 1963) have uniformly failed.

Additional Observations and Conclusions. Lund (1959) attempted to immunize

young turkeys by introducing, rectally or with Heterakis eggs, a naturally occurring nonpathogenic histomonad that differs from *Histomonas meleagridis* in several respects. Among these, it does not cause blackhead, and is not known to multiply in the tissues but apparently only in the lumen of the cecum. Rectal inoculations with this histomonad, given three to four weeks before the poults were challenged, afforded some protection against virulent strains of *H. meleagridis* introduced rectally, but virtually none against such organisms introduced with cecal worm eggs. Apparently the immune response was localized in the cecal mucosa immediately in contact with the lumen-dwelling histomonads, and Heterakis larvae readily penetrated this barrier and released their histomonads beyond it. Perhaps Tyzzer's strains of *H. meleagridis*, attenuated by extremely long culture on artificial media, failed to produce an effective immunity for similar reasons.

The search for a means of immunizing chickens and turkeys against blackhead should continue. There is presently no method of immunization of practical use to commercial growers. Consequently, anyone instituting practices designed to protect his birds from blackhead by immunization should be aware that he is definitely experimenting.

Treatment

The treatment of blackhead in turkeys is discussed in Chapter 41, Diseases of Turkeys. In general, the same drugs or classes of substances used with turkeys have been found to have comparable effects with chickens, but less emphasis has been placed on the treatment of chickens because blackhead is less frequently of great economic importance with these birds. As is the case with turkeys, no one method of treatment, nor, indeed, any combination, is completely satisfactory. Control by good management

practices is essential to the success of any program of prophylaxis or therapy.

Many drugs, some closely related to others, and all comprising about half a dozen categories of compounds from the standpoint of chemical constitution, have been used with some success against either the histomonad, the cecal worm, or, in rare instances, both. Wehr et al. (1958) gave an excellent, concise review of the more important of these drugs, their use, and effects. They also included a very useful list of references. Persons interested in pursuing the subject of chemical control in detail should consult this paper and the literature cited therein. Anyone interested merely in treating birds to prevent economic loss should seek information from local sources as to the treatments that have been most successful in his area. Soil structure, climate, local practices, and other considerations may influence the choice of a drug.

Since the appearance of the aforementioned review, there have been reports of the use of certain other substances. Lucas (1961, 1962) and Condren et al. (1962) have reported on tests employing 1,2-dimethyl-5-nitroimidazole, and Lindquist (1962) reported that an antibiotic, Paromomycin sulfate, provided 70 to 80 per cent protection against histomonads introduced by means of Heterakis ova. The effect of the latter substance may be primarily on the intestinal flora, and only secondarily on the histomonads. (See the preceding section on "Cultivation.")

Reid et al. (1960) reported that in controlled experiments a nitrofuran presently used for other purposes suppressed lesions of blackhead in young chickens each of which received about 800 embryonated Heterakis eggs. These workers conclude that the use of this drug in large-scale broiler operations might result in better weight gains and feed conversion if blackhead is present in the flock.

LEUCOCYTOZOON INFECTIONS

The genus Leucocytozoon Danilewsky, 1890, is difficult to define, but it is fundamentally very close to Plasmodium and Haemoproteus. Levine (1961), after examining the life cycles as reported for representatives of each of the three genera, concluded that "there is no point in retaining more than a single family in the suborder" (which he designated as Hemospororina). But Fallis and Bennett (1961), after comparing several stages in the life cycles of members of the three genera, proposed that each genus occupy a separate family, all being in the order Hemosporidiida. Variations in interpretations appear to rest largely on the relative significance ascribed to similarities and differences in the life cycles. The similarities are, of course, impressive.

The gametocytes of Leucocytozoon, supposedly without pigment, appear in the circulating blood inside distorted host cells, presumably leucocytes, and multiplication is by schizogony undergone only in the internal organs. As in the malarias, there is a blood-sucking dipterous intermediate host in which fertilization and sporogony take place, very much as in the case of the true malarial parasites. There has been considerable difference of opinion over the nature of the host cell of the gametocytes, but Huff (1942) found evidence that in *Leucocytozoon simondi*, while various types of cells are initially invaded, this stage becomes fully grown only in "monocytes, or more possibly macrophages." Hartman (1929) and O'Roke (1934) and others have observed pigment granules in the cytoplasm. Huff (1942), however, has pointed out that such granules may not be true hematin such as occurs in malarial parasites that develop in erythrocytes, because it is not visible as pigment in unstained preparations and its optical properties are different from those of malarial pigment. Borg (1953) could remove the pigment from *L. mansoni* with dilute acetic acid and ammonia, but not from Haemoproteus. The nucleus of the male gameto-

cyte is somewhat larger than that of the female and stains less deeply, and its cytoplasm also stains less deeply. (See illustration of Leucocytozoon in Chapter 41.)

Birds seem to be the sole hosts of Leucocytozoon. Coatney (1937) has cataloged and host-indexed 68 species up to that year. The card files of the U.S.D.A. Index Catalog of Medical and Veterinary Zoology list almost 100 species of Leucocytozoon, but perhaps a quarter of these are now regarded as synonyms, or are otherwise out of use. At least two, and probably three, species occur in domestic birds in North America. Leucocytozoon simondi occurs in domestic ducks and geese, and has been reported from many wild anseriform birds. Levine and Hanson (1953) tabulated reports of this parasite from 23 species of wild waterfowl. Leucocytozoon smithi occurs in domestic and wild turkeys. Atchley (1951) described Leucocytozoon andrewsi, n. sp., from chickens in South Carolina. Levine (1961) regards this as a synonym of L. caulleryi, a species reported by several investigators as present in chickens in southern and eastern Asia. Wehr (1962) observed, "The status of L. andrewsi is in doubt, and cannot be determined until more is known of its development and mode of transmission in the chicken."

L. simondi Mathis and Leger, 1910, first described from an oriental teal in Tonkin, is found in the blood as gametocytes measuring 14μ–15μ by 4.5μ–5.5μ inside for the most part, elongate spindle-shaped host cells pointed at both ends and about 48μ in length. The parasite either lies beside a conspicuously staining bar or between two such bars representing the nucleus of the host cell. Huff identifies the latter as a distorted monocyte or macrophage. Fallis et al. (1951) observed round gametocytes in addition to the spindle-shaped, which were mature because of the ability to exflagellate. L. anatis Wickware (1915), described from tame ducks, appears on morphological grounds to be a synonym of L. simondi. (See Coatney and Roudabush, 1937; Herman, 1938.) L. anseris Knuth and Magdeburg, 1922, described

from geese, appears to be another synonym. Fallis et al. (1954) found in cross-infection trials that ducks and geese were suitable hosts for this species, but chickens, turkeys, pheasants, and ruffed grouse were not.

Schizogony takes place in such internal organs as the liver, heart, brain, spleen, and lungs. According to Huff (1942), the earliest stages consist of small ovoid bodies inside macrophages, extracellular, or within liver (parenchyma) cells, and showing some degree of separation of their more densely staining material. The "hepatic schizonts" in liver cells, measuring 11μ–18μ, undergo differentiation into, first, cytomeres, and these in the final step in schizogony break up into small merozoites. The "megaloschizonts," measuring 60μ–105μ when mature, mostly develop inside cells, possibly lymphoid cells or macrophages, within or outside blood vessels. The earliest stages observed were inside cells and were already multinuclear. Later stages were very large and contained numerous cytomeres (intermediate subdivisions of a schizont) and a large, conspicuous "central body" concerning whose true nature Huff is not certain, but he conjectures that it is the hypertrophied nucleus of the host cell. (Cowan, 1955, on the other hand, interprets the "central body" as an integral part of the parasite—a "primordium"—from whose surface bud off the primary cytomeres.) In the last step of schizogony the megaloschizont contains many thousands of bipolar merozoites being released into the gametocytes after invading suitable cells. Fallis et al. (1951) noted mature forms in peripheral blood as early as 7 days after exposure to natural infection, and later Fallis et al. (1956), 5 to 6 days after. Parasitemia may terminate in about 30 days of its first appearance (Chernin, 1952c).

O'Roke (1931) first showed a blood-sucking fly, Simulium venustum, to be the vector among ducks in Michigan and outlined the development in this insect. Fallis et al. (1951, 1956) have added S. croxtoni, S. euradminiculum, and S. rugglesi to the list of transmitters, with the suggestion

that the latter is the natural vector in Canada. Development in the fly may be completed in a minimal time of 4 days and a fly may remain infective for as long as 18 days.

There is no doubt about the pathogenicity of *L. simondi* in ducks and geese. O'Roke in Michigan noted 35 per cent mortality in an outbreak among ducks, confirming in general the observations of Wickware (1915) in Canada, while Knuth (1922) and Knuth and Magdeburg (1922) reported on a serious and often fatal disease among young geese in Germany apparently caused by the same organism. (See also Stephan, 1922.) About 68 per cent of the fatalities occur from 11 to 19 days after exposure (Chernin, 1952a). Some of the pathological effects of the disease are anemia, leucocytosis, splenomegaly, and liver degeneration and hypertrophy (Fallis *et al.*, 1951). Extensive tissue damage was noted by Huff (1942) in the spleens and hearts of ducks carrying megaloschizonts. O'Roke (1930), Chernin and Sadun (1949), and Chernin (1952a) have noted that the greatest number of infections in Northern Michigan is coincident with the hottest part of the summer and occurs mostly in July.

O'Roke (1934) and Huff (1942) both observed that the gametocytes decrease in number in the blood until in midwinter they had either disappeared or become scarce, and that they reappeared in the spring. The sporadic occurrence of parasites in the blood during the entire winter, however sparse they may be, indicates that sporogony is proceeding at a low level. After a three-year investigation of the spring relapse phenomenon, Chernin (1952b) concluded that it was associated with the onset of renewed reproductive activity in both sexes of the avian host. Female ducks subjected to increased hours of artificial light per day in the fall and winter not only commenced egg laying earlier, but experienced earlier onset of the relapse parasitemia.

L. smithi Laveran and Lucet, 1905, was first seen in turkeys in eastern United States by Theobald Smith (1895), after whom it is named. It has been reported by Volkmar (1929) as occurring in North Dakota and Minnesota, by Skidmore (1932) in Nebraska, by Johnson (1942, 1945) in Virginia, and Hinshaw and McNeil (1943) in California. Other reports indicate its presence in France, Germany, Crimea, and Canada. The parasite in general resembles *L. simondi* of Anseriformes, but turkeys are probably not susceptible to the latter (Fallis *et al.*, 1954; Byrd, 1959). Terrific losses have been experienced among poults, and even adults, e. g., Stoddard *et al.* (1952) reported an outbreak in Georgia wherein a grower suffered a 75 per cent loss in a flock of 1600 five-month-old turkeys presumably due to Leucocytozoon disease. Flies of the genus *Simulium* were observed in the vicinity of roosts and feeding troughs. The widespread occurrence of the parasite in certain areas is emphasized by the survey of Travis *et al.* (1939) on adult domesticated turkeys during which 289 of 357 were found infected in Georgia, 60 of 67 in Florida, 4 of 12 in Alabama, and 7 of 9 in South Carolina. Mosby and Handley (1943) reported the parasite in 40 per cent of 268 turkeys in Virginia, of which 40 were domestic, 183 were captivity-reared wild turkeys, and 45 were wild. Others who have reported Leucocytozoon in captive wild turkeys are Johnson *et al.* (1938), Wehr and Coburn (1943), and Travis *et al.* (1939), while Kozicky (1948) found it in all of 5 native wild turkeys taken in the field in Pennsylvania.

Byrd (1959), who studied Leucocytozoon in pen-raised and free-ranging wild turkeys in the Cumberland State Forest of Virginia, reported incidences of almost 100 per cent among mature birds maintained in large, open pens in the spring. However, he observed, "Heavy infections, comparable to those reported for *L. simondi* in ducks, do not seem to occur," and "Few symptoms were observed in wild turkeys that could be attributed to the disease." He attempts to relate this lack of pathogenicity to local factors, such as the time at which suitable vectors were prevalent, and the age of the

birds at first exposure. With regard to the vector, Byrd observed, "The period of infection for the disease on the Cumberland forest is such that *P. [Prosimulium] hirtipes* appears to be the only species responsible for its transmission." Byrd considers the possibility, also, that wild turkeys may "have developed some degree of natural resistance to the disease" (leucocytozoonosis).

Skidmore considered *Simulium occidentale* to be the vector concerned in a Nebraska outbreak of leucocytozoonosis in domestic turkeys, while Johnson (1938) found *S. nigroparvum* to be the vector in Virginia. Wehr (1962) studying outbreaks of Leucocytozoon infection in domestic turkeys in South Carolina, transmitted the parasite experimentally by intramuscular injections of suspensions of ground blackflies, *Simulium slossonae*. He cites communications with others working in the same region who also found this species of blackfly to transmit the disease. Wehr, studying schizogony in the domestic turkey, found indications that the life cycle of *L. smithi* may differ in some details from that of *L. simondi* in ducks. These observations were in agreement with those of some earlier workers, such as Richey and Ware (1955) and Newberne (1955).

The single instance in which Leucocytozoon has been reported from chickens in North America (Atchley, 1951) gives no indication of the pathogenicity of the parasite in this host. Levine (1961), who regards Atchley's organism as having probably been *L. caulleri*, concludes, "This species is presumably pathogenic, but accounts of it have been so mixed up with those of *L. sabrazesi* (a species thus far known only from southeast Asia) "that its pathogenicity is uncertain."

L. sabrazesi Mathis and Leger, 1910, was frequently found by its describers in chickens in Tonkin. Kuppusamy (1936) considers it a pathogen of *economic* importance in Malay. The gametocytes in the blood, like *L. simondi*, are enveloped in elongate spindle-shaped host cells, pointed at both ends. *L. schüffneri* Prowazek, 1912,

from domestic fowl in Sumatra, may be a synonym. *L. caulleryi* Mathis and Leger, 1909, was also observed in the blood of chickens in Tonkin. The gametocytes were enveloped in round host cells which, when the parasites were mature, were frequently without nuclei.

L. andrewsi is a species with rounded gametocytes described by Atchley (1951), who found it in 15.3 per cent of 400 chickens examined in South Carolina. This parasite may be synonymous with *L. caulleryi*, but the describer considered the regular presence of the nucleus in the host cell sufficient basis for the creation of the new species.

L. mansoni Sambon, 1908, from the Swedish capercaillie *(Tetrao urogallus)* has been the subject of an intensive investigation by Borg (1953), whose results led him to conclude that this and similar parasites occurring in Swedish forest game birds have no significant role in the widespread mortality in their hosts (capercaillie, black grouse, hazel grouse). Gametocytes were of three types — round, oval, and elongated. The host cells of the latter two types had tails at the two extremities unless they were worn off.

Treatment. Drug treatment has been reviewed by O'Roke (1934) and Coatney and West (1937). Pamakin (plasmochin) proved unsatisfactory, but quinine showed promise if fed for a time before adult gametocytes showed in the blood, but did not affect adult gametocytes. Coatney found that atabrin did attack the adult gametocytes. On the other hand, Fallis (1948) had no success in curing or suppressing infections of *L. simondi* in ducks with paludrine, atabrin, or sulfamerazine. He was inclined to blame the resistance of the tissue stages for the failure.

Control. Control is only to be attained through management. This means, principally, that duck and turkey culture should not be attempted in regions where there is running water serving as breeding places for an abundance of black flies (Simulium). Otherwise, it is necessary to screen the young ducks from the flies,

which is difficult. Removing parasitized young and adult birds from the flock would also prove helpful in some instances. Since the young are more susceptible to the disease than the adults, it would help also to control the disease if ducklings were hatched either before or after the main black fly season (see O'Roke, 1934).

Anthony and Richey (1958) attempted to control outbreaks of *L. smithi* in domestic turkeys in South Carolina by spraying the breeding grounds of the black flies with DDT. This was very effective for two weeks and moderately so for another two weeks. After that, near drought conditions developed, so black fly control actually averaged almost 95 per cent effective over a 10-week period. Nevertheless, poults placed on range four weeks after the application of DDT to the black fly breeding grounds started showing Leucocytozoon disease within two weeks of release. Within another 4 weeks, 80 to 100 per cent of the birds were infected. Anthony and Richey suggested that other diptera may have been responsible for the transmission of the disease.

TOXOPLASMA INFECTIONS

Toxoplasmosis is an infection of mammals and birds with *Toxoplasma gondii* Nicolle and Manceaux, 1909, whose type host is the rodent *Ctenodactylus gundi*, the gundi of North Africa. This microorganism is known to occur naturally in at least 24 genera of mammals belonging to 7 orders and a number of species of birds of several orders (Manwell and Drobeck, 1953a), and, perhaps, in certain reptiles also (Fig. 37.6). Some of these hosts (Jacobs, 1956) are moles, gundis, guinea pigs, mice (but laboratory strains do not ordinarily harbor the organism), rats, rabbits and hares, dogs, foxes, cats, swine, sheep, cattle, baboons, chimpanzees, monkeys, man, pigeons, and chickens. Capercaillie,

black grouse, hazel grouse (Borg, 1953), crows (Finlay and Manwell, 1956), and barnyard geese (Biering-Sorensen [1957] dye test) may be added to this list. Interest in the parasite increased sharply about 1939 when its importance in man became evident. Thereafter interest in toxoplasmosis in all animals burgeoned, partly because of its potentially serious and multifarious effects on human beings and the epidemiological community of interest people share with animals in its dissemination, and partly because of its actual or potential role in causing losses among livestock. Expanding interest reflected in publications on the subject required 2,000 titles by 1956 (Hoare), most of which are listed in two bibliographies (Eyles and Frenkel, 1952, 1954). (See also Markham, 1956.)
FIG. 37.6 -- 1, 2--Toxoplasma bodies in lymphoid cells of a ground squirrel. 3--Free Toxoplasma in same host, individual on left in division. 4--Toxoplasma in cytoplasm of nerve cell of rabbit. (1-3, after Sossuchin; 4, after Levaditi et coll.)

Present interest is restricted to avian toxoplasmosis, but more general information is available in reviews by Hoare (1956), Jacobs (1953), Manwell and Drobeck (1953a, b), Brooke (1955), and the 1956 symposium papers (in order) by Markham, Jacobs, Feldman and Miller, Siim, Eichenwald, Frenkel, and Eyles.

The taxonomic position of Toxoplasma remains uncertain. Wenyon (1926) placed it among organisms of doubtful nature, perhaps not protozoal at all. Manwell and Drobeck (1953a) and Ludvík (1956) have indicated ways in which it resembles Sarcocystis. Goldman et al. (1957) have pointed out structural similarities in Toxoplasma gondii and Besnoitia jellisoni, although they found these two organisms to be serologically distinct. Levine (1961) considered Toxoplasma as belonging to the same order as Sarcocystis, but separated the two at the family level, placing Toxoplasma in the same family as Besnoitia and Encephalitozoon. Westphal (1954) regarded Toxoplasma as a nonflagellated, kinetoplast-free leishmanial type, and suggested that it is a member of the Trypanosomidae, but this view has apparently received little support.

The trophozoite of Toxoplasma is a crescentic body, less rounded at one end than the other, measuring 4μ-7μ in length and 2μ-4μ in width. The nucleus is nearest the thicker end. An electron microscope

study (Gustafson et al., 1954) has revealed a small hollow cone at the more tapering end, and, radiating from the cone's base toward the thicker end, 14 to 16 homogenous fibrils. The toxoplasm is capable of several types of movement of translation (Manwell and Drobeck, 1953a). Reproduction is principally by binary fission of this stage inside a vacuole in one of a considerable variety of host cells — macrophages, lymphocytes, parenchymal cells of liver, adrenals, lungs and brain, microglia, neuroglia, etc. A form of internal budding (endodyogeny) was described by Goldman et al. (1958), and this was in part confirmed by Gangi and Manwell (1961). However, the latter investigators did not see all stages characteristic of endodyogeny, and they made the interesting observation, "the inability to demonstrate cytochemically DNA in the parasites stained with silver protein suggests that morphologic structures seen in endodyogeny are not primarily involved with the distribution of gametic material." Repeated binary fissions result in an accumulation of toxoplasms, which has been called a terminal colony, occupying the greater part of the host cell. The members of the colony are released by rupture of the cell and invade other cells. Certain workers, apparently with good evidence, insist that schizogony also occurs but that it is unusual (see Pereira de Castro, 1955). In the chronic or

latent infection a cystlike stage is characteristic and predominant. It is a round or oval agglomeration of toxoplasma, usually found in the brain, measuring $14.5\mu–37.7\mu$ across and enclosed by a wall of sufficient tenacity to hold the structure together when the surrounding tissue is disintegrated by shaking with glass beads (Rodhain, 1950). Jacobs et al. (1960) reviewed the recent literature dealing with these cystlike bodies and concluded that they may properly be called "cysts" rather than "pseudocysts," as some have suggested. They also demonstrated that the cyst wall was destroyed immediately on contact with a peptic digest solution heated to 37° C., and that the toxoplasmas so liberated remained infective for mice after exposure to the pepsin·HCl solution $1\frac{1}{2}$ to 2 hours, but not after exposures of 3 hours or more. The cyst wall was digested in 1 per cent trypsin, also, and toxoplasmas remained viable in this solution after 6 hours. Proliferative toxoplasmas did not withstand the action of artificial gastric juice for even very brief intervals.

The manner in which toxoplasmosis is spread is unknown. Congenital transmission has positively been established in such mammals as human beings (Feldman and Miller, 1956), dogs (Koestner and Cole, 1960), pigs, and cattle. Presumably in such cases the mother was experiencing an acute attack, either the primary one or an exacerbation of a chronic infection. The possibility of filth transmission exists because the parasites have been found in the feces, urine, and other bodily eliminations of infected animals, though corroborative experimental evidence of it is mostly lacking. The organisms have been found in cow's milk. The ingestion of infested flesh is another likely possibility, particularly the flesh of chronic cases where pseudocysts are present. The susceptibility of the parasites to drying, freezing, moderate heat, gastric juice, and even under ordinary conditions to such fluids as physiological salt solution and culture media outside the animal body militates against the contact or filth-borne hypothesis, but does not al-together exclude it. Venereal transmission is another possibility, but again corroboration is lacking.

Transmission by blood-sucking arthropods such as ticks, mites, mosquitoes, fleas, and lice has been suggested and deserves a certain degree of plausibility because of the occurrence of the parasites in the circulating blood, usually inside monocytes. Wolfson (1941) worked with a strain which she obtained from a worker who had first observed it in a guinea pig which had been "injected with some ticks." A limited number of successful experimental transmissions with certain ticks and a species of louse lend further credence to the hypothesis (Woke et al., 1953).

The first report of spontaneous toxoplasmosis in chickens was that by the German veterinarian Hepding (1939), who found the organisms, which he considered secondary invaders, in the retina of a hen with neurolymphomatosis. Other early observers are mentioned by Erichsen and Harboe (1953a). The latter workers studied an outbreak with some fatal illnesses in a small flock of White Leghorns in southern Norway. The outstanding symptoms of the sick birds were anorexia, emaciation, paleness and shrinking of the comb, and, in some instances, diarrhea and blindness. Nine birds from the flock were necropsied and of these Toxoplasma was observed in sections of the organs of five, but not in the eye despite the diffuse chorioiditis. In an important later study by the same authors, two experimentally infected birds and one naturally infected bird were found to have developed multiple gliomas in their brains. Intracerebral or intraperitoneal injections of suspensions of tissue from three birds resulted in Toxoplasma infection in three mice. The most outstanding lesions were focal and diffuse pericarditis, myocarditis, necrotizing encephalitis, necrotic hepatitis, and ulcerative gastroenteritis. The dye tests were either negative or feebly positive.

A rapidly developing outbreak (in Brazil), in which the total mortality was 50 per cent and almost the entire flock was

affected, was reported by Nobrega et al. (1955). Symptoms were similar to those of coccidiosis except that the stools were whitish. Outstanding necropsy findings were enlarged liver and spleen with necrotic foci, heart pale with yellowish-white nodules of various sizes, and lungs with extensive areas of congestion and consolidation. Toxoplasma was observed in 10 of 15 chicks examined, both in smears of lungs, liver, and spleen stained with Giemsa and in tissue sections of spleen, heart, and lungs, but with one exception not in the central nervous system. The parasite was demonstrated in mice four to six months after intracerebral inoculation with organ suspensions.

Biering-Sorensen (1956) in Denmark diagnosed toxoplasmosis in 35 hens from 21 flocks out of 26,000 fowls necropsied. Of these, 11 showed necrosis of the optic chiasma. In an epidemiological study of an area where toxoplasmosis had been found in fowls, the same author (1957) found 15 of 57 hens, all of 6 human beings, 4 of 22 geese, 2 of 6 horses and 7 of 8 pigs positive to the dye test. Furthermore, mouse inoculation tests showed 8 fowls to be harboring the parasite. Pseudocysts were demonstrated in 8 fowls.

A number of workers have reported the natural occurrence of toxoplasmosis in the common pigeon (Carini, 1911; Reis, Nobrega, and Reis, 1936; Nobrega and Reis, 1942; Springer, 1942; Johnson, 1944; Feldman and Sabin, 1949; Wiktor, 1950; Manwell and Drobeck, 1951; Jacobs et al., 1952). The last-named authors found positive evidence of toxoplasma infection in 10 of 80 pigeons trapped in Washington, D.C. In a study of experimental toxoplasmosis in pigeons, Jacobs et al. (1953) demonstrated that antibody persists in the blood of birds infected with strains of low virulence for shorter periods of time than in birds infected with a strain of high virulence.

Diagnosis. (See Brooke, 1955; Eichenwald, 1956; Jacobs et al., 1952, 1953; Westphal, 1949; Westphal and Palm, 1953, 1954.) According to Sabin (1939), the

capacity to multiply and produce disease in a variety of hosts, including mammals and birds, is to be regarded as the chief taxonomic characteristic of Toxoplasma. Morphology as the only guide may be confusing (see also Wolfson, 1940). For these reasons, intracerebral (0.03 ml.) and intraperitoneal (0.1 ml.) injections of body fluids and suspensions of tissues (brain, liver, lungs, spleen, etc.) of suspect hosts into laboratory mice, hamsters, guinea pigs, or young chicks, and subsequent microscopic examinations of both fresh and stained smears of the inoculated hosts, is depended upon both for confirmation of positive microscopic diagnosis and for revealing the presence of the etiological agent in cases where the microscopic examination is negative. Of course, the actual demonstration of the parasite in the original case is in itself a valuable diagnostic accomplishment. Positive animal transmission adds much to the reliability of the diagnosis. When ascites or other symptoms of illness develop in the experimental host, the peritoneal fluid and smears of brain, liver, lungs, spleen, etc., should be examined for the parasite. If no parasites are found, or if the inoculated animals do not show symptoms in 7 or 8 days, blind passages should be made from the inoculated animals to another series. With chickens and pigeons, a large number of blind subpassages in laboratory mice may be required before the parasite can be observed microscopically, or it may not be demonstrated at all.

Direct impression smears of tissues or smears of peritoneal fluid stained in Giemsa, or tissue sections of brain, lung, liver, spleen, lymph nodes, eye, etc., often serve for the direct microscopic observation of Toxoplasma when the oil-immersion lens is employed. Rarely, the parasites are seen in blood smears, inside monocytes, or free.

There are at least four serological tests: the rabbit skin neutralization test, the complement-fixation test, the skin test, and Sabin and Feldman's (1948) alkaline methylene blue dye test, simply called the

dye test. The latter is the most practical under a variety of conditions. Unfortunately, infected chickens often respond but weakly to the dye test, but pigeons perform better, except in infections of long standing.

Symptomatology and necropsy findings alone are not sufficiently reliable to be depended upon for final diagnosis.

Cultivation. Cook and Jacobs (1958) tabulated the history of *in vitro* cultivation of Toxoplasma. Kaufman and Maloney (1962) studied the organism's multiplication in tissue culture, and suggested that certain relationships may exist between the rate of multiplication of a strain of Toxo-

plasma and its susceptibility to antimetabolic drugs such as pyrimethamine and the sulfonamides.

Treatment. (See Eyles, 1956.) Both sulfonamides (especially sulfadiazine, sulfamethazine, sulfamerazine, and sulfapyrazine) and the 2,4-diamino pyrimidines (especially pyrimethamine = Daraprim) have been shown to be effective in treating mouse and human infection. Eyles and Coleman (1953) discovered that Daraprim and sulfonamides act synergistically, so that it was possible to obtain chemotherapeutic effect with much lower combined dosages than with the two drugs separately.

HAEMOPROTEUS INFECTIONS

The genus Haemoproteus belongs to the family Haemoproteidae which is fundamentally like the family Plasmodiidae, to which the true malaria parasites belong, except that schizogony occurs in endothelial cells of internal organs rather than in circulating blood cells. Ordinarily it is impossible to transfer the infection by inoculation of infected blood, as can be done with the true malarias. (Cf. Lastra and Coatney, 1950.) Haemoproteus differs from Leucocytozoon in two important respects: (1) while in both genera the mature gametocytes are the stages generally occurring in the circulating blood, those of Haemoproteus occupy erythrocytes and those of Leucocytozoon, supposedly, only white cells, such as monocytes or macrophages; (2) true malarial pigment is produced in the gametocytes of Haemoproteus, while the pigmentlike granules of Leucocytozoon, if any, disappear from specimens on stained slides after washing in dilute acetic acid and ammonia. The life cycle in general parallels that of Plasmodium and Leucocytozoon, but the intermediate hosts of Haemoproteus species are usually hippoboscid flies, commonly called louse flies, though Fallis and Wood (1957) have shown that an orthorrhaphous insect, a biting midge, *Culicoides* sp., is a suitable intermediate host and transmitting agent of *H. nettionis* of ducks. Coatney (1936) published a check list and host index of the genus Haemoproteus in which appear 45 specific names, most of which are described from birds. The genus occurs widely in passerine birds, owls, flickers, woodpeckers, ducks, and other types of birds, and in certain reptiles as well. Herman (1938a) found 50 per cent of the chipping sparrows on Cape Cod infected.

Haemoproteus lophortyx O'Roke, 1929, is a pathogenic parasite of California valley quail (see O'Roke, 1930, and Herman and Glading, 1942). It is doubtful if this bird ever completely recovers once it has become infected (Herman and Bischoff, 1949). The vectors are louse flies *Lynchia hirsuta* (cf. O'Roke, 1930) and *Stilbometopa impressa* (cf. Herman and Bischoff, 1949).

Other species of quail have also been found infected, as follows: in California, San Quentin quail, Cambel's quail, and mountain quail (see Wood and Herman, 1943); in New Mexico and Arizona, Cambel's quail and scaled quail; in District of Columbia and vicinity, the bobwhite (Campbell and Lee, 1953; Hungerford, 1955).

H. nettionis Cleland and Johnston, 1909, has for its type host the Australian teal, *Anas* (= *Nettion*) *castaneum*. Herman (1954), in a critical review, suggests that this is the correct name for the *Haemoproteus* of Anatidae, and assigns *H. anatis* Haiba, 1946, and *H. hermani* Haiba, 1948, to synonymy. The gametocytes do not affect the size of infected cell, but may push the nucleus aside. The following are some of the other known hosts: Indian runner duck, common tame duck (White Pekin) (Chernin and Sadun, 1949), white

Chinese goose, Canada goose, whistling swan, mallard, black duck, green-winged teal, blue-winged teal, cotton tast, shoveller, American pintal, wood duck, baldpate, common goldeneye, ring-necked duck, and common merganser. (See Herman, 1951, 1951; Wood and Herman, 1913; Wetmore, 1911; Levine and Hanson, 1953; Fallis and Wood, 1957.) The vector in certain parts of North America is probably a species of *Culicoides*, since Fallis and Wood have shown that biting midges of this genus occur in areas where the parasite occurs in ducks, will feed on ducks, are suitable hosts for the parasite, and, when infected specimens are ground up and injected into clean ducks, carry the sporozoites capable of producing the infection with an incubation period of 14 to 21 days. The infection appears to be well tolerated by its hosts.

H. danilewskyi Kruse, 1890, whose type host is the gray crow and has been found in various types of birds, was merely recorded as occurring in the Red Jungle Fowl of Malay (*Gallus gallus*) by Plimmer (1913). The bird had been kept in a London zoo.

H columbae Kruse, 1890, from the common pigeon (Fig. 37.7) and *H. maccallumi* Novy and MacNeal, 1905, from the mourning dove seem to be morphologically identical. Besides, the parasite from both hosts has been transferred to the pigeon by means of the blood-sucking intermediate host, *Pseudolynchia canariensis* (= *Lynchia maura* = *P. maura*) by Huff (1932). Since it was the first of the genus to have its life cycle in the pigeon and louse fly completely outlined, accounts of it appear in standard works on protozoology such as Wenyon (1926) and Kudo (1954). *Microlynchia pusilla* in South America and *Ornithomyia avicularia* in England are two other louse flies suspected of being vectors (cf. Baker, 1957). Although schizogony does not take place in the peripheral blood, Lastra and Coatney (1950) showed that it is possible to transfer the infection by direct injection of considerable quantities of blood or transplan-

tation of tissues from donor pigeons taken early in the course of its infection. The infection occurs in pigeons widely throughout the tropical and subtropical regions and in the temperate zones wherever the insect vector can survive, but only sporadically in a climate such as prevails in Iowa where the vector ordinarily dies out in the winter if introduced by chance during the spring or summer (Drake and Jones, 1930). In England it occurs in wood pigeons (Baker 1957). Becker (1959) reported that he frequently found gametocytes of *H. columbae* in the blood of adult and nestling mourning doves in Iowa, but never observed louse flies on these birds (cf. Hanson *et al.*, 1957, in Illinois). Wood and Herman (1913) record it in the western mourning dove, western white-winged dove, and band-tailed pigeon. Levine and Kantor (1959) tabulated reports of *Haemoproteus*, judged to be *H. columbae*, from 45 species of columbiform birds. This parasite is not a severe pathogen, although Coatney (1933) observed one bird with a heavy infection whose behavior was for a while definitely abnormal.

H. sacharovi Novy and MacNeal, 1904.

is one of the numerous species of Haemoproteus, described from various wild birds, that should be mentioned because, while normally a parasite of mourning doves, it occurs at times in the common pigeon (see Coatney and West, 1940; Becker *et al.*, 1956). Other known hosts are the western mourning dove and the western white-winged dove. The oval or round gametocytes, unlike those of most other species of Haemoproteus, enlarge their host cells, erythrocytes, about 1.3 times in width and 1.4 times in length, and push the nucleus to one side, although it sometimes surrounds it. The amount of pigment is small. The known bird hosts are the eastern mourning dove, the western mourning dove, and the western white-winged dove (see Wood and Herman, 1943; Herman, 1944). Huff (1932) transferred this species from the dove to a pigeon using the louse fly, *Pseudolynchia canariensis*, for the vector. However, as he points out in a later publication (1963), "demonstration of one means of transmission has often been followed by the *only* means," and he then cites instances to show how such assumptions may retard research. As Levine (1961) observes, the natural vector of *H. sacharovi* is unknown; the *Culicoides* is a possibility.

Haemoproteus meleagridis Levine, 1961. Wetmore, 1941, seems to have been the first to record Haemoproteus as a parasite of domestic turkeys (from District of Columbia and vicinity). Morehouse (1945)

next observed the gametocytes of Haemoproteus in the blood of a turkey sent from Texas. The infection was a heavy one in an anemic bird from a flock that "seemed to have a good appetite, but just wasted away." The parasite was also observed by Kozicky (1948) in a native wild gobbler and four wild turkey hens reared in captivity—a total of five out of 97 blood smears of wild turkeys collected in 1947. Goldsby (1951) reported the occurrence of Haemoproteus in a flock of turkeys in North Dakota. Three out of ten turkeys examined in South Carolina by Atchley (1951) harbored the parasite. Bierer *et al.* (1959), also working in South Carolina, found a "Haemoproteuslike" organism in 22 of 52 domestic turkeys. Two of the birds were heavily parasitized, and were obviously ill. These workers suggested that wild turkeys might have been the source of infection. Love *et al.* (1953) found Haemoproteus in 1 of 2 wild turkeys taken in Georgia. Morehouse's figures indicate little or no enlargement of the infected erythrocyte, and the position of the cell nucleus seems to be altered in some but not in others.

Treatment. Atabrin and pamakin (plasmochin), according to Coatney (1935), affect *Haemoproteus columbae* infection. Atabrin inhibits the development of young gametocytes, while pamakin (plasmochin) does not. The latter is parasiticidal to adult gametocytes, however; neither seems to affect the schizonts.

PLASMODIUM INFECTIONS

The true malarial organisms belong to the genus Plasmodium, which in turn is closely related to Haemoproteus and Leu- cocytozoon. The principal significant difference between Plasmodium and the other two genera is that the asexual stages (schizonts) of the former occur in erythro-

cytes of the circulating blood, while those of the two latter occur in the internal organs (lung, liver, spleen, kidney, etc.). As a result, Plasmodium can be transmitted regularly from one susceptible host to another by injection of infected blood from the vessels or heart, while in the case of the other two this procedure will result in infection only at certain times when merozoites are in the blood by chance, because the only stages ordinarily in the blood are gametocytes which continue development in the proper invertebrate host. Like Haemoproteus, Plasmodium contains pigment. The life cycle, as is well known, involves two hosts: an intermediate host, a vertebrate, in which asexual multiplication (schizogony) and the formation of immature sexual forms (gametocytes) occur, and a definitive host, presumably always a mosquito, in which maturation of the gametes, fertilization, and sporogony take place. It is of special interest that mammalian malarias are carried by Anopheles mosquitoes, while those of birds are carried by culicine (Culex, Aedes) mosquitoes, although some of the latter have also anopheline vectors.

The story of the development of Plasmodium in vertebrates from sporozoite, the stage introduced by the mosquito while biting, to the earliest stages observed in erythrocytes, was the contribution resulting from the brilliant researches of a number of investigators, among them Huff and Coulston (1944). The sporozoite of *P. gallinaceum* enters a "lymphoid macrophage" cell to develop in about 42 hours into a "cryptozoite," or a schizont undergoing schizogony. The merozoites of this generation enter other similar cells to repeat schizogony in another 40 hours (the "metacryptozoites"). Blood infections then ensue, presumably from the merozoites from the fixed tissue stages. Subsequent development of Plasmodium within the vertebrate host usually follows the general course outlined below.

The parasite as first seen in the red blood cells in films treated with a Romanowsky stain may have the appearance of a signet ring. The center of the parasite is occupied by a vacuole, which does not stain. The surrounding cytoplasm, which stains blue, therefore appears as a ring. The nucleus, also located peripherally, stains red. The signet ring effect is observed when this stage, now called a trophozoite, is viewed at right angles to the plane containing the nucleus. The trophozoite grows at the expense of the red cell, actually engulfing hemoglobin which, when digested, leaves a residue of pigment. Eventually the chromatin material divides, followed by division of the cytoplasm, and the segmenting schizont gives rise to merozoites. The number of merozoites formed depends upon the species, as does the time required for their development, at least under fixed conditions. The schizonts of different cells usually mature at about the same time, so large numbers of red blood cells may be destroyed in a short time, resulting in the liberation of toxic products, as well as merozoites. The merozoites so liberated now enter other red cells, and repeat the asexual cycle until some develop into sexual forms, microgametes and macrogametes, also within red blood cells. These sexual cells undergo no further development until taken up by a mosquito. The gametes and the schizonts, both in the peripheral blood, may be sufficiently characteristic for a given species of Plasmodium to make specific identification possible.

More than 30 species of Plasmodium have been described from birds of various kinds (see Hewitt, 1940), but fewer than half are presently regarded as valid (see Levine, 1961; Bray, 1957; Laird and Lari, 1958). The volume of literature on avian malaria is immense, many of the contributions having dealt with drug screening and other studies related to malaricidal properties of various drugs. There are also a great many contributions on other aspects of experimental research, such as studies on immunity, genetics, *in vitro* cultivation, interrelationship with other infections, and basic physiology and biochemistry. A brief but excellent review of representative contributions to these and other fields of ex-

perimental research on avian malaria has been presented by Huff (1963). He was, however, obliged to restrict his coverage largely to the period 1955–1962. Nevertheless, the papers cited by Huff, together with the references cited therein, will lead the interested investigator to the literature on almost any aspect of avian malaria with little difficulty.

The following more or less general papers and their bibliographies are also commended to the interested reader: Coatney and Roudabush (1937), Coatney and West (1938), Herman (1938, 1944), Herman et al. (1954), Hewitt (1940), Huff (1932, 1935a, 1939), Kikuth (1931), Levine and Hanson (1953), Manwell (1935, 1938), Sergent et al. (1931), and Wolfson (1941).

Most of the avian species of Plasmodium are far less host specific than are some of the better known mammalian forms. Some occur naturally in a considerable number of species of wild birds, and some have been adapted by experimental passage to develop in birds in which they are not known to occur naturally. Only a few species have been reported as responsible for natural infections in domestic birds, and it is by no means certain that all of these are of veterinary importance. Some are at least of potential importance, and these species will be discussed briefly.

Before doing so, however, it should be noted that naturally occurring Plasmodium infections have been found in chickens in the United States for the first time (Krishnamurti et al., 1962), and that the organism did not correspond exactly to any thus far reported as occurring naturally in the domestic fowl. The authors compare their organism to P. gallinaceum, but do not identify it specifically as such.

Plasmodium gallinaceum Brumpt, 1935. The British veterinarian M. Crawford, while stationed in Ceylon, announced in the official 1933 report to his government that cases of bird malaria had developed on that island in chickens recently imported from England, and he described the symptoms and advocated quinine for treatment. He assigned the microorganism to "Plasmodium praecox." Later, Crawford (1915) carefully narrated the history of the parasite and the manner in which it became available as a satisfactory laboratory subject in the war program for obtaining new and better antimalarial drugs. Also, he acknowledged the correct name to be P. gallinaceum, described by Brumpt in 1935 from a blood smear presented to him in 1910 by a Dr. Broussais who had seen the malarial organism in fowls in Indo-China. Brumpt stated that from 1935 to 1948 more than 600 publications on P. gallinaceum had enriched practical and theoretical knowledge concerning malaria, and many more papers have appeared since 1948.

Crawford considered jungle fowls to be the natural hosts—Gallus lafayetti in Ceylon, G. bankiva in India, and G. sonnerati in Sumatra. (Brumpt, however, believed the native host to be a still undetected wild bird.) These native fowl (Gallus) are quite resistant to the infection, but when imported breeds are introduced into areas where the wild fowl are infected, they suffer intense infections which generally lead to death after a brief illness. Birds may at times develop paralysis and die after drug treatment owing to blocking of brain capillaries with the large nonpigmented exoerythrocytic stages of the parasite discovered by James and Tate (1937, 1938). Because he believed the chicken not susceptible to known avian malarias (see, however, Manwell, 1933), Brumpt felt confident he was dealing with a new species. Ducks, guinea fowl, pigeons, turtle doves, quail, buzzards, canaries, sparrows, calfats, and finches were later shown by him to be resistant to P. gallinaceum, while chickens of various breeds, geese, pheasants, partridges, and peacocks were susceptible. The infection assumed a more acute form in young chicks and a more chronic course in the adult birds (see also Coggeshall, 1938).

Since Crawford's (1915) summary, Haiba (1948) reported the parasite in the blood of a dead chicken in Egypt, but its occurrence in that country requires con-
FIG. 37.8 — Plasmodium gallinaceum. A and B—group of erythrocytes showing alterations in the chromatin of the infected cells. 1—12—simple or multiple infections of the erythrocytes by trophozoites and schizonts in different stages of development; 13, 14, 10, 11, and 12 represent the formation of merozoites; 13, 14, and 15, male gametocytes; 16, 17, and 18, female gametocytes; 18, female gametocyte in an enucleated erythrocyte. (Note: The solid black bodies are the nuclei of the erythrocytes.) (After Brumpt, 1935.)

firmation. Occurrence of two naturally acquired infections in exotic fowl at the Izatnagar (India) Poultry Farm was first noted by Rao et al. (1951), and later Das et al. (1952). The symptoms, postmortem lesions and histopathology observed in fowls infected by direct blood inoculation are described in considerable detail. Kranceveld and Mansjoer (1953) found the parasite in West Java, and submitted authority for its occurrence also in Sumatra, Java, and the Celebes.

Beltran (1941a) published a summary of the state of our knowledge concerning this species up to that year, but much information has been added since. Jacobi (1939) has studied the pathology of P. gallinaceum infection. The discovery of an exoecythrocytic phase, i.e., an asexual developmental cycle in endothelial cells or reticuloendothelial cells of spleen, brain, liver, etc., by James and Tate (1938) and James (1939), has attracted a great deal of attention, because it was formerly believed that the increment of malaria parasites in the vertebrate host occurred entirely within erythrocytes. For morphological and other details the reader should consult Brumpt's papers. The exoerythrocytic stages preceding the erythrocytic stages described by Huff and Coulston (1944) have been mentioned above.

The natural vectors, of course, are not known, but some prominently mentioned potential mosquito vectors are *Aedes aegypti, A. albopictus, A. geniculatus,* and *Culex quinquefasciatus* (see Brumpt, 1936a, b; Vargas and Beltran, 1941). Huff (1954) has listed 29 susceptible species and one questionable belonging to various genera as follows: Anopheles, 1; Culiseta, 1; Mansonia, 1; Aedes, 19; Armigeres, 5; Culex, 2 proved, 1 questionable (*quinquefasciatus*). Beltran and Larenas (1911) have also demonstrated its transmission by the oral route.

Plasmodium juxtanucleare Versiani and Furtado Gomes, 1941, occurs chiefly in chickens. It has been recorded only from South America and from the State of Chiapas, Mexico (Beltran, 1941b). The parasites tend to lie in contact with the host cell nucleus and distort the cell. There are about four merozoites. The cycle is about 24 hours, and this parasite is said to be a severe pathogen. It does not grow in canaries.

Plasmodium durae Herman, 1941. This species was found in a blood smear of one out of 75 domestic turkeys examined in Kenya Colony, British East Africa It was capable of afflicting young turkeys fatally.

Plasmodium cathemerium Hartman, 1927, the type host of which is the English sparrow, resembles *P. relictum* in that it occurs commonly in passerine birds, causes the nucleus of the infected cell to be displaced more or less toward one pole or expelled, and has roundish gametocytes; but it differs from that species in that the pigment grains in the gametocytes are relatively coarse and rodlike. An outbreak of *P. cathemerium* malaria in California that cost a canary raiser possibly 165 out of 700 of these birds was reported by Mathey (1955b). The sick birds exhibited swelling in the region of the eyes. The characteristic parasites were found in blood smears. Necropsy disclosed subcutaneous hemorrhage, splenomegaly and hepatomegaly. Sick birds responded to atabrin. Herman and Vail (1942) reported

a fatal case of spontaneous malaria in a canary from Temple City, California. Hewitt (1939) made a special study of splenic enlargement and infarction in infected canaries.

Plasmodium relictum Crassi and Feletti, 1891. *P. relictum,* of which *P. praecox* is a synonym, is a species occurring in many species of wild birds, among them the eastern (Coatney, 1938) and western mourning doves (Herman *et al.,* 1954) and certain wild waterfowl such as the pintail, cinnamon teal (Herman, 1951), wood duck (Mielcarek, 1954), and American coot (Roudabush, 1912). Coatney (1938) obtained identical strains from the wild mourning dove and common pigeon. The strain was extremely pathogenic in pigeons, but in doves and canaries the infections were light and transitory. When transferred to chicks, the infections lasted 6 to 11 days. The first observers of naturally occurring *P. relictum* in pigeons, however, were Sergent and Sergent (1904), working in Algeria. Others were as follows: Pelaez *et al.* (1951), in Mexico; Mathey (1955a), in California; and Becker *et al.* (1956), in Iowa. Mathey observed three infected pigeons, at least two of which succumbed to malaria. He also succeeded in infecting the chick and the canary with parasites from the pigeon. This species resembles *P. cathemerium* morphologically, but its pigment grains are roundish instead of elongate. Some strains of it, like *P. cathemerium,* have diurnal periodicity. The infection responds readily to treatment with quinine or atabrin. Wolfson (1938) also obtained infections in ducks with two other strains of *P. relictum.* Hill (1942) has proved rather conclusively that anemia may be regarded as the cause of death of pigeons in *P. relictum* infections.

Plasmodium circumflexum Kikuth, 1931, has for its type host a German thrush (*Turdus pilaris*). Its morphological characteristics are as follows: all stages occurring in the circulating blood; elongate gametocytes; from 13 to 30 merozoites produced per schizont; and both schizonts and

gametocytes tending to encircle the nucleus of the infected cell without displacing it. A Plasmodium morphologically similar in many respects to this one was observed by Fallis (1945, 1946) in ruffed grouse in Ontario, Canada. It developed in canaries, but not so readily as in grouse, while a canary strain would not develop in grouse. The grouse strain is not pathogenic in grouse, canaries, or ducks, and would not develop in chickens or pheasants.

Plasmodium lophurae Coggeshall, 1938. This species was isolated by Coggeshall (1938) from a Borneo fireback pheasant, *Lophura igniti igniti*, at the New York Zoological Park. It is transmissible to very young chicks, but as a rule produces a moderately severe attack that does not terminate fatally. Only mild infections may be produced in adult fowls, and canaries are not susceptible. The original description should be consulted for morphological and other details. Terzian (1941a and b) has recently made an excellent study of the biological characteristics, pathology, and effects of this interesting species in chicks. Laird (1941) showed that *P. lophurae* can be transmitted from duck to duck through the agency of the mosquito *Aedes albopictus*, and he succeeded in infecting also *Culex restuans* and *Aedes atropalpus*. *Anopheles quadrimaculatus* can also be infected, at least lightly (cf. Coggeshall, 1941, and Hurlbut and Hewitt, 1941, 1942). Trager (1942) obtained by selective breeding a strain of *Aedes aegypti* which was more susceptible to *P. lophurae* than the stock from which it had its origin.

Severe infections with high parasitemias are produced in ducks (see Wolfson, 1941). Hewitt's (1942) study of host-

parasite relationship of *P. lophurae* infection in ducks, with its excellent colored plates of the parasite and types of blood cells affected by the infection, is especially commended to the reader's attention. The course of unrelated blood-induced infections in 1,200 young White Pekin ducks was charted by Hewitt et al. (1942). Becker *et al.* (1949) studied the course of infection in some of the comparatively few ducks that had survived the primary attack, and found that in only one of 26 did the infection become permanently latent, while in all the rest it followed a relapsing course with subpatent periods of varying length alternating with patent periods of varying length and with parasitemias of varying intensity. Ducks exhibit reverse age resistance to this parasite in contrast to chicks, which become more resistant as they grow older (Becker, 1950).

Exoerythrocytic forms (phanerozoites) have never been detected in chickens or ducks, although Becker and Manresa (1950) and Manresa (1953) located them in brain capillaries in turkey infections. As in *P. gallinaceum*, they may cause the death of the host by blocking the capillaries, even though the parasitemia is low. Stauber and van Dyke (1945) have compared *P. cathemerium* and *P. lophurae* infections in duck embryos. Goslings are highly susceptible (Becker, 1951). This species, like *P. gallinaceum*, has served as an excellent subject for antimalarial investigations.

For information on domesticated birds as experimental hosts of avian plasmodia, the reader is referred to Wolfson (1941), Manwell (1933, 1943, 1952), and Huff (1963).

AEGYPTIANELLA INFECTIONS

This protozoon was seen by Balfour (1907 and 1914) in Sudanese fowls. His first interpretation of the organism was that it represented intracellular developmental phases of the fowl spirochaete (*Treponema anserinum*) which accompanied the infection Hindle (1912) and Wenyon (1926) suggested that the intracellular granular bodies represented portions of nuclei extruded into the cytoplasm of the red cell as a result of concomitant spirochaete infection. Balfour (1914) and Carpano (1929) believed that the spirochaete infection and the infection with the granular bodies in the blood cells were distinct, for either could occur in the absence of the other Carpano, who found the organism in both chickens and geese in Egypt, named the organism *Aegyptianella pullorum*, and considered it a piroplasm (Fig. 37.9).

Carpano's definition of the genus Aegyptianella is as follows: Protozoa of red cells: of small size; in shape, rounded, oval, or pyriform, not producing pigment; producing no change in size or shape of infected cell; multiplying in circulating blood by schizogony, producing up to 25 minute merozoites.

A. pullorum can vary in size from 0.5μ–4.0μ, depending upon the stage of development. The parasites are infrequently found in the circulating blood, and when found are present for only a day or two, but may be encountered in the lungs, heart, liver, spleen, and bone marrow. In life the parasites may show slow movements of translation. Since the organisms stain with difficulty and the size is small, morphological study is difficult.

Pathogenicity. As was previously noted,

A. pullorum is usually found in association with the fowl spirochaete in Africa. Carpano observed pure infection of both organisms, however, and found that subinoculations with the pure protozoan infection at no time produced spirochaetes.

The protozoan infection may appear in the acute, subacute, or chronic form. Native fowls show the chronic form. Imported birds which become infected are ill for a few days and then succumb. Fowls crossed with foreign strains show the subacute or chronic form.

The symptoms are ruffing of the feathers, anorexia, hyperthermia, immobility, drooping, paralysis of the joints, and often diarrhea. Necropsy shows anemia, swollen spleen, enlarged liver, yellowish-green kidneys, punctiform hemorrhage in the serosa, and sometimes an infiltration of gelatinous hemorrhage in the coronary sulcus.

Brumpt (1930) reported that splenectomy of fowls recovered from heavy infections caused a reappearance of the parasites in the blood. The fowls recovered from this artificially induced relapse.

Host-specificity. The infection is found naturally in geese and chickens. Experimental attempts to transmit it to ducks, pigeons, and canaries have been unsuccessful.

Transmission. Carpano believes that the frequent presence of Treponema and Aegyptianella in the same bird indicates that *Argas persicus*, the tick transmitter of *T. anserinum*, is also the vector of *A. pullorum*. According to Reis and Nobrega (1936), Coles and Bedford demonstrated carriage by *A. persicus*, although Chaillot and Saunie in 1932 could not confirm it. Coles (1939a) states that only adults of this species act as transmitters.
FIG. 37.9 — Aegyptianella pullorum and Spirochaeta gallinarum. (Carpano.)

Geographical distribution. What appears to be this infection has been reported from Egypt, the British and French Sudan, Tunis, South Africa, Transcaucasia, Greece, Yugoslavia, and Albania.

Organisms resembling *A. pullorum* have been described by several investigators under a variety of names. Laird and Lari (1957), who found one of these forms in the heart blood of an Indian house crow, have reviewed the literature on the avian babesiods, compared the findings of the several investigators, and suggest that all of these organisms should be included in the genus Babesia. They liken the organisms found by Schurenkova (1938) and Henry

(1939), Toumanoff (1940), and Mohamed (1952), in the eagle, chicken, heron, and Egyptian kestrel, respectively, to that found in the crow, and suggest that all be considered as belonging to "a single polymorphic species," *Babesia moshkovskii* (Schurenkova, 1938). Levine (1961), for convenience and pending further details on life cycles, prefers to retain *Aegyptianella pullorum* as the name of the organism described above, and considers the rest under the name *A. mushkovskii* (Schurenkova, 1938) Poisson, 1953. In doing so, he includes as organisms of uncertain relationships those of Coles (1937), Abdussalam (1945), McNeil and Hinshaw (1944), and

Rousselot (1917). These latter were found in chickens, turkeys, and pheasants, and could be found to be of veterinary importance, presumably. The accounts of Laird and Lari (1957) and Levine (1961) should be consulted by those interested in studying the avian babesoids in detail.

SPIROCHETE INFECTIONS

Although spirochetes were discussed in this chapter in earlier editions, they are not protozoa, and are now dealt with in Chapters 14 and 41 of this book.

TRYPANOSOMA INFECTIONS

Trypanosomes have been reported as occurring naturally in a large number of wild birds, and in the chicken, pigeon, and guinea fowl. In most instances the organism was known only from the vertebrate host, and frequently it was designated as a new species if its morphology differed from that of trypanosomes previously reported from birds. Sometimes the organism observed was named as a new species merely because a similar trypanosome had not previously been reported from that particular host. It is now known that most of the trypanosomes of birds can vary considerably, morphologically, and that some, at least, are not specific as to the vertebrate host. They may, indeed, show considerably more specificity for the invertebrate host (see Bennett, 1961). Pending additional studies, it may be well to regard them as Levine (1961) has, who observed, "They all look very much alike and probably belong to a relatively few species. However,

extensive cross transmission studies are needed to establish their relationships and, until these are carried out, it is probably best to refer to them by the names under which they were first described."

Trypanosoma avium Danilewsky, 1885. This trypanosoma was first reported from owls and roller birds in Europe. Since then, trypanosomes regarded as being of this species have been reported by numerous workers. Among the recent reports are those of Diamond and Herman (1954), who found it in Canada geese; Baker (1956a), who obtained it from rooks (*Corvus frugilegus* L.) and jackdaws (*C. monedula spermologus* Vieill.); and Bennett (1961), who observed it in more than 30 species of birds belonging to more than a dozen orders. Diamond and Herman described a technique "for the cultural isolation of trypanosomes from avian bone marrow obtained from living birds or at autopsy." They found the method to be vastly superior to that of merely examining stained smears, or of culturing heart blood, as a means of detecting trypanosome infections. Consequently, reports of the incidence of infection with avian trypanosomes probably have little meaning unless the methods of detection are comparable, or can be brought to comparable bases.

Baker (1956a) gave a good description of the strain of *T. avium* used in his studies, and included references to all pertinent literature. The morphological characteristics of the trypanosome varied somewhat according to the vertebrate host, as well as showing the usual variation within a given host, but in summary Baker describes his flagellate as follows:

"The trypanosome in question is a large spindle-shaped form, measuring an average of 48.2μ in length (excluding flagellum) and 5.5μ in width. There is a tapering flagellar region extending 14.1μ (on the average) beyond the kinetoplast. This trypanosome is assigned to the species *T. avium* Danilewsky, 1885."

Bennett (1961), who also reviewed the literature, including the work of Baker, tabulated measurements for the trypanosomes he found in several species of birds, and came to similar conclusions regarding the morphology and identity of the organism, but recognized that "many physiologically distinct strains or species may exist" in what he termed the *"avium* complex."

The natural methods of transmission of the trypanosomes presently considered to be members of this "complex" are by no means clear. Baker (1956b) described experimental transmission by the hippoboscid *Ornithomyia avicularia* L. He concluded, "The metacyclic trypanosomes develop in the insect's hind-gut, and infect birds by penetrating the membranes of buccal cavity and/or esophagus and crop." Transmission did not occur by the bite of infected louse flies, and he had only very limited success with efforts to produce infections in canaries by rubbing fecal matter from infected flies into scarifications in the skin. Bennett (1961) obtained quite different results using infected mosquitoes (*Aedes aegypti*) and ornithophilic simulids. Infections could be produced by ingestion of macerated insects, but not by feeding the insects intact. Emulsions of material from the hind-gut or feces of infected insects readily produced infections after having been rubbed into scarifications in the skin. The flagellates apparently were unable to penetrate unbroken membranes. However, trypanosomes from some species of birds were quite unable to develop in some insects that successfully transmitted the flagellates acquired from birds of other species. Bennett summed up the situation by commenting as follows: "New criteria for the identification of avian trypanosomes must be developed. It is suggested that the ability of the trypanosome to develop in and produce infective flagellates in a variety of bloodsucking Diptera, whether or not such Diptera are true vectors, be used as criteria. Other criteria, such as serological evidence, or perhaps, the ability to develop on cultures lacking certain chemicals, may yet be needed to definitely separate the species."

Baker (1956c) has given for *Trypanosoma avium* the most complete description of the life cycle in both the vertebrate and

FIG 37.10 — Trypanosoma hannai. (H. de B. Aragão)

invertebrate host that has thus far been presented for an avian trypanosome. Although this species is not known to occur in chickens, it is quite common in Canada geese, and has been transmitted to domestic ducks. In view of the intricate relationships between it (or its "complex") and the many vertebrate and invertebrate hosts from which it has been reported, natural infection of domestic birds can hardly be ruled out. Like infections with other avian trypanosomes, it would probably be of little or no economic importance. *T. avium* has been considered at length here because it is the only avian trypanosome that have received much attention in recent years.

The species mentioned below are included principally because they were described from domestic birds. Little is known concerning their life cycles.

Trypanosoma hannai Pittaluga, 1904. Hanna in 1903 observed a trypanosome in scanty numbers in the blood of domesticated pigeons in India (Fig. 37.10). It was named *Trypanosoma hannai* by Pittaluga (1905). Aragão (1927) also observed the parasite in the blood of a pigeon in Brazil.

The mode of transmission is still unknown, although Aragão noted numerous flagellates of the crithidia type in the alimentary tracts of hippoboscid flies, *Lynchia maura*, which had fed upon a pigeon infected with trypanosomes, but none in flies that had fed upon uninfected birds. Two types of crithidias were noted, the respective dimensions being 40.0μ by 3.0μ and 49.0μ by 1.5μ. Attempts to transmit the infection to clean pigeons by the bite of the fly, by injection of the emulsified intestines of infected flies, or even by blood inoculation were unsuccessful.

Trypanosoma gallinarum Bruce, Hamerton, Bateman, Mackie, and Bruce, 1911. This trypanosome, and another described about the same time by Mathis and Leger (1911) under the name *Trichomonas calmelli*, were both found in chickens. The flagellate described by Bruce et al. (1911) was about $1.5 \times$ as long, and slightly broader than that of Mathis and Leger, but many years ago Wenyon (1926) suggested that they were possibly the same trypanosome. Bennett (1961) went even further, suggesting that both *T. gallinarum* and *T. calmelli* could be considered as belonging to the complex presently regarded as *T. avium*.

INTESTINAL FLAGELLATES

Trichomonas Infections

Trichomonads are flagellated protozoa that are characterized by the possession of a longitudinal axial rod, the axostyle, an undulating membrane bordered by a posteriorly directed flagellum, and 3 to 5 "free" flagella that arise (as does the marginal flagellum) from basal granules near the front end of the body. Some students of this group of protozoa have attempted to classify the trichomonads on the basis of the number of "free" flagella characteristic of the genus, while others have regarded the nature of the axostyle, the undulating membrane, and other organelles as better criteria for grouping the trichomonads. For our purposes we may consider all species that are likely to be found in domestic poultry as of the genus *Trichomonas* except for one cecal form for which the name *Tritrichomonas eberthi* has been generally accepted. The reader who has a special interest in presumed evolutionary relationships and the systematics of the trichomonads and related protozoa should consult Honigberg (1963) and some of the papers mentioned in his extensive list of references.

The principal structural components of Trichomonas are designated in Fig. 37.12, which depicts *T. gallinae* semidiagrammatically. Figure 37.11 shows, diagrammatically, how two other trichomonads of poultry differ in details, from each other, and from *T. gallinae*. These are *Trichomonas gallinarum* and *Tritrichomonas eberthi*, mentioned above.

Trichomonas gallinarum Martin and Robertson, 1911. This trichomonad was said by Martin and Robertson (1911) to be one of the most common of the flagellates of fowls. McDowell (1953) found it in more than 60 per cent of "several hundred fowl of varying ages and from many sources." Chickens and turkeys are the hosts from which *T. gallinarum* is most frequently reported, but it has been found in the guinea fowl by several observers, and in chukar partridges by Wichmann and Bankowski (1956). Diamond (1957) found "a *T. gallinarum*-like form" in the Canada goose, and the senior author has observed trichomonads resembling this species in the ceca of pheasants raised in captivity.

T. gallinarum varies considerably in both shape and size. Usually it is pyriform, but sometimes many or most of the individuals may be spherical or slightly elongate. Living organisms viewed in wet smears or hanging drops commonly range in length 7μ–15μ and in breadth 4μ–10μ. The axostyle extends well beyond the body and is slender and pointed. The undulating membrane is prominent, traversing the entire length of the body and ending near the point at which the axostyle emerges. The marginal flagellum often extends well beyond the axostyle. Characteristically, there are 4 anterior flagella which, in living specimens, are best seen by the use of a dark-field or phase-contrast microscope. For a detailed description of structures visible in stained preparations, see McDowell (1953).

Although the usual habitat of *T. gallinarum* is the cecum, organisms may often be found in the adjacent small intestine. Several observers have reported finding this trichomonad in the liver of chickens, and Wichmann and Bankowski (1956) found it in the liver of chukar partridges that were dead upon arrival at the laboratory. Indeed, most if not all reports of the finding

of *T. gallinarum* in the livers of gallinaceous birds have been based on studies of birds dead long enough to permit postmortem invasion or on studies of birds heavily parasitized by *Histomonas meleagridis*. The livers of birds so parasitized were probably only secondarily invaded by the trichomonad. Rarely, trichomonads may escape into the coelomic cavity and multiply profusely on the serous membranes. Such was the origin of strain TG79 (Soc. Protozool. Comm. on Cultures, 1958). In that instance, apparently, ulceration of the cecum attributable to histomoniasis provided the trichomonads access to the peritoneal and pleural cavities (senior author's unpublished observations and records). It is questionable that *T. gallinarum*, unaided, may invade sites other than the ceca and

adjacent intestine. McDowell's guarded statement (1953) concerning the possible ill effects of heavy cecal infections may approximate the impressions of many workers who have studied farm flocks of either chickens or turkeys. He comments as follows: "The present study discloses that there is a definite association of a yellowish foamy discharge from the caeca and the presence of many *T. gallinarum* in both young fowl and adults, but this diarrhea is most common on range in June and July when every two- to three-month-old fowl will show bedraggled feathers and general unthriftiness as indications of this disease. Severe emaciation may ensue followed occasionally by death." There does, indeed, appear to be a "definite association," but even if a specific parasitical disorder such as hexamitiasis is ruled out, the presence of harmful bacteria or viruses must be considered.

Inasmuch as trichomonads do not form cysts, infection by the ingestion of trophozoites in contaminated food or water must be assumed. However, the intervention of insects, such as flies, as mechanical carriers has long been postulated.

The vast body of literature on the physiology of the trichomonads has been reviewed by Shorb (1964).

Tritrichomonas eberthi (Martin and Robertson, 1911) Kofoid, 1920. This trichomonad inhabits the cecum of chickens and turkeys, and has once been reported from ducks (Kotlán, 1923). According to McDowell (1953), who found it in 35 per cent of the several hundred chickens that he examined, it occurs principally in older birds, and usually in association with *T. gallinarum* and *Chilomastix*.

The body of *T. eberthi* was described by McDowell as "carrot-shaped," with an average length, in fixed specimens, of 13μ, and a width of 6.5μ. There is considerable variation in size, however, and spherical forms sometimes occur. The undulating membrane is prominent, and traverses virtually the entire length of the body. The marginal flagellum trails well behind. In these respects *T. eberthi* resembles *T. gallinarum*. However, it is frequently rather larger, and the cytoplasm is more heavily vacuolated than that of *T. gallinarum*. Also, the axostyle of *T. eberthi* is more massive and tends to taper more abruptly at its posterior end than that of *T. gallinarum*. Usually, only 3 anterior flagella can be demonstrated, and according to McDowell, it is their beating in unison that imparts to the organism its jerky movement. McDowell also gives in considerable detail the distinctive internal features visible in stained preparations.

T. eberthi is nonpathogenic, and the modes of transmission are assumed to be similar to those for *T. gallinarum*. Diamond (1957) cultivated *T. eberthi* axenically for the first time.

Trichomonas gallinae (Rivolta, 1878) Stabler, 1938. Synonyms, *T. columbae* auct.; *T. hepaticum* (Rivolta, 1878); *T. diversa* Volkmar, 1930; *T. halli* Yakimoff,

1934. According to Stabler (1938a), the turkey and pigeon trichomonad of the upper digestive tract are identical species, and (Stabler, 1938b) the correct name is *T. gallinae* (Fig. 37.12) The flagellate occurs almost universally in pigeons, and this bird is probably the primary host (Stabler, 1951a).

Its occurrence in these birds in America was first reported by Waller (1934), who compiled a brief historical account. Its natural host range includes several varieties of domestic pigeons, the band-tailed pigeon, eastern mourning dove, western mourning dove, ring-necked dove, various hawks, falcons and owls, turkeys and chickens (Stabler, 1941b; Stabler and Herman, 1951; Locke and James, 1962). It can easily be transferred from one of these hosts to another, as from doves to clean pigeons (Stabler, 1951b), or from pigeons to hawks or falcons (Stabler and Shelanski, 1936). Levine et al. (1941) transmitted *T. gallinae* from chickens to the turkey, quail, canary, and English sparrow with lesions, and to a duckling without lesions. Additional accounts of transfer experiments with *T. gallinae* are given in Stabler's excellent 1954 review of virtually all of the important literature on this organism.

Among the better accounts of the morphology of *T. gallinae* are those of Stabler (1941a, 1954) and Levine and Brandly (1939). The organism is roughly pear-shaped, but may be rounded under adverse conditions. It ranges in length 6μ–19μ, and in width 2.5–9μ, averaging 10.5μ by 5.2μ. As in *T. gallinarum*, there are 4 free anterior flagella, but the body is more elongate, the undulating membrane and costa are shorter, and the marginal flagellum terminates at the end of the undulating membrane as shown in the figure.

T. gallinae of pigeons occurs in the mouth, pharynx, esophagus, and crop of apparently healthy carriers. The squabs become infected through the ingestion of their natural food, "pigeon milk." The infection can probably be spread also through contamination of feed ...ter. The incidence in pigeons and ...

be very high. Stabler (1951a) in Colorado found infection in 19.3 per cent of trapped band-tailed pigeons, 23 per cent of western mourning doves, and 69 per cent of captured common pigeons. The diseased conditions produced in the hosts, as described by Stabler (1947) and Stabler and Herman (1951), vary considerably. In chronic infections there are no lesions, but in mild cases the apparently healthy bird may show "small, yellowish, adherent masses in the oral or upper oesophageal regions of the digestive tract," which may disappear later. More severe cases frequently end in death, even certain cases where the lesions appear to be slight and confined to the mouth and pharynx. First, yellowish lesions appear on the oral mucosa. These grow into large caseous lumps which may prevent swallowing food or drink. The bird wastes away and may die on about the eighth day of the infection. Pigeon fanciers call the disease "canker," and Stabler states that falconers refer to the condition as "frounce." Involvement of the internal organs may be noted at necropsy, particularly of the liver, which may show only a few yellowish necrotic spots, or more extensive caseation. Heavy losses from the disease have been reported in wild pigeons and pigeon colonies.

Wild mourning doves are frequently victims of this form of trichomoniasis. The 1950 Alabama outbreak killed many thousands of these birds (Haugen, 1952). Most of the deaths occurred after the spring migration or during the nesting season. The dead birds were emaciated and showed throat swellings that probably made it impossible for the stricken birds to swallow food or drink. Herman (1953) has prepared a brief paper on recognition of the disease in doves.

T. gallinae infections in turkeys on range frequented by pigeons are fairly common. In some flocks losses may be considerable. A discussion of trichomoniasis of the upper digestive tract of turkeys appears in Chapter 41, Diseases of the Turkey, in this volume. Levine and Brandly (1939, 1940)

have reported on the disease in pullets and chicks.

Strains of the organism of varying degrees of virulence have been reported (Stabler, 1948a). Of five strains, each passed serially through five Trichomonas-free pigeons, one produced not the slightest evidence of disease in any of the five recipients; one produced but mild cankers in the throat of three, one killed one bird and produced moderate to severe caseation in the throats of the other four, one killed four and produced moderate caseation in the survivor, while the last killed three and produced very severe caseation in the two survivors. The first four strains stemmed from pigeon infections, the last from a cankerous Peregrine falcon which died of the disease. Stabler (1948b) then proceeded to demonstrate that eight squabs given a very mild strain developed either no or evanescent lesions, and, when challenged with a virulent, killing strain, survived with little or no evidence of pathological changes in seven of them. Later Stabler (1951b) isolated from mourning doves one strain that was avirulent in pigeons, and four others of varying degrees of virulence. When the survivors were challenged with virulent, killing strains, mostly of pigeon origin, not a bird died.

That the virulence of a strain ("Jones' Barn") is retained for a long time is supported by Stabler (1953b), who passed the flagellate in succession through 119 Trichomonas-free pigeons of which 114 died. This strain is so pathogenic that of ten clean pigeons, each administered a single trichomonad by Stabler and Kihara (1954), five became infected and died of canker in 8 to 13 days (av. 11.8 days). The five uninfected pigeons were later given 5 to 10 thousand trichomonads each, and they died within (av.) 7.6 days. Later, 293 deaths were reported in 300 birds (Stabler, 1957).

With flagellates inhabiting any part of the digestive tract, the question always arises: Is the flagellate itself pathogenic, or

is it the accompanying bacteria that are pathogenic? The lesions of *T. gallinae* in the upper digestive tract of pigeons are, of course, accompanied by bacteria, but the caseations of the liver and other internal organs may not be. Bos (1933), Cauthen (1936), and Stabler and Engley (1946) first succeeded in obtaining bacteria-free cultures stemming from such bacteria-free lesions. The last-named authors demonstrated that the microorganism fully retained its pathogenicity when grown in bacteria-free culture on modified Boeck-Drbohlav (1925) medium originally used for cultivating *Entamoeba histolytica*.

Copper sulfate in the drinking water was one of the older and partially successful treatments (Jaquette, 1948). Enheptin in the daily dose of 5.0 mg., administered in a gelatin capsule, was effective in pigeons weighing 350 to 550 gm., even against highly pathogenic strains (Stabler, 1953a). A more convenient method of treatment using soluble enheptin was later described by Stabler *et al.* (1958). This consisted of the use of 6.3 grams of soluble enheptin per gallon of drinking water, continued for 7 to 14 days. Its use was recommended only for nonbreeding birds. The method cannot be used for free-flying flocks that have access to unmedicated water because the medicated water is somewhat unpalatable. On controlled tests, all birds infected with the virulent Jones' Barn strain of trichomonad three days before treatment was started survived, but about 13 per cent still harbored some trichomonads. These were assumed to be the birds lowest in the social hierarchy ("peck-order"), that were permitted only limited access to the medicated water.

Still more recently a drug showing very considerable promise for the treatment of trichomoniasis in several hosts has been used successfully for the treatment of *T. gallinae* infections in pigeons. The drug is metronidazole (1-beta-hydroxyethyl – 2 – methyl–5-nitro–imidazole). According to Bussiéras *et al.* (1961), it prevented mortal-

ity when given orally at the level of 60 mg/kg body weight on 5 consecutive days. Fertility of the breeders was not affected.

Trichomonas anatis (Kotlán, 1923). Synonym, *Tetratrichomonas anatis*, Kotlán, 1923. Kotlán (1923) made a study of the intestinal flagellates of ducks. His work, except for some random observations, is the only information on this subject available. *T. anatis* has a broadly beet-shaped body which measures 13μ–27μ in length and 8μ–18μ in breadth. There are 4 free anterior flagella of about the same length as the body. The well-developed undulating membrane has a sturdy marginal flagellum along its border.

The habitat is the posterior region of the intestine of *Anas boschas dom.* Kotlán states that massive infections are established only when the mucosa is in a catarrhal condition.

Trichomonas anseri Hegner, 1929. Hegner (1929) inoculated three-day-old chicks with cecal material from a goose containing a very few trichomonads. Some of the chicks became heavily infected. The description of the species is based upon the forms which appeared in the chicks. Hegner finds that *T. anseri* has peculiarities which distinguish it from other trichomonads. The body is oval in shape; size, 6μ–9μ by 3.5μ–6.5μ with a mean of 7.9μ by 4.7μ. There are 4 free anterior flagella which arise from 2 blepharoplasts, and a fifth one which forms the border of the undulating membrane and becomes a free lash near the posterior end. The chromatic basal rod is distinct; the axostyle is broad and hyaline and protrudes considerably; the nucleus contains an eccentric karyosome and is otherwise filled with minute chromatin granules. Bacteria are ingested into the cytoplasm through a prominent cytostome.

Chilomastix gallinarum Martin and Robertson, 1911. This flagellate and its cysts were first reported from fowls by Martin and Robertson (1911). The best account is that of Boeck and Tanabe (1926), who also described the process of binary fission in
FIG. 37.13 – *Chilomastix gallinarum*, semidiagrammatic, illustrating details of morphology. ×5,000. (Boeck and Tanabe, Am. Jour. Hyg.)

detail (Fig. 37.13) (cf. McDowell, 1953).

The trophozoites of *Chilomastix* are pyriform, somewhat asymmetrical, and plastic. They vary considerably in size, the length ranging commonly 11μ–18μ and the width 5μ–12μ. Occasionally a considerable number of the individuals reach a length of 20μ, or slightly more. After fixation with Schaudinn's fluid the dimensions are 10–20 per cent less. A large cytostomal groove originates near the anterior end and terminates as a pouch just short of the center of the body. It contributes to the asymmetry of the trophozoite, and because it spirals slightly, the organism sometimes seems to be somewhat twisted. The margin of the cytostome appears to be supported by fibrils, but their exact nature, number, extent, and function have been interpreted in various ways. As shown in Fig. 37.13, *Chilomastix* has 3 free anterior flagella, and a fourth flagellum that undulates in the cytostome and aids in the ingestion of bacteria and other food particles. The blepharoplasts which give rise to the flagella, supporting fibrils, and peristomal flagella are difficult to count, but there seem to be 4 of them with the relationships

to the other organelles shown in the figure. The nucleus is rounded and of the vesicular type.

Cysts are infrequently observed in fresh cecal material, but McDowell (1953) asserts that they are common in cultures. They measure 7μ–8.5μ in length and 4.5μ–5.5μ in width. The internal structures are similar to those in the motile form except that the nucleus has moved to a more central position.

For additional details concerning the structure of either the trophozoites or the cysts, as well as for information on a simple method of culturing the organism, the reader is referred to McDowell (1953).

Occurrence and host specificity. *Chilomastix gallinarum* is a common and usually harmless inhabitant of the ceca of chickens and turkeys. McDowell reported having found it in 40 per cent of the "several hundred fowl of varying ages" used in his studies. The senior author's records show that there is considerable variation in the incidence in both chickens and turkeys, from season to season and year to year. The factors responsible for these variations have not been determined. Only rarely is *Chilomastix* present alone, so some of the circumstances favoring infections with trichomonads, amoebae, and coccidia are probably operative.

Chilomastix has also been observed by the senior author in pheasants raised in close confinement, and in one instance in pen-raised chukar partridges. Kimura (1934) reported having found it in ducks, and May (1963) described an outbreak in quail.

Protrichomonas anatis Kotlán, 1923. This species, observed by Kotlán in the duck, has a more or less pear-shaped body measuring 10μ–13μ by 4μ–6μ. There are 3 active flagella which arise from an anterior blepharoplast. It appears as if the axostyle is formed of 2 fibrils which arise from the blepharoplast, pass posteriad, and meet at a point a considerable distance from the caudal tip of the body. The nucleus appears to lie between the fibrils at about the middle of the body.

Cochlosoma anatis Kotlán, 1923. This curious flagellate has a sharply outlined depression at the anterior end of one side. This concavity, similar to the sucking disc of Giardia, marks the ventral surface. The dorsal surface shows a convexity at the anterior end. The body measures $10\mu–12\mu$ by $6\mu–7\mu$. From a blepharoplast on the anterior border of the body there arises a tuft of about 6 flagella, all of which are directed posteriad adjacent to the surface of the body. Two axial fibrils (axostyle?) arise from a granule near the blepharoplast and traverse the body to beyond the caudal tip. A vesicular nucleus lies in about the center of the body. Ovoid cysts with 4 or more nuclei are formed. Reproduction is either by binary fission of the trophozoite or by multiplication within the cysts (Fig. 37.14).

This organism was found in the feces and intestinal mucus of a duckling which was suffering with coccidiosis of the intestine, and in the ceca of a growing duck. Travis located them also in the cloaca and large intestine of ducks. Kotlán found the same flagellate in *Nyroca ferruginea* and *Fulica atra*. Pathogenicity of the flagellate has not been proved. Travis (1938) observed it in the wild mallard, shoveller, pintail, lesser scaup, and domesticated mallard. Other species were observed in the magpie and Eastern robin.

Kimura in 1934 found a *Cochlosoma* in Muscovy and white Pekin ducks in California which he named *C. rostratum*. It measured $6\mu–10\mu$ by $3.9\mu–6.7\mu$. McNeil and Hinshaw (1942) have found it throughout the intestinal tract of turkey poults, and in the region of the cecal tonsil in adults. It occurred in turkeys associated with Hexamita or in combinations of Hexamita and Salmonella. The true significance of this parasite in turkey poults or ducklings has not been determined.

A severe outbreak of cochlosomiasis, attributed to *C. anatis*, in poults of two to ten weeks on a turkey farm in Scotland was recorded by Campbell (1945). The birds were affected with a condition clinically and pathologically indistinguishable from infectious catarrhal enteritis due to Hexamita. The symptoms were as follows: intense thirst, frothy diarrhea, depression, ruffled plumage, drooping head, closed eyes, loss of appetite, weakness, coma, and death. Only 2 or 3 days intervened between the first appearance of symptoms and death. Among the findings at necropsy was the atonic intestine with dilations or bullae filled with yellow fluid swarming with the jerkily swimming flagellates. The flagellate was revealed in every fresh case. Trichomonas and Hexamita were also usually present, but *Cochlosoma* predominated.

HEXAMITA INFECTION

Hexamitiasis is of importance principally as a disease of turkeys, and as such, it is adequately discussed in Chapter 41, Diseases of the Turkey. The organism re-
FIG. 37.14 — *Cochlosoma*. Diagrammatic drawing naming structures. (Travis, Jour. of Parasit.)

sponsible for the disease in turkeys, *Hexamita meleagridis* McNeil, Hinshaw, and Kofoid, 1941, has been found in quail, pheasants, and chukar partridges, also (Hinshaw and McNeil, 1941; McNeil, 1958). It can be transmitted experimentally to chickens and ducks, but is not known to occur naturally in these birds. Another species, *H. columbae*, had been described from pigeons (Noller and Buttgereit, 1923) before the specific identity of *H. meleagridis* was set forth by McNeil *et al.* in 1941. *H. columbae* was recognized in California by McNeil and Hinshaw (1941), and Levi (1957) mentions other reports of it in pigeons in California in 1954 and 1956. He calls it "an uncommon protozoan infection" in pigeons, but describes symptons similar to those observed in turkeys. However, in comparison to hexamitiasis of turkeys, that of pigeons is of little economic importance.

The U.S Department of Agriculture (1954) estimated the annual losses attributable to hexamitiasis of turkeys to have averaged about $667,000 for the period 1942–1951 During the decade following that period, the number of turkeys raised in the U.S. doubled (U.S.D.A. Agricultural Statistics 1962), but no indications have been found that losses attributable to hexamitiasis have increased proportionately However, the disease has been reported from areas in which it had previously not been sought or recognized (as in Illinois: Levine, 1961). As McNeil (1958) pointed out, the symptoms of hexamitiasis and bluecomb are very similar, and there may have been some confusion of the two diseases. Furthermore, as she observed, they undoubtedly occur together at times, and it would be of interest to know whether the relationship is more than one of mere coincidence.

A comprehensive paper by Wilson and Slavin (1955) on symptomatology, pathology, and diagnosis of hexamitiasis of turkeys in Great Britain, and a previous paper by Slavin and Wilson (1953), describe a complicated life cycle for *Hexamita meleagridis* involving schizogony, cysts, etc. According to Hoare (1955), this unusual life cycle cannot be accepted without more plausible evidence.

Bacteria-free cultures of *H. meleagridis* in the allantoic cavity of embryonating chicken eggs were obtained by Hughes and Zander (1954), who used rapid passage initially to adapt the flagellates to the new environment, and then the antibiotics streptomycin and bacitracin to eliminate contaminating bacteria. Eight- to 12-day-old embryos proved most satisfactory. No deleterious effects were noted in either the embryos or the chicks which were permitted to hatch.

PARASITIC AMEBAS

Entamoeba gallinarum Tyzzer, 1920. This ameba was described by Tyzzer (1920) from the cecal excrement of both young turkeys and the common fowl. The trophozoites measure from 9μ–25μ in diameter; average size, 16μ–18μ. They are continuously and actively motile at room temperature. Pseudopod formation is said by Tyzzer to be gradual rather than eruptive in character, but Hegner (1929b) finds that it is almost as explosive as in *E. histolytica.* The ectoplasm is differentiated from the endoplasm. The latter stains intensely and usually contains a variety of inclusions such as cell fragments, flagellates, amebas of the genus *Endolimax*, and other material from the cecal contents. Tyzzer stated that bacteria are not utilized as food, but McDowell (1953) disagrees. The nucleus is spherical, and measures from 3μ–5μ across. A dense layer of chromatin is closely applied to the nuclear membrane. Tyzzer states that the endosome is centrally located, but in his figures he shows it in an eccentric position (cf. McDowell, 1953).

The cysts are eight-nucleate when mature, but immature quadrinucleate forms occur. The cysts are spheroidal and have an average size of 12μ by 15μ.

This ameba is not known to affect the host adversely in life, but within a short time after death the organisms migrate through the tissue and can be found in large numbers throughout the cecal mucosa and submucosa. Under these conditions the parasite may also ingest epithelial cells. Several workers have found this ameba in blackhead lesions in livers of turkeys along with other microorganisms.

If it should eventually be determined that this *Entamoeba* is identical with that found in the red grouse, the correct name would be *E. lagopodis* Fantham, 1910. Although only four-nucleate cysts of the latter species were noted by Fantham, it is not unlikely that the mature cysts possess eight nuclei. What seems to be *E. gallinarum* was reported from guinea fowls by Hegner (1929b).

Endolimax gregariniformis (Tyzzer, 1920). Synonyms, *Pygolimax gregariniformis* Tyzzer, 1920; *Endolimax janisae* Hegner, 1926.

This small ameba, found by Tyzzer (1920) in the ceca of diseased and normal

Poultry Surgery

Avian surgery was given little or no consideration for many years. The low value of the individual fowl in the farm flock made it economically unsound to resort to individual treatment. In recent years, as the result of the growth and development of the poultry industry to its present large-scale production methods, there has been an increased demand for better and more effective veterinary service to reduce poultry losses to a minimum. The comparatively high individual value of show birds and ornamental and game birds, as well as avian pets, has created considerable demand for individual medication and improved surgical methods. Consequently, substantial progress in avian surgery has been made for practical and experimental purposes.

The avian species make excellent surgical subjects because their sensory nervous systems are apparently not as highly developed as those of the majority of our domesticated animals, and consequently, they suffer less from surgical shock. They also respond to both general and local anesthetics if properly administered. Birds also have a very high resistance to pyogenic infection, which simplifies effective surgical technique under field conditions with little danger of postoperative infection.

Avian surgery may be classified in two distinct groups, practical, or applied, and experimental. The first group includes those operations necessary to relieve certain conditions which are quite commonly encountered in poultry practice. The second group has been developed for the purpose of studying various problems in physiologic and pathologic research. Experimental surgery is of little practical value. It will be treated briefly together with references for the benefit of those desiring this information. Burrows (1936) developed a technique for the removal of the gizzard of the domestic fowl. Sloan (1936) successfully removed the yolk from newly hatched chicks. Durant (1926), Schlotthauer *et al.* (1933), and Delaplane

and Stuart (1933) have developed surgical techniques for cecal abligation in an effort to control infectious enterohepatitis in turkeys. Some of the surgical methods developed in poultry research have contributed much toward our present knowledge of avian physiology and pathology.

Anesthesia. Anesthetics are not generally used in poultry practice. They have been used successfully in experimental investigations which involved major operations. The anatomical structure of the avian respiratory system renders the use of inhalation anesthesia rather unsatisfactory. This type of anesthesia cannot be controlled adequately because of the infiltration of inhaled anesthetic into the air sacs which constitute part of the respiratory system in birds. Frequently, excessive amounts of the anesthetic are absorbed, resulting in respiratory failure, cardiac inhibition, and death. Consequently, ether and chloroform have been replaced by some of the more recently developed anesthetics which can be administered intravenously. Chloral hydrate injected intravenously in doses from 0.2 to 0.1 gm. produces a complete anesthesia lasting from 15 minutes to 1 hour. Hole (1933) reported the minimum lethal dose of chloral to be between 0.1 and 0.6 gm. Gandal (1956) administered chloral hydrate in various ways and found it to be toxic and difficult to control. King and Biggs (1957) reported that the prolonged action and toxicity of urethane made it undesirable for surgical anesthesia. The intravenous administration of sodium amytol solution (0.1 gm. per cc.) is quite satisfactory as a general anesthetic according to Fretz (1952). Injections of 0.5 to 1.0 cc. of this solution is adequate for birds ranging from 4 to 8 pounds in weight. Warren and Scott (1935) consider sodium pentobarbital (nembutal) the most satisfactory general anesthetic for poultry practice. Intravenous injections of 0.5 to 0.75 cc. produce effective anesthesia for as long as 2 hours. The intravenous use of nembutal for turkeys in doses of 1.1 cc. per 5 pounds of body weight was reported by Durant and McDougle (1935) as an effective anesthetic. Arañez and Rosario (1960) reported on the use of kemithal sodium as a general anesthetic for chickens. Friedburg (1962) describes successful techniques for anesthesia of parakeets and canaries. For anesthesia of short duration, ether or ethyl chloride, preferably the latter, is administered by intermittent application. For more prolonged operations he suggested pentobarbital sodium or a chloral hydrate-pentobarbital-magnesium sulfate combination (Equi-Thesin, Jensen-Salsbery Laboratories, Kansas City, Missouri). The dose is 0.25 cc. per 100 gm. body weight. The average parakeet weighs about 50 gm. or 1 oz., and would require about 0.08 cc. in the pectoral muscle. A 1.0 cc. glass tuberculin syringe with a 26 gauge, ¼ inch needle is suitable for the administration of the anesthetic. The average canary weighs about 20 gm. but the exact weight should be obtained for calculation of dosage of anesthetic. Pentobarbital sodium may be used if properly diluted. A concentration of 7 mg. per 1 cc. is suitable. For a 30 gram bird 0.2 cc. of this dilution injected into the pectoral muscle is used. After five to ten minutes, suitable anesthesia lasts about ½ hour.

Local anesthetics have a limited use in poultry practice. Schalm (1936) reported the successful use of 2 per cent solution of novocain as a local anesthetic. Butyn in a 2 per cent solution is regarded very satisfactory by Sweebe (1925) for local anesthesia of the eye.

ABDOMINAL SURGERY

Abdominal surgery is limited to a few operations for conditions which are quite common in poultry practice. Caponizing is probably the most extensive operation performed for the production of birds for a specialized market. The premium received for this class of poultry products makes the operation practical and economically profitable. The removal of eggs in the various stages of development from the abdominal cavity of birds is practiced, especially in cases involving birds

which are known to be high producers or those which have high individual values. The removal of excessive quantities of fluids which accumulate in the abdominal cavity is often indicated. Cecal abligation has been given considerable attention in recent years in an attempt to control blackhead in turkeys. At the present time, this operation must be considered only as an experimental procedure. An effective method of sanitation and hygiene instituted in the system of management has proven to be more practical and satisfactory in controlling this disease. Because of the interest shown in this work, a brief review of some of the methods developed will be presented.

Caponizing. The castration or desexing of cockerels is commonly known as caponizing. The optimum stage of development is reached at 8 to 10 weeks of age when the birds reach about 1½ pounds in weight. At this age there are fewer so-called slips, and the mortality can be kept at a minimum. However, Quigley (1961) recommends caponizing earlier; from 5 to 6 weeks of age. The water should be withheld for 12 to 18 hours prior to operation. This permits the intestinal contents to be reduced to a minimum, causing the intestines to settle away from the testicles as well as the upper wall of the abdominal cavity. Consequently, when the intercostal incision is made, there is a clearer field of operation in the abdominal cavity and less danger of intestinal puncture. A suitable table, proper confinement, adequate light, and proper instruments are essential for satisfactory results.

The cockerel is placed on the operating table on its left side. The wings are securely held together above the body by a suitable restraining device and fastened to the upper side of the table. The legs are likewise secured together and fully extended, being fastened to the lower edge of the table. This position permits free access to the field of operation (Fig. 38.1). Some of the soft feathers are plucked from the region of the hips and ribs. The field of operation is cleansed with a piece of

FIG. 38.1 — Field of operation for caponizing.

cotton moistened with clean warm water or weak antiseptic solution. With the fingers of the left hand, locate the area midway between the last two ribs (6th and 7th) where the incision is to be made. Draw the skin back over the hip and with it the sartorius or thigh muscle with the left hand. An incision is made about ¾ inch long through the skin and intercostal structures, midway between the last two ribs slightly below the upper abdominal wall (Fig. 38.2). If the incision is too near the vertebral column or too low, difficulty may be experienced in locating and removing the genital organs. The incision of the vein which runs diagonally across the body from thigh to wing should be avoided. The spreader is placed in the incision, the handle of which should be
FIG. 38.2 — Incision with insertion of spreaders.

directed toward the back so as not to interfere with the operator. The peritoneal membrane medial to the intercostal structures which forms the abdominal air sac is punctured with a sharp hook or probe exposing the abdominal organs. The gonads, which are about the size of a wheat kernel, can be seen attached dorsally at the anterior extremity of the kidney. These organs are usually yellowish in color but may vary from white to gray or even black. The lower gonad (left) should be removed first by clamping it securely with forceps and twisting it free from its attachments. The upper one (right) is removed in the same way. The spreaders are then removed and the bird is released from the operating table. The skin and thigh muscle slip back in place as the

limbs regain their normal positions, serving effectually to close the opening in the abdominal cavity.

The principal danger in this operative procedure is death from internal hemorrhage which takes place within a few minutes following rupture of a primary blood vessel. The testicles are located at a point where the right and left iliac veins converge into the posterior vena cava (Fig. 38.3). The aorta is situated below the vena cava when the bird is on the operating table. The spermatic vessels which supply the circulation of the testicles are ruptured when the testicles are removed; but in the young cockerel these vessels are so small that serious hemorrhages are seldom experienced. The operative field is such that injury to the major blood vessels can be avoided with ordinary care.

Electrical instruments have been devised and sold on the market for the removal of the gonads to take the place of the more commonly used instruments. They have the advantage of cauterizing the tissue to which the gonads are attached and possibly reduce the number of slips. They are not as easy to manipulate as some other instruments and not suitable for use under field conditions where electricity is not available.

The removal of the entire organ is very essential in order to prevent so-called slips. Any fragments which remain intact may result in the proliferation of this reproductive tissue, and the operation will fail to achieve the desired objectives. The secretions from the incised tissues rapidly form hard crusts or scabs. It takes much longer for the healing of the incised tissue to become complete. A certain percentage of operated birds will develop wind puffs which are caused by the air escaping from the body cavity through the intercostal incision becoming enclosed in the subcutaneous tissues. This condition is relieved by puncturing the skin and releasing the enclosed air. The birds should be transferred to clean houses with plenty of clean litter on the floors. They should be confined and kept as quiet as possible

FIG. 38.3 — Ventral view showing the relative position of the gonads to that of the major blood vessels in the operative field. (1) Left testicle slightly posterior to the right. (2) Vena cava formed by the union of the right and left iliacs (3). (4) Dorsal aorta. (5) Coccygeal vein. (6) Mesenteric artery. (7) Operative incision on the right side through which both the gonads are removed. (Kans. Agr. Exper. Sta.)

for a week or 10 days following caponizing, after which they may be given free range and managed to produce the maximum growth and development.

Considerable work has been done in an effort to produce capons by the use of chemicals rather than by the usual operative procedure. Guinn (1944) reported a method which apparently is quite effective and may prove to be of practical importance. Male birds, ranging in age from 8 to 10 weeks, received a highly compressed pellet containing an average of 15 milligrams of diethylstilbestrol implanted under the skin of the neck. An incision

about one-fourth of an inch long was made in the skin of the neck and the pellet was introduced into the incision and pushed about one inch forward from the point of incision. The treated birds gradually lost all male characteristics and to all external appearances and tissue examination could be considered as true capons. There was no recurrence of male characteristics up to the time at which the birds reached 5 or 6 pounds in weight. Mature male birds receiving diethylstilbestrol pellets showed considerable improvement in body fat and quality of meat. Lorenz (1945) and Watel (1948) found that the

subcutaneous implantation of diethylstil-bestrol was much more effective than the oral administration of this agent. It should be remembered that such subcutaneous implants of any product should be made in the discarded or inedible portions of the bird, such as the upper cervical region. The consumption of the tissue containing either a whole or residual diethylstilbestrol pellet might cause an unfavorable reaction in those who consume such material. Lauffer (1957) found that estrogen treatment was superior to caponizing, producing heavier birds in which the finish, feathering, and fleshing were superior.

The U.S. Food and Drug Administration has not permitted the use of diethylstilbestrol in pellet or paste form in poultry since December, 1959. Residues of this chemical were found in the tissues of treated poultry and such poultry products were considered to be unsuitable for food purposes.

Poulardization. Poulardization is the surgical removal of the ovary in birds. This operation has been performed in poultry for many years but is rarely done. Experimental surgery has shown that the removal of the reproductive capacity of birds hastens the growth and improves the quality of the flesh. Apparently poulardization of ducks has gained limited acceptance in the Philippines recently. The operative technique described by Arañez and Saguin (1955) is quite satisfactory, especially in ducks. Undoubtedly, suitable estrogen treatments could be developed which would achieve the same objectives without surgery or the surgical risks involved.

Cecal abligation. The surgical technique developed for this operation has been reported by Durant (1926) for fowls and at a later date for turkeys with reference to the control of blackhead (Durant, 1930). The general procedure is similar to that for caponizing. The incision is made on the left side between the last two ribs, as the junction of the ceca and the intestine is located opposite this point.

The proximal terminations of the ceca can be easily lifted through the incision to a convenient position for ligation. Each cecum is occluded by means of two catgut ligatures about 4 mm. apart as close as possible to the junction of the ceca and the intestine. These ligatures should be drawn tight enough to close the lumen of the ceca, and yet not tight enough to cut through the cecal wall. The organs are then replaced and the incision is closed by a single suture. Durant reported that if the ligature is passed around the two adjacent ribs and drawn tight enough effectively to close the margins of the incision, the subsequent danger of wind puffs is practically eliminated. The ceca do not become necrotic because the blood supply to these organs is not destroyed. Atrophy of the ceca from disuse follows in most instances, and they become scaled pouches suspended on the mesenteric ligaments. Occasionally, both ceca may become greatly enlarged in from 7 to 32 months after the operation. While the complete occlusion of the ceca was effective in preventing blackhead in turkeys, the mortality was so great as to make the procedure economically unprofitable.

The use of aluminum clamps in place of the cecal ligatures as reported by Delaplane and Stuart (1933) reduced the mortality considerably, but this method did not entirely prevent the ceca from resuming their functional activity.

A different operative technique, which proved to be more successful, was developed by Schlotthauer and his associates. They made the abdominal incision, medial and parallel to the left pubic bone, about 1¼ inches in length. A small aneurysm needle was slipped through the mesentery under the ceca near their proximal terminations and the organs exposed through the abdominal incision. A small hemostat was placed across both ceca through the aperture in the mesentery made by the aneurysm needle, and the cecal walls were completely crushed by the hemostats. Silk ligatures were placed above and below the crushing

clamp. No losses were reported from this operation, and the resumption of functional activity of the ceca was not observed.

Egg retention. The retention of eggs in the posterior portion of the oviduct is not uncommon in fowls during heavy production. This condition may be caused by temporary suspension of the normal physiological activity or may be caused by an obstruction. Abnormally large eggs also may be rather firmly lodged in the oviduct, which require manipulation or surgical removal.

In many cases where there is no indication of pathological conditions, the retained eggs may be removed easily without surgical methods. A lubricant such as mineral oil may be introduced into the oviduct. The forefinger is inserted through the vent; gentle pressure on the abdomen is exerted with the other hand forcing the egg toward the vent. In cases involving eggs of excessive size which cannot be removed without injury to the tissues of the oviduct and cloaca, the egg may be moved posteriorly by manipulation to a position where the shell may be seen through the vent. The shell is then punctured with a sharp instrument, after which the egg contents and shell fragments are removed. The cloaca and posterior portion of the oviduct may be irrigated with a cool, mild antiseptic solution to reduce the inflammatory reaction. In cases where it is apparent that tumors are responsible for the obstruction, the fowl should be destroyed.

Removal of eggs from the abdomen. The accumulation of eggs in the abdominal cavity occurs in fowls during periods of high production. The abdomen becomes greatly distended, often reaching the ground (Fig. 38.4A and B). The feathers are removed from the operative field on the abdomen below the vent. The surface of the skin should be cleansed and disinfected with a mild solution of a suitable antiseptic. General anesthesia may be used effectively. An incision about 3 inches long is made through the skin and abdominal wall between the xiphoid terminal of the sternum and the cloaca. The eggs may be removed from the abdominal cavity by manipulation and pressure on the abdominal wall. The incision is then closed by using a continuous catgut suture. McKenney (1929) reports continuous production following a successful operation. Gandal (1960) describes a practical technique for relief of egg-bound birds. For parakeets, canaries, and smaller birds a serrated-tip thumb forceps is inserted into the cloaca in closed position and then allowed to expand slowly to make
FIG. 38.4 — (A) Characteristic posture of hen with ova in the peritoneal cavity before operation. (B) The hen 8 days after operation. (McKenney, Jour. A.V.M.A.)

applied to the wound. Feed and water should be withheld for about 12 hours, after which the bird should be fed sparingly for a few days.

Crop impaction. The ingestion of large quantities of bulky or dry feed frequently results in the overdistention of the crop and the inhibition of the normal physiological activity. In some cases a rubber tube may be inserted in the esophagus, and the injection of water into the crop may soften the crop contents sufficiently to relieve the condition. When the removal of the crop contents is indicated, the operative technique used in the removal of foreign bodies may be successfully employed. In cases of greatly enlarged or pendulous crops, a portion of the wall may be removed before suturing. The postoperative care of the bird is similar to that described in the discussion of foreign bodies. Fisher and Weiss (1956) found that surgical crop removal in chicks had no untoward effect on subsequent growth and development.

Amputation of comb and wattles. The surgical removal of the comb and wattles is commonly known as "dubbing" and "cropping" in poultry practice. Extensive injury, edema, or infection of these appendages indicates removal. The abnormal development of the combs and wattles frequently makes it advisable to remove them in order to prevent possible injury. The operative technique developed by Schalm (1936) has been highly satisfactory. The combs of birds are very vascular,

and their removal may be followed by profuse and often fatal hemorrhage unless proper operative technique is employed. A suitable local anesthetic such as a 2 per cent solution of novocain in combination with adrenalin or another hemostatic agent can be used effectively. A special clamp for this purpose (Fig. 38.5) is applied to the base of the comb and tightened sufficiently to arrest the circulation of the appendage (Fig. 38.6A). The comb is amputated with a scalpel or scissors one-eighth of an inch above the clamp, following the curvature of the clamp. The cut surface is thoroughly seared with a hot iron and the clamp is removed (Fig. 38.6B). The small posterior portion of the comb remaining is removed and seared (Fig. 38.6B). Complete healing follows as a rule in 30 days.

The wattles may be removed with a heavy pair of shears, followed immediately by the application of a suitable astringent such as iron subsulfate. The arterial hemorrhage can be controlled with hemostatic forceps. These operations can be performed at any age, but less hemorrhage is experienced and more rapid healing is observed in younger birds.

Laurent and Carmon (1959) reported a 2 to 3 per cent increase in egg production and lower feed cost following dubbing White Leghorn pullets.

Trimming of claws and spurs. The trimming of the toenails of poultry and pets, including canaries, parrots, and cage birds, can be done easily with heavy surgical shears. The sharp points and edges

FIG. 38.5 — Dubbing clamp.
(Schalm, Jour. A.V.M.A.)
FIG. 38.6 — (A) Cockerel with dubbing clamp applied. (B) Cockerel 24 hours after being dubbed. (Schalm, Jour A.V.M.A.)

should be removed with a flat nail file. The spurs of male birds are frequently removed because of injuries inflicted during fights. During the breeding season injuries to the backs of turkey hens caused by the spurs of the males may be quite serious, and consequently the removal of the spurs is indicated. A pair of canine bone shears is an ideal instrument for this purpose. These appendages can be amputated with little or no hemorrhage if properly done. In turkeys it is well to trim the toenails down almost to the corium. If the toenail should be cut too short, tannic acid powder or any other suitable astringent will effectively control the hemorrhage.

Prevention of spur development. When large numbers of birds in a breeding flock are kept together, it is often advisable to prevent the development of spurs on the male birds. The technique developed by Smith (1932) is simple and effective. This treatment is applied when the spur cap has started to develop and is not over ¼ inch long. Male birds reach this stage of development at 10 to 16 weeks of age, de-

pending on the breed. The spur caps are cut off close to the leg, and a stick of potassium hydroxide is applied and rubbed well into the wound. The cauterizing action of the potassium hydroxide arrests the hemorrhage, destroys the embryonic spur tissue, and prevents the subsequent development of spurs.

Flight control. It is often necessary to arrest the flight of birds either temporarily or permanently. Temporary flight control can be secured by brailing or clipping. Brailing is accomplished by tying one wing closed with a soft cord or bandage. Wing clipping is commonly practiced by poultrymen and consists of cutting the first ten flight feathers close to the wing on one wing only. Clipping is effective in adult birds for a period of about one year while this procedure must be repeated in young birds every month.

The removal of the last segment of the wing at the joint is referred to as pinioning. A tourniquet should be applied to the wing to control hemorrhage. The distal segment of the wing may be removed at the joint with a scalpel or a strong pair

of shears. The wound should be thoroughly cauterized with some good caustic agent to prevent hemorrhage and subsequent infection. This operation should be performed on one wing only and should not be done just prior to or during the breeding season. Sperling and Faber (1951) have recommended wing tip amputation in flight control of game birds.

Permanent flight control may also be obtained effectively by tenectomy, which consists in the removal of a section of the tendon which extends along the under side of the wing and runs parallel to the major blood vessels. Pinioning and tendon resection are recommended for game birds bred in captivity.

Debeaking. The removal of the tip of the upper segment of the beak is known as debeaking. This operation is indicated to control cannibalism and prevent fighting in male birds. The technique developed by Kennard (1937) has been quite effective. The tip of the beak is not cut off but is separated from the deeper structures by traction or tearing. A short cut is made into one side of the beak only, extending into the margin about 1/16 to 1/8 of an inch (depending on the size of the beak) at a point ¼ to ¼ inch posterior to the tip. The flat side of the knife blade is placed against the cut portion of the beak and raised to loosen the edge. The tip is torn off by applying traction toward the opposite side and down toward the lower mandible. This procedure causes little discomfort to the bird and practically no hemorrhage. This removes the tip of the beak, rendering the bird harmless for 2 or 3 weeks. Debeaking does not prevent the bird from eating or drinking nor does it materially affect the egg production in hens. A more recently developed technique, using an improved electrical debeaker, has replaced the surgical removal of the tip of the upper segment of the beak in large-scale poultry production. Debeaking now is a routine process in commercial production, especially the large-scale broiler industry. Lonsdale et al. (1957), Keene et. al. (1959),

and Wyne et al. (1959) found that the removal of one-third of both the maxilla and mandible of day-old baby chicks had no significant effect upon growth and development or feed conversion efficiency. Darrow and Stotts (1954) reported similar experiences. This procedure is effective in the control of various forms of cannibalism.

Draining sinuses of the head. There are several avian diseases associated with infection in the sinuses of the head. In the domesticated fowl the exudate which accumulates in the sinuses rapidly becomes solidified or caseated. In turkeys the exudate remains more or less liquid in form especially in the early stages of sinusitis. The consistency of the exudate can be as certained by palpation of the enlarged sinuses. If the exudate is solidified or caseated, the surgical removal of the exudate and the irrigation of the sinuses are indicated. The incision of the swollen sinus is made at the anterior ventral margin with a pointed scalpel, making an incision from ¼ to ½ inch in length. The exudate may be scraped or curetted out of the sinus and an aqueous solution of silver nitrate applied to the mucous membranes of the sinus. Madsen (1938) reported that a 4 per cent aqueous solution of silver nitrate is slightly more effective than a 2 per cent solution for this purpose. It may be necessary to repeat the application of the silver nitrate solution before the secretion of the exudate is arrested.

The method of treatment recommended by Hinshaw (1937), especially suitable for the treatment of sinusitis in turkeys, consists of the withdrawal of the serous or gelatinous exudate from the sinus with a syringe and hypodermic needle, followed by the injection of silver nitrate solution into the cavities of the sinus. A 5 or 10 cc. syringe fitted with an 18-gauge needle 1½ inches in length is suitable for the aspiration of the exudate from the sinus. The ration of the exudate should be inserted through the skin and sinus membranes into the sinus. The withdrawal of the syringe plunger removes the fluid exudate from the sinus

cavity. About 1 cc. of 4 per cent silver nitrate solution is then injected into the sinus and distributed over the entire surface of the sinus mucosa by gentle massage. Excessive quantities of the silver nitrate solution should be avoided. This method of treatment has been extensively used with satisfactory results. (See sinusitis discussion under turkey diseases.)

Tumors. Neoplastic formations are commonly encountered in poultry practice. According to Feldman (1932), birds are subject to many different types of neoplasms involving practically all tissues and organs. From the clinical standpoint, we are interested in two distinct types—benign and malignant. The benign tumors are localized and develop from a central focus. The malignant tumors spread to the surrounding structures and are capable of establishing multiple foci in the course of their development. Because of the common recurrence of malignant tumors, surgical removal is seldom effective.

Benign tumors may attain such a size as to interfere with the normal physiological processes of the bird. When they occur on the exterior surface or in the superficial structures of the body, they can be removed surgically. Local anesthesia may be employed successfully. The neoplastic tissues are excised and the wounds treated as the local conditions may indicate. Gandal and Saunders (1959) developed a surgical technique for the successful removal of subcutaneous tumors in parakeets. Internal tumor formations are seldom diagnosed in the living bird. In cases where this condition is suspected, it is advisable to destroy the bird.

Fractures. Fractures of the long bones of the wings and legs of birds are not infrequent. Treatment is warranted only in the case of exceptionally valuable birds or in pets. Simple fractures heal readily in a week or 10 days if the fracture is properly reduced and the limb is immobilized. Suitable splints can be fashioned from pieces of light wood, quills, or cork which can be held in place effectively with gauze bandage coated with sodium silicate. In cases of compound fractures, windows may be left in the cast for the purpose of dressing the wound with a powdered antiseptic. Care must be taken not to obstruct the circulation of the limb when applying the splints and bandage.

Blood samples. Blood samples are usually obtained from the wing veins of our domesticated birds. Under certain conditions it is desirable to secure blood samples from various species of the smaller birds. Sooter (1954) used cardiac puncture. McClure and Cedeno (1955) secured blood samples from the right jugular vein. O'Meara (1960) developed a technique by which suitable blood samples could be secured by one person under aseptic conditions. The wings are fastened together above the back with a suitable clamp applied at the primary feather area. The wings are inserted in a narrow slot cut in a cardboard box with the clamp on the underside. The bird's feet may be secured with a cord loop or suitable rubber band placed over the legs. The bird and the support board are placed on a box and the neck of the bird extended over the edge of the support. The suprasternal cleft is cleansed with an alcohol swab, hypodermic needle is inserted and directed from this point posterior and ventral into the heart. The blood sample is slowly aspirated into a small sterile syringe.

Vices and Miscellaneous Conditions

Vices

Vices of poultry are those undesirable behavior patterns manifested by a few or many individuals in the flock which result in injury, death, or economic loss.

CANNIBALISM

Cannibalism occurs in various forms in all breeds of domestic fowl. According to Weaver and Bird (1934), the light breeds of the Mediterranean class are much more susceptible to these vices than the heavier breeds of the American and Asiatic classes.

Causes

Many causes of cannibalism have been suggested but often outbreaks of cannibalism occur in one pen whereas similar environmental conditions or feeding practices in other pens on the same farm do not cause any difficulty. Conditions that have been suggested as predisposing to

cannibalism are: feeding only pellets, cafeteria system of feeding, too much corn, insufficient feeder or drinker space, being without feed too long, not enough nests, nests too light, and too much light in the house (Huston *et al.*, 1956; Ostrander, 1957).

Types of Cannibalism

Picking of the vent or the region of the abdomen several inches directly below the vent is the severest form of cannibalism. This condition is generally observed in pullet flocks in high production. Predisposing factors are prolapsus of the oviduct or tearing of the tissues by passage of an abnormally large egg. Once birds acquire the taste for blood they will continue their cannibalistic habits without provocation. Many poultrymen will pick up dead birds day after day without observing that they have been picked about the vent and in some instances eviscerated.

Feather pulling is most frequently ob-

served in flocks kept in close confinement with lack of sufficient exercise. Nutritional and mineral deficiencies may be contributing factors. Irritation caused by lice and mites may induce feather pulling (see External Parasites).

Toe picking is most commonly seen among chicks. This generally starts because the chicks cannot find feed either because the hoppers are too high, they are too far from the source of heat, or there is insufficient feeder space. It is a common practice to start chicks on paper for the first few days so that they will not eat the litter. This means that there is nothing for the chick to peck at except his neighbor's toes if feed is unavailable. It is a wise practice to put mash on newspapers or on chick box covers and place them under the hover during the first few days of brooding.

Head picking usually follows injuries to the comb or wattles caused by freezing or fighting among males. A different form of cannibalism is now being observed in debeaked birds kept in cages. In this type the area about the eyes is black and blue with subcutaneous hemorrhage, the wattles are dark and swollen with extravasated blood, and the ear lobes are black and necrotic (Fig. 39.1). Even though the birds

are debeaked and kept in separate cages they will reach through the wire and peck at the neighboring bird or they will grasp the ear lobes or wattles of the bird and shake their heads in much the same fashion as a terrier shaking a rat (Angstrom, 1962).

Wing and tail picking frequently follow feather pulling or external injuries. Pin feathers are highly vascular and bleeding follows their removal or breakage. Birds will exsanguinate themselves by continual picking at a feather follicle that oozes blood or by pecking at a small lesion on the foot or other part of the body.

An unusual form of cannibalism was reported in quail by Bass (1939). It has been termed "nose-picking" as the birds peck at the top of the nose where the fleshy portion merges with the beak. The condition is generally seen in birds 2 to 7 weeks of age kept under crowded conditions. If the picking is severe enough the bird will die as the result of blood loss. If the bird survives, the beak will be permanently deformed and the males will be unsatisfactory for breeding stock. This vice occurs only when birds are brooded under artificial conditions. It seldom develops in large pens on the ground in which there is opportunity to pick and scratch. It was observed that the addition of raw
FIG. 39.1 — Cannibalism. This bird was a victim of its pen mates even though they were debeaked. Note black and necrotic ear lobe and blackening around eye and wattles due to subcutaneous hemorrhage.

meat to the ration was very effective in preventing and controlling outbreaks. It may be necessary to withhold the grain ration for a few days until the birds become accustomed to the meat.

Control

In the past, many remedies have been used to stop cannibalism such as hanging cabbages or sugar beets in the pen, putting pine boughs on the floor, painting the windows red, using a red light bulb, darkening the pen and nests, applying pine tar to picked birds, using no-pick salves, using repellent sprays, adding additional salt to the feed or water, and feeding oats. Miller and Bearse (1937) reported that an increase in fibre content of the ration reduced the incidence of cannibalism. Kennard and Chamberlin (1936) reported that feather pulling and other vices in confined birds largely disappeared when the ration was supplemented with oats. Kull (1913) found that cannibalism and feather picking were stopped by the addition of manganese sulfate and horn meal to the mash. Nelson (1956) reported effective results in 21 to 48 hours in many instances by the addition of several vitamin preparations to the feed. Willimon and Morgan (1955) reported that the addition of minor nutrient mineral elements to the ration did not show any consistent effect on feather pulling and cannibalism under experimental conditions. Neal (1956) reported that DL-methionine was effective in controlling cannibalism in laying hens, but Creek and Dendy (1957) claimed their investigations did not indicate that methionine counteracted cannibalistic tendencies.

When cannibalism has become established in a flock the only method to stop it is to apply mechanical devices such as specs or pickguards, or by debeaking. The mechanical devices have several disadvantages because they can only be put on birds of pullet size or larger, they are relatively expensive, and it takes considerable time to put them on. They do have an advantage since the operation needs to be done only once whereas it may be necessary to debeak several times.

Today the most widely accepted means of preventing and stopping cannibalism is debeaking. Debeaking can be done on birds of any age from one day to maturity. Ostrander (1957) described and illustrated in detail the various debeaking techniques. Many broiler growers and some egg producers have their chicks debeaked at one day of age (Lonsdale et al., 1957; Morgan, 1957). Care must be used in debeaking chicks to prevent adverse effects. If the beak is not cut squarely across many chicks will develop cross beaks. About one-third of the upper beak and just the tip of the lower beak are removed. Care should be observed in cauterizing the beak of chicks. Too little cauterization results in excessive bleeding and too much causes necrosis of the tissues. The incidence of "starve-outs" (failure to eat) is much higher in debeaked chicks. Therefore, every effort should be made to have the feed and water readily available for the first few days.

Many poultrymen debeak their laying stock before housing time. This is particularly true where they are kept under close confinement in colony cages. The upper beak is cut and cauterized with the electric debeaker midway between the point of the beak and the nostrils. Some also advocate that the lower beak be cut. If debeaking is done on a flock in production because of an emergency, it is best to debeak only to the "quick." This will usually stop cannibalism but will not upset production. If an electric debeaker is not available this temporary form of debeaking can be done by using a sharp jackknife. A nick is made in the beak about ¼ of an inch from the tip and with the thumb holding the cut portion of the beak against the blade the nick is rolled around the tip of the beak tearing off the horny portion and exposing the "quick." If properly done there is little or no bleeding following debeaking. If birds are debeaked severely the lower beak may grow very
FIG. 39.2—Debeaking. Note how the lower beak has become excessively long following debeaking of the upper beak. This interferes with eating and drinking.

long in time and interfere with eating and drinking (Fig. 39.2). If this occurs it may be necessary to cut off the lower beak to permit the bird to eat and drink properly.

EGG EATING

This costly vice of chickens is similar in some respects to cannibalism in that once a few individuals acquire the habit it quickly spreads throughout the flock. Predisposing factors to egg eating are conditions which favor egg breakage such as inadequate nesting facilities, failure to collect eggs frequently, insufficient nesting material, and soft-shelled or thin-shelled eggs. If a large number of soft-shelled or thin-shelled eggs are being laid, then conditions that may be responsible for these abnormal eggs should be investigated (see the section on abnormal eggs).

The prevention of this vice is best accomplished by eliminating those conditions which favor egg breakage. Stopping the egg-eating habit is very difficult. If the birds have not been debeaked, then debeaking should be done. Once birds have developed a liking for eggs they will not only eat broken eggs but will deliberately eat any egg whether or not it has an intact

shell. Debeaking will make the end of the beak sensitive for a few days and the birds will be reluctant to peck against a hard shell. Darkening the nests by putting bags over the front or end of the nests will aid in stopping the habit. The frequent collection of eggs is mandatory if the egg-eating habit is to be checked.

HIDING OF EGGS

The primitive instinct of wild birds to lay a clutch of eggs or "steal a nest" is often manifested in all breeds of domestic poultry. It happens less frequently with chickens than with other fowl. In commercial flocks the practice rarely occurs, but in the small barnyard flocks, nests are frequently made in the haymow, hay fields, hay stacks, under buildings or woodpiles, or in various outbuildings such as tool sheds. With ducks and geese the practice most commonly occurs in the spring and seems to be a manifestation of the maternal instinct. Confinement of the birds and provision of nests will discourage the habit. The nests should be provided with clean shavings or straw and placed in a secluded spot where they will not receive too much light and should be kept free of mites and

tality from the heat are constant problems, the installation of foggers and sprinklers may be necessary.

Physical Injury

Mechanical feeder trauma. In chicks an unusual injury of the toes is caused by mechanical feeder trauma. This has been observed in flocks where there is no wire guard over the metal thrust rod that pushes against the chain link in the feed trough. The motor operating the movement of the chain runs intermittently and the chicks develop a conditioned response to the sound of the motor as they know fresh feed will enter the beginning of the trough when the motor starts. As a consequence, the chicks crowd around the beginning of the feeder and some of them have their toes crushed between the thrust bar and chain link. There is little or no bleeding associated with the injury and scab formation is followed by gangrene, necrosis, and sloughing of the toe (Fig. 39.3).

Emphysema. Subcutaneous emphysema is caused by an injury or defect in the respiratory tract that permits the accumulation of air beneath the skin (Fig. 39.4). This condition has been observed following rough handling and caponizing. After the caponizing operation the skin incision
FIG. 39.4 — Subcutaneous emphysema. Note ballooning of the skin over the crop, neck, and head region.

may heal before the opening in the body wall with a subsequent accumulation of air beneath the skin. This condition, commonly called a "windpuff" can be alleviated by puncturing the skin with a sharp instrument. In aquatic or flying birds some of the pneumatic bones as the humerus, coracoid, and sternum, may fracture, allowing air to accumulate beneath the skin.

Sternal lesions. Keel bursitis occurs most commonly in *heavy, rapidly growing birds.* Pressure of the keel on the roost causes irritation and inflammation followed by callus formation or infection of the bursa. The accumulation of cheesy exudate caused by the infection produces a blemish resulting in down-grading of the carcass. Van Ness (1946) reported the isolation of *Staphylococcus citreus* from the livers, joints, and sternal bursae of birds with keel bursitis. In this case the birds were injuring the skin on sharp pieces of wire protruding from the floor of the porch. Infection developed at the site of injury and metastasized to various parts of the body. Losses ceased after the sharp ends

FIG. 39.5 — Curvature of the sternum in an adult White Leghorn.

of wire were covered. Curvature or deformity of the sternum is also associated with certain strains and breeds. Nutrition and management may play a role in the development of this condition (Fig. 39.5).

Improper sexing technique. Levine (1952) reported finding ascites, nephritis, and mortality in chicks resulting from physical injury during sexing. Affected chicks were inactive, the skin on the medial aspect of the shanks was wrinkled, and the beaks were bluish in color. These chicks died within 24 to 48 hours. The abdomen was distended with a cloudy but odorless fluid. Marked nephritis was present. Practically all of the chicks had ruptured yolk sacs. In addition there was an ecchymotic, hemorrhagic area in the inner musculature of the pelvis adjacent to the cloaca. It was found that the output of one Japanese sexer suffered a 15 per cent mortality. Losses did not occur in chicks sexed by other workers or in unsexed chicks.

Rupture of the gastrocnemius tendon. An unusual lameness of chickens described

as rupture of the gastrocnemius tendon was first reported in the United States by Bullis and Van Roekel (1944). Subsequent reports were made in Scotland by Harris (1947), in Canada by Chute (1950a and b), and by Jordan (1955) and Carnaghan (1958) in England.

The condition is characterized by an acute lameness of one or both legs. If both legs are affected the bird will rest on its hocks with the toes flexed (Fig. 39.6). At the onset of the condition, affected birds are in good condition, alert, and may even be in production. Harris (1947) indicated that birds three to nine months of age were affected. Bullis and Van Roekel (1944) and Chute (1950a and b) observed that the disease occurred most frequently in birds 4 to 7 months of age which were just starting to lay. The same investigators noted that the fall-hatched chicks had a higher incidence than chicks hatched in the spring.

Bullis and Van Roekel (1944) observed the condition only in females whereas Harris (1947) and Chute (1950a and b) re-

FIG. 39.6 — Ruptured tendons. White Rock unable to stand because of bilateral ruptured gastrocnemius tendons.

ported that males, capons, and pullets were affected. It was noted by Carnaghan (1958) that females were affected at an earlier age than males and this tended to coincide with sexual maturity. Ruptured tendons have been reported in light breeds, heavy breeds, and crosses among heavy breeds.

Harris (1947) reported a flock incidence of 3.8 per cent but Bullis and Van Roekel (1944) reported an incidence of 10 per cent and Chute (1950a and b) reported 15 per cent affected in one flock. In one experiment where the offspring were derived from previously affected parents, Carnaghan (1958) observed 20 per cent of the flock became affected.

Externally the lesion is manifested by a bluish green discoloration of the skin above the hock. It is often possible to palpate a break in the gastrocnemius tendon in the live bird. Fibrosis and thickening occurs

around the tendon in old lesions and indurated areas can be palpated through the skin. The gastrocnemius tendon may have a complete transverse break (Fig. 39.7) or the tendon may have a grey water-soaked appearance. Hemorrhage into the affected area may be slight or extensive.

On histological examination, Harris (1947) noted round cell infiltration in the grossly thickened tendons but none where complete rupture without fibrosis had occurred. Chute (1950a and b) found that muscle fibers were degenerated and some had disappeared adjacent to its tendinous attachment. There was hyaline degeneration of the tendon. Adjacent to this area was a network of collagen which surrounded lacunae containing individual, variously shaped darkly blue staining cells. Proliferating fibroblasts were present which constituted the thickening about the tendon. Upon examination of blood from
FIG. 39.7 — Ruptured tendon. Skin reflected from the hock joint revealing the ruptured and hemorrhagic ends of the gastrocnemius tendon

affected birds, Chute (1950a and b) did not find any abnormalities in the hemoglobin content, red cell count, white cell count, and differential count.

The exact cause of ruptured tendon is unknown. Bullis and Van Roekel (1944) observed the condition in the spring in birds hatched out of season. He suggested that the tendons may lack strength and are predisposed to rupture under the strain of jumping from roosts, nests, or feeders. Chute (1950a and b) failed to find any bacterial agent using aerobic and anaerobic techniques. He discussed three theories as to the possible etiology—nutrition and management, genetics, and predation, but drew no conclusions. The results of Carnaghan's experiment (1958) suggest that a susceptibility to the condition may be inherited. Jordan (1955) was of the belief that genetic factors were concerned in the etiology, although he believed that out-of-season hatching, environmental conditions, and early maturity were contributing factors.

Cranial injury. Injury to the skull and brain is most commonly seen in quail, pheasants, and pet birds such as canaries and parakeets. Quail and pheasant take off from the ground with great thrust and will fly directly into objects under the stress of fear. The force of the impact will cause hemorrhage in the cancellous bone of the skull, and intracranial hemorrhage. Sudden death in a quail or pheasant in excellent physical condition with no evidence of internal lesions or infectious disease should prompt one to examine the skull for injury. Pet birds that escape from their cages or are released for exercise in the house will frequently fly against windows or walls and sustain cerebral injury. The bird does not die immediately but generally succumbs within a period of hours following the accident. The bird may act sleepy or manifest nervous symptoms prior to death. A history of acute death in a well-nourished pet bird with no obvious sign of disease should lead one to investigate the possibility of cranial injury.

Smothering. This condition is generally caused by birds crowding or piling up in a corner. It may occur when birds are moved to new quarters, when they are frightened, or in young birds when they are chilled. The history of the case generally indicates that mortality occurs only at night and the flock in general looks healthy. Smothering of baby chicks can occur in chick

boxes that are piled too high without an air space between each box, or in boxes that do not have sufficient ventilation holes and in boxes that are placed in a closed compartment such as the trunk of a car. Postmortem examination of chicks that have smothered usually does not reveal enough gross pathology to make a positive diagnosis but will aid in the elimination of other possible causes of death. In broilers and older birds that have smothered there is congestion of the trachea and lungs, and the feathers will be worn off the birds where they have been trampled. Smothering of chicks in the brooder house can be controlled by putting a circle of corrugated cardboard around the hover for the first week and gradually widening its diameter as the chicks get older. This will prevent the chicks from piling up in a corner during the night. When birds are moved to new quarters the use of a dim light or lantern the first few nights will decrease the possibility of smothering. Birds transferred to new quarters should be checked late in the evening for signs of piling. Care is important the first few days after acquiring a batch of new chicks or grown birds.

Dehydration. Dehydration can occur in birds of any age. It is generally caused by failure of the birds to find the water, inability to reach the water, and in some cases by a deterring factor in the water. Baby chicks can survive several days without water but will start to die by the fourth and fifth day if they have not taken any water. The mortality will reach its peak during the fifth and sixth days and terminate abruptly thereafter. The chicks that are not drinking will have succumbed by this period and the survivors are those that have found the water and are drinking. Dehydration can be detected in a chick as it is unable to "peep" during the later stages. The chick lacks sufficient weight for its size and age, and the skin on the medial aspect of the shanks is dehydrated and folded. Other changes in a dehydrated chick are a blue discoloration of the beak, the drying and darkening of the breast musculature, darkening of the kidneys, an accumulation of urates in the ureters, and darkening of the blood. Symptoms and lesions in older birds are similar to those in chicks and the loss in weight is more noticeable. To prevent dehydration in chicks the water fountains should be placed at the edge of the hover directly upon the litter without any platform. When a change is made from a small drinker to a larger type or to automatic drinkers, the old type of drinker should be kept for a few days and moved towards the new source of water supply to gradually accustom the birds to the change. When birds are moved from range shelters to laying houses, drinking pans should be placed on the floor for the first few days until the birds become adjusted to their new environment. On occasion an electrical charge may be present in the water caused by faulty electrical heating devices used to prevent water from freezing. The drinkers will be full of water and the owner will be unaware that dehydration is occurring if the system is automatic. Even if the problem of dehydration is made known to the owner he may be unaware of the reason why the birds are not drinking unless he puts his hand in the water. On one occasion a short circuit was occurring in the laying house and the same water pipes also supplied the drinkers on range. The owner put temporary drinkers in the laying house because the birds had become conditioned to the electric shock and refused to drink from the old drinkers. However, he was unaware that the same situation occurred on the range and only after more mortality had occurred and the situation re-evaluated at the laboratory did he come to the realization that the birds on range had also been conditioned by the electric shock and would not drink from the usual pans. Laying birds need a constant water supply or production will drop. Frozen pipelines or frozen water pans are followed by dips in the production charts. Cold weather followed by a drop in production should lead to an investigation of the possibility of a frozen water supply.

Chemical Injury

Brooder stove fuel burns. Bullis and Van Roekel (1944) reported exfoliation of the cranial skin in chicks caused by contact with kerosene or fuel oil. This problem occurred where kerosene or fuel oil brooder stoves had a small leak in the fuel line which dampened the bottom of the pipe. The chicks became exposed by brushing their heads against the pipe. When the cause was explained to the flock owner he usually expressed disbelief until he ran his hand along the bottom edge of the pipe. The kerosene causes irritation and necrosis. An eschar is formed which eventually drops off leaving the surface smooth and devoid of down. The shrinkage of the skin on top of the head produces tension on the eyelids causing distortion and angulation (Fig. 39.8). This combination of bald head and angular eyelids has led to a description of the condition as "china boy" disease. The chicks rapidly recover once the source of irritation is removed.

Dickinson and Clark (1946) reported brooder stove residue burns in turkey poults. The poults came into contact with the tarlike residue that leaked from the pipes of brooder stoves burning gas briquettes. There was severe coagulation necrosis of the skin over the skull and on the back of the neck. It was discovered that exposure to sunlight was necessary for irritation and subsequent lesions to occur. Birds exposed to sunlight would rub the base of the skull and neck over the wings and back. Some birds would shake their heads so violently as to fall over. The intense irritation would cause the birds to scratch almost continually and scratches or lacerations would be produced on the head and eyelids. Birds with severe irritation would quickly get relief when removed from the sunlight. In one experiment, four 6-week-old poults were rubbed with residue on the head and neck. The birds were exposed to sunlight for 2 hours on 4 successive days. Three of the birds died on the fourth day. Four other poults treated with the same material but not exposed to sunlight developed a mild dermatitis but showed no visible signs of discomfort. The condition was readily corrected by confining affected birds for 10–14 days until the lesions healed.

Keratoconjunctivitis caused by ammonia burns. The first description of keratoconjunctivitis in poultry was given by Barber (1947) who observed this condition when birds were reared under unsanitary conditions. Bullis et al. (1950) thoroughly investigated the circumstances under which this condition appeared and drew the conclu-

FIG. 39.8 – Angular eyelids and loss of down on top of the head in the chick on the left caused by kerosene burn. Normal chick on right.
FIG. 39.9 — Photophobia in a chicken with keratoconjunctivitis caused by ammonia burn.

sion that it was caused by exposure to ammonia fumes. Experimental reproduction of the syndrome was carried out by Faddoul and Ringrose (1950). Wright and Frank (1957) recorded the condition in Canada and more recently Saunders (1958) in England described a field outbreak in broilers.

The condition is usually seen in young birds during the winter and spring months. The first symptoms manifested are a rubbing of the head and eyes against the wing. The bird remains quietly in one

spot with the eyelids closed as there is a marked photophobia (Fig. 39.9). Upon close examination of the conjunctiva, edema and inflammation are evident and the surface of the cornea may be roughened or opaque (Fig. 39.10). The center of the cornea may have a shallow ulceration with irregular edges while the remaining area of the cornea is normal in appearance. Generally the condition is bilateral but may be unilateral. In chronic cases, the outline of the eyelids is irregular. Affected birds soon become emaciated because they do not eat.

The condition is apparently caused by continued exposure to ammonia fumes generated by decomposition processes occurring in the droppings (Bullis *et al.*, 1950; Wright and Frank, 1957; Saunders, 1958).

The experimental exposure of birds to ammonia fumes by Faddoul and Ringrose (1950), Wright and Frank (1957), and Saunders (1958) resulted in the production of lesions similar to those occurring in field cases. Prevention of this condition is based on sound management practices with particular attention to ventilation, clean litter, and adequate floor space. Affected birds may take a month or longer to recover even though removed to well-
FIG 39.10 — Corneal opacity caused by ammonia burn.

FIG. 39.11 — Diphtheritic patches in the mouth of a chicken caused by *Spirillum pulli* infection.

ventilated quarters. Under commercial conditions disposal of severely affected birds is indicated.

CONDITIONS AFFECTING THE DIGESTIVE SYSTEM

Stomatitis. Mathey (1956) reported the occurrence of diphtheritic patches in the oral cavity of chickens caused by *Spirillum pulli* sp. *nova* (Fig. 39.11). The organism could be demonstrated in fresh scrapings taken from salivary glands or diphtheritic lesions and examined by dark-field illumination or in Giemsa-stained preparations.

The organism was not grown in pure culture but transmission was accomplished by experimental inoculation of tissue suspensions and by contact.

String eating. Respiratory distress caused by string looped around the base of the tongue and passing down the esophagus has been observed in chickens and turkey poults. Poults are commonly reared in batteries with crinoline cloth covering the floor. Strands of thread protrude from the cut edges and the poults ingest these fibers, some of which are looped around the tongue. Continual swallowing movements draw the string tighter until it cuts into the tissue causing edema of the glottis. Although the condition could easily be alleviated it is usually detected only at necropsy. Chickens frequently pick up the long white strings used to stitch together the tops of feed sacks. The string becomes looped around the base of the tongue (Fig. 39.12) and the bird will keep extending its head and neck in much the same manner as a bird with laryngotracheitis.

Occasionally pieces of grain or pellets become lodged in the larynx or trachea. Frequently they may be retracted through the oral cavity with a suitable instrument. Foreign bodies which cannot be reached in this manner can be removed by tracheotomy. Procaine is suitable for local anesthesia.

FIG. 39.12 — String looped around the base of the tongue and larynx of a chicken.

Beak necrosis. Beak necrosis is practically a condition of the past with our modern feeding practices. It is caused by a gradual accumulation of feed inside the mouth along the edge of the beak. Infection and necrosis gradually occur followed by sloughing of the beak. The condition is more prevalent with finely ground feeds or those that tend to paste when eaten. Supplying finely ground corn or a coarser diet usually corrects the condition.

Curled tongue condition. The first report of this condition was made by Hudson (1939) who reported on a curled tongue condition in turkey poults a few days old (Fig. 39.13). Twenty-five per cent of a flock of 200 poults were affected. The outcome or cause was not discussed.

Grau (1945) first noted that chicks fed a diet deficient in any one of three amino acids (leucine, isoleucine, and phenylalanine) developed a folded condition of the tip of the tongue (Fig. 39.14). He could cure the condition in a few days following the addition of the deficient amino acid to the diet. In the same chicks the folded tongue condition reappeared when one of the amino acids was withheld from the diet.

Sanger et al. (1953) described a curled tongue condition occurring in Broad Breasted Bronze and Beltsville White turkeys over a period of several years. In

FIG. 39.14 – Curled tongue condition in a young chick.

one case the birds received a commercial feed and in another case a home-mixed ration was fed. The condition was first noticed at 10 days of age and by 6 weeks of age 200 in a flock of 4,000 were affected (Fig. 39.15). In addition to its folded state the tongue rested in a submandibular pocket that protruded between the rami of the mandible (Fig. 39.16). Feed adhered to the floor of the mouth in the anterior portion of the intermandibular space. Surgical removal of the curled portion of the tongue did not improve the ventral displacement. Histological examination of the tongue revealed nothing unusual.

The defect in the tongue had interfered with feed intake and affected birds were below normal weight. Although the ration was changed to commercial crumbles at 6 weeks of age, the condition was not improved in affected birds but no new cases developed. It is possible that the pathological change had reached an irreversible state even though the causative factor or factors had been removed.

Scott, in 1951, quoted by Bragg (1953), found a high incidence of the curled tongue condition among poults used in an

FIG. 39.13 – Curled tongue condition in a turkey poult.

experiment testing various high energy ingredients from carbohydrate sources. The leucine, isoleucine, and phenylalanine were calculated to be 1.3 times the known chick requirement and he concluded the curled tongue condition was not caused by an amino acid deficiency in this case but was

FIG. 39.16 — Submandibular pocket caused by ventral displacement of the tongue in a turkey with curled tongue condition. (Courtesy Dr. V. L. Sanger, Dept. of Veterinary Pathology, Ohio State University.)

probably due to a high amount of red dog flour in the ration which caused pasting in the beaks of the poults and caused the tongue to curl back mechanically. He further stated that when the level of red dog flour was reduced or replaced by cornmeal, pulverized oats, or standard middlings, no cases of curled tongue condition occurred.

Bragg (1953) conducted extensive experiments in studying the curled tongue condition in poults and he made several observations. First, that some cases of curled tongue occur at hatching time. He stated, "This may be explained by a fairly rare recessive genetic factor or a genetic difference in the nutritional requirements of the breeding hen, or the differential depletion of nutrients in a few breeder hens in the flock supplying the hatching eggs." Second, a greater incidence of the condition occurs among poults fed fine mash than among those fed a coarser type ration. Third, under normal growing conditions, it appears that the deformity is not caused by a deficiency of the amino acids—leucine, isoleucine, or phenylalanine—in the poults' diet.

Wright and Temperton (1955) in Great

Britain reported that poults of four different breeds and one cross-breed group developed typical symptoms of curled tongue when fed a home-mixed dry mash. The condition also occurred when commercial mash was fed in the dry state. From 5 to 26 per cent of the poults became affected. When the rations were fed in a moistened condition from the time of hatching, only an isolated case of curled tongue was observed. A large proportion of affected poults recovered when a change was made from dry to wet mash feeding. They concluded that the primary cause of curled tongue condition in turkey poults is the feeding of a dry mash of fine physical consistency during the first few weeks of life.

Impaction. Crop impaction occurs when large amounts of fibrous material are ingested (Fig. 39.17). This is apt to occur when birds are first put on range that has long tough grass. If birds are allowed to go without feed for any length of time and there is straw or grass available they will eat this material. In some cases where straw is used for litter, birds will eat this material even though feed is available. The fibrous material will form a ball in the crop and if not too large it will begin to pass through the remainder of the digestive tract. It may become lodged at any point along the digestive tract (Fig. 39.18). Birds with impaction may survive for days but gradually they become emaciated and die of inanition. Early detection of crop impaction can be corrected by surgery. If the condition is allowed to remain too long, atony of the muscles may occur.

Proventricular hypertrophy. A peculiar hypertrophy of the proventriculus in 4-week-old chicks fed a purified diet was reported by Newberne *et al.* (1956). Approximately 15 per cent of the chicks which originated from 3 different sources were

Normal
affected. It was suggested that the condition may have been dietary in origin (Fig. 39.19). The author has also noted unusual enlargement of the proventriculus in chicks fed a commercial ration.

Traumatic ventriculitis. Traumatic ventriculitis is generally caused by a sharp object such as a nail, wire, or stick perforating the wall of the gizzard. Contraction of the powerful gizzard muscle forces the object through the wall (Fig. 39.20). Birds with this condition become emaciated and death follows. Adhesions and inflammatory exudate mark the site of injury (Fig. 39.21).

Intussusception. Intussusception rarely occurs in the fowl. The invagination of the upper portion of the intestine into the lower portion with subsequent circulatory arrest and adhesions of the involved parts makes the diagnosis obvious. The cause is not always apparent but cases have been observed where the birds were affected with ulcerative enteritis and coccidiosis (Fig. 39.22). Birds may show signs of illness for several days before death. If an early diagnosis were made, resection of the affected intestine could be performed.

Typhylitis. Mathey and Zander (1955) described a typhylitis of chickens, turkeys, and pheasants characterized by caseous granulomas (Figs. 39.23 and 39.24). A spirochete which they believed was *Spironema ceci-gallorum* was isolated from the lesions (Fig. 39.25). The organism could not be grown in artificial media but was grown in embryonating eggs. The feeding of cecal tissues containing spirochetes to one-week-old chicks produced cecal nodules 30 days postinoculation. Spirochetes were demonstrated in the lesions of the inoculated chicks. Lesions were not produced with pure cultures.

Anomaly. Occasionally an anomaly of the cecum is encountered in which only one cecum is present with a bifurcation forming two cul-de-sacs at its blind end (Fig. 39.26).

CONDITIONS AFFECTING THE SKIN AND INTEGUMENT

Stunted chick disease. During the decade between 1943 and 1953 a condition in chicks characterized by stunting and mortality during the first weeks of life was of common occurrence. In subsequent years the number of cases has declined according to diagnostic laboratory reports. Typical symptoms reported by Robertson *et al.* (1949) are rough feathering with brittle

and broken primary and secondary wing feathers producing a characteristic ragged appearance. Some chicks have encrustations at the commissures of the mouth and granulations on the eyelids causing them to adhere. Growth is severely depressed (Fig. 39.27). Mortality progressively increases to a peak ranging from 25–75 per cent at about the fourth week. Survivors at 5–6 weeks of age recover and grow normally and at maturity show no ill effects from their earlier condition. Field trials were conducted by Robertson *et al.* (1949) in an effort to find the cause of this condition.

The addition of 5 per cent liver meal or 5 per cent dried brewer's yeast to the ration improved weight gains but did not prevent the condition. Once the condition became established, the injection of 100 micrograms of pantothenic acid or riboflavin had little effect although growth was slightly improved. It was concluded from their field trials that neither feed nor source of chicks appeared to be predisposing factors in the production of stunted chick disease. Angstrom (1962) believed that the problem may have been the result of several factors, primarily mismanagement, rather than a single etiological factor.

FIG. 39.27 — Stunted chick disease. Ragged feathering, granulations on the eyelids and encrustations at the commissures of the mouth in a 19-day-old chick. (Courtesy Dr. P. P. Levine, Dept. of Avian Dis., Cornell Univ.)

of *Ammi visnaga* seeds and subsequent exposure to sunlight caused vesicular dermatitis in chickens and ducks in 4 to 7 days. Birds fed *Ammi visnaga* seeds and shielded from the sun did not develop dermatitis. The lesions and course of the disease were similar to that described by Hoffman (1939) and Perek (1958). Staphylococci and other bacteria were isolated from the vesicles. Subcutaneous and intramuscular inoculations of these organisms produced no visible change. Scab suspensions swabbed on scarified areas on the comb and wattles produced no effect. Trenchi (1962) reported on comparative experimental studies of the lesions produced by ergot poisoning and vesicular dermatitis produced by photosensitization after the ingestion of *Ammi visnaga* seeds. He stated that vesicles were not produced by ergot poisoning and that it took two weeks for lesions to appear in ergot poisoning.

In summary, reports have indicated that vesicular dermatitis may be caused by micrococci, *Lolium temulentum* seeds contaminated with *Cladosporium herbarum*, and photosensitization by ingestion of *Ammi visnaga* seeds and subsequent exposure to sunlight.

Xanthomatosis. This unusual skin condition has been reported in chickens from numerous areas in the United States and from Belgium by Thoonen *et al.* (1959). Hudson (1953) observed three flocks of White Leghorns affected with swollen wattles and cutaneous swellings. Clinical cases and investigational studies were reported by Peckham (1955), Corner *et al.* (1959), Greve and Moses (1961), and Meinecke *et al.* (1962).

The condition has been observed primarily in White Leghorns of varying genetic background. Lesions usually become evident as birds approach maturity at 6–7

FIG. 39.32 — Nodular swellings on the abdomen and thighs of a chicken with xanthomatosis.

histopathologic changes occurring in xanthomatosis. The microscopic lesions vary but all have similarities depending upon the stage of the lesion. Early lesions are infiltrated with vacuolated lipoid-laden macrophages commonly called "foam cells" (Fig. 39.33). Lymphocytes, occurring singly or in clumps, are characteristic and often numerous. A striking feature is the presence of lenticular spaces or clefts produced by cholesterol deposits in the tissue (Fig. 39.34). Multinucleated giant cells may surround the cholesterol crystals. Frozen sections when viewed with polarized light reveal birefringent, rhombic crystals (Fig. 39.35) and the typical "maltese cross" effect of cholesterol esters (Fig. 39.36). Schultze's histochemical test for cholesterol and related substances is positive on frozen skin sections. Cholesterol determinations on the affected skin show a marked increase over normal. Blood cholesterol determinations are normal.

The skin lesions are permanent and affected birds are unfit for meat consumption. Control measures are lacking until more is learned regarding the etiology of this condition.

Bumblefoot. This term is used to designate a localized infection in the foot causing bulbous swelling of the foot pad and surrounding tissues. The condition may be unilateral or bilateral. Generally only a few individuals in the flock are affected but in some cases it is widespread throughout the flock. Infection is believed to occur by means of an injury to the ball of the foot. As the infection progresses, the lesion enlarges and the tissue between the toes become greatly distended (Fig. 39.37). Eventually the swelling will ulcerate through the plantar surface (Fig. 39.38). The birds be-

FIG. 39.37 — Bumblefoot. Marked swelling of the foot pad and surrounding tissues in a chicken.

come lame, have a diminished appetite, and stop laying. Staphylococci may be isolated from the lesion and where ulceration has occurred, mixed infections will be encountered. If treated early, surgery and antibiotic therapy may alleviate the condition. In commercial flocks, disposal of the affected bird is generally indicated.

Plantar necrosis. Angstrom (1961) observed a condition in adult chickens characterized by necrosis and exfoliation of the skin on the plantar surface of the feet (Fig. 39.39). The litter in the pens was wet and filthy and masses of fecal material were caked on the feet. The hardened masses of material on the feet did not allow for normal exfoliation of the epithelial cells and the accumulation of dead tissue and moisture provided a favorable site for growth of organisms of the necrophorus type. When litter conditions were improved the problem stopped.

Abscess of the uropygial gland. The uropygial gland is a sebaceous gland lo-

FIG. 39.38 — Bumblefoot in a turkey with ulceration of the plantar surface.

FIG. 39 39 – Plantar necrosis. Necrosis and exfoliation of the skin on the foot pad and toes of a chicken.

cated on the back of the bird at the base of the tail. Infection of the gland or obstruction of the excretory duct may cause an accumulation of cheesy exudate. When this happens, the area surrounding the gland becomes inflamed and swollen. Incising the area, removing the exudate, and applying an antibiotic will generally cure the condition.

DISEASES OF THE CIRCULATORY SYSTEM

Round heart disease. Matzke (1942) in Germany first reported on "Eierherzen" (egg heart) in chickens. Fischel (1946) reported on cases of "toxic heart degeneration" which he had observed in New Zealand as early as 1941. Luke (1917) in Australia described a similar disease in fowls under the name of "round heart disease." According to Adsersen (1948) the disease has been prevalent in Denmark since 1936 where it is described by the term "yellow heart degeneration." Since these early reports, numerous workers have recorded observing this condition in many countries including the United States.

The disease affects both males and females and manifests an acute or subacute course. Most losses occur following exertion by the birds, and death often occurs in the presence of the owner at feeding time. The birds topple over or fall off the perches and kick aimlessly for a few minutes. In some birds there is a short period of inappetence and cyanosis of the comb before death. Adsersen (1948) reported the highest incidence occurred in Brown Leghorns. Wilson (1957) also noted that the condition occurred most frequently in Leghorn types but had seen Rhode Island Reds affected. Levine (1958) reported two outbreaks in White Leghorns.

Most observers have recorded a seasonal incidence of the disease with the greatest number of cases occurring during the fall and winter months. Levine (1958) however recorded the heaviest losses during July. Mortality is variable but may reach 50 per cent and higher over a period of several months (Fischel, 1946). Pullets are most commonly affected but Wilson (1957) reported having seen the disease in birds varying in age from 8 weeks to over a year.

On postmortem examination the birds are well fleshed with a marked congestion of the venous system. The pericardial sac may be distended with fluid or yellow gelatinous transudate. The heart is enlarged and has a blunt apex that may have whorled indentation at its apex (Fig. 39.40). The myocardium has a parboiled or yellowish appearance with linear streaks running parallel with the muscle fibers. Ascites may be accompanied by a layer of gefatinous transudate over the liver surface.

On histological examination of the heart, Fischel (1946) reported there was a loss of cross striations and pyknosis and karyolysis of nuclei. The muscle fibers had lost their eosinophilic property and there was evidence of granular disintegration. Adsersen (1948) reported fatty infiltration of the myocardium. Wilson and Siller (1954) and Iyer et al. (1959) reported the presence of intranuclear inclusions in myocardial fibers.

The etiology of round heart disease is unknown at the present time. All attempts to incriminate bacterial, viral, fungal, or

FIG. 39.40 — "Round heart" on the right with enlarged and dimpled apex. Normal heart on the left.

toxic agents have failed. Nutritional studies have met with failure. The role of genetics needs further investigation. Wilson (1958) and Levine (1958) have noted that most outbreaks occur on built-up litter, and when survivors of an outbreak were transferred to clean litter they showed a striking and almost immediate improvement. Wilson also demonstrated in two experiments that the disease can be induced in pullets by running them on litter previously used by affected birds.

Hemorrhagic syndrome. In the past decade a condition characterized by hemorrhages and mortality has been seen in chickens with increasing frequency. The first report on this condition was by Baker and Jaquette (1953) who recorded their observations concerning a "hemorrhagic syndrome" in poultry. They indicated that for the 3 years preceding their report an increasing number of birds were submitted to the diagnostic laboratory with unexplainable hemorrhages occurring in various tissues. Goldhaft and Wernicoff (1954) described a similar pathological syndrome and indicated that they had seen the disease as early as 1951.

Clinical signs. The disease has been seen in birds ranging in age from 5–15 weeks with most cases occurring between 5 and 9 weeks of age. Mortality is variable, ranging from a low of 1 per cent to a high of 40 per cent with an average of 5–10 per cent (Baker and Jaquette, 1953; Gray et al., 1954; Goldhaft and Wernicoff, 1954).

Signs manifested by affected birds are paleness or icteric discoloration of the tissues about the head. Hemorrhage may be noted in the anterior chamber of the eye (Fig. 39.41). The feathers are ruffled, the birds act droopy and have a tendency to huddle. A diarrhea has been noted in some cases (Gray et al., 1954; Cover et al., 1955). Washko and Mushett (1955) indicated that the course of the disease was usually about 3 weeks and in many flocks the prime cause of economic losses was decreased feed consumption and poor feed conversion with a resultant delay in marketing.

Gross lesions. At necropsy characteristic findings are hemorrhages in the musculature and viscera. The blood may have a pale, watery appearance. An occasional bird may have hydropericardium (Fig. 39.42). The most constant lesion and of great aid in making a diagnosis, if exten-
FIG. 39.41 — Hemorrhage in the anterior chamber of the eye in a chicken with hemorrhagic disease.

sive hemorrhagic changes have not occurred, is a pale and fatty bone marrow (Fig. 39.43). This change in the appearance of the bone marrow is due to a decrease in hematopoietic elements which are replaced by fatty tissue (Gray *et al.*, 1954). Irregular, scattered hemorrhages may be

present in the breast and thigh muscles (Figs. 39.44 and 39.45). Punctate hemorrhages may be found in the mucosa of the proventriculus at its junction with the gizzard, and hemorrhage may occur beneath the gizzard lining causing blackening and sloughing (Fig. 39.46). In addition, focal hemorrhages may be found in the wall of the crop, and "paint-brush" splotches may occur in the myocardium. The intestine may have punctate hemorrhages in the mucosal and serosal surfaces and on occasion a bloody core is present in the cecum (Fig. 39.47). The presence of blood in the cecum necessitates a differential diagnosis from cecal coccidiosis. A microscopic examination of the cecal contents together with a careful evaluation of the history and other clinical findings should aid in arriving at a diagnosis. Gray *et al.* (1954) reported that subcutaneous hemorrhage of the shanks and feet frequently resulted in the formation of ulcers. Hemorrhages may be present in the liver, spleen, and kidney. The liver may be yellow in color with pinpoint hemorrhages scattered throughout the parenchyma or it may present a reticulated network particularly along the edges (Marthedal and Velling, 1961) (Fig. 39.48). Occasionally a yellow gelatinous transudate

FIG. 39.42 — Hydropericardium associated with hemorrhagic disease.
FIG. 39.43 — Hemorrhagic disease. Pale aplastic marrow in tibia from a chicken with hemorrhagic disease (bottom) contrasted with the dark red marrow in the tibia from a normal bird (top).

may be noted in the subcutis of the neck, breast, and thighs (Hanley, 1962). Baker and Jaquette (1953) reported that the affected birds may have nephritis. Marthedal and Velling (1961) noted hemorrhages and fungal granulomas in the lungs which they regarded as a manifestation of reduced resistance. Gray et al. (1954) noted liver necrosis and intestinal ulcers associated secondarily with the disease during the terminal stages.

Hematology. Gray et al. (1954) observed leukopenia and anemia associated with depressed bone marrow activity. The anemia was the normocytic, normochromic type. Abnormal thrombocytes were consistently observed on blood smears. These cells were enlarged, more circular than normal, and highly vacuolated. Cover et al. (1955) observed similar blood changes and noted that the prothrombin time was never prolonged. Hanley (1962) confirmed the results of earlier investigators and noted that the blood picture showed a reduction in red blood cells, granulocytes, and thrombocytes.

FIG. 39.44 — Hemorrhages in the breast muscle of chicken with hemorrhagic disease.

FIG. 39.45 — Hemorrhages in the thigh and leg muscles of a chicken with hemorrhagic disease.

Histology. Gray *et al.* (1951) reported that the marrow of affected birds was devoid of hematopoietic elements and was replaced with fatty tissue. Most of the sinusoids were collapsed. Hypoplastic bone marrow showed conspicuous reduction of myelocytic elements. In extreme cases, only sinusoidal endothelial cells, interstitial reticular cells, and fat cells were present. A few lymphocytic loci were seen. Cover *et al.* (1955) noted varying degrees of hemorrhage and necrosis in the liver. The parenchyma adjacent to the surface was

most frequently involved. Vessels in the affected area appeared congested and bile stasis was evident. The lymphoid nodules of the spleen had indistinct borders and appeared hypoplastic. Irregular areas of hemorrhage were seen in the red pulp. Hyalinized material was common in the adenoid sheaths and lymphoid nodules. The kidney showed evidence of coagulation necrosis in the tubular epithelium, and infiltration of lymphocytes was frequently seen.

Etiology. There is a lack of general

agreement among the investigators as to the etiology of hemorrhagic syndrome. The pathological and hematological changes of aplastic anemia in cattle caused by feeding trichloroethylene-extracted soybean oil meal are similar to those encountered in chickens affected with hemorrhagic syndrome, and this prompted investigation into the role of trichloroethylene-extracted soybean oil meal in the hemorrhagic syndrome. Pritchard et al. (1952) and Sautter et al. (1952) reported that chickens were unaffected by eating soybean oil meal that was toxic for cattle. Eveleth and Goldsby (1953) reported mortality, retarded growth, pliable bones, and lowered resistance to disease in chicks fed experimentally with a ration containing trichloroethylene-extracted soybean oil meal. Gray et al. (1954) indicated the hematology of birds fed trichloroethylene-extracted soybean oil meal did not indicate the marked depression in numbers of blood cells found in birds severely affected with the hemorrhagic syndrome. Baker and Jacquette (1953), Gray et al. (1954), and Washko and Mushett (1955) reported hemorrhagic syndromes occurring in flocks that had not been fed trichloroethylene-extracted soybean oil meal.

All attempts to isolate or demonstrate an infectious organism from cases of hemorrhagic syndrome have been unsuccessful. Baker and Jaquette (1953) indicated that culture and embryo inoculation trials were negative. Cover et al. (1955) failed to transmit the syndrome by parenteral inoculation of chicks with blood, liver, spleen, and kidney from affected chickens. Embryo inoculations with tissues from affected birds were negative. Washko and Mushett (1955) reported that cultural examination of blood and tissues failed to yield an etiological agent. Hanley (1962) reported that aerobic and anaerobic culture attempts and bird inoculation trials were negative.

The significance of vitamin K in the role of hemorrhagic syndrome is not fully understood. Baker et al. (1953) reported that the addition of alfalfa leaf meal to the ration was of no benefit. Gray et al. (1954) stated that they could not relate some of their findings to vitamin K deficiency. Cover et al. (1955) made a detailed comparison of hemorrhagic syndrome and experimentally produced vitamin K deficiency. They noted that birds affected with hemorrhagic syndrome did not have the increased prothrombin time and massive hemorrhages found with vitamin K deficiency. They concluded that a comparison of the two syndromes showed them to be definitely distinct and dissimilar. Washko and Mushett (1955) found that prothrombin times and whole blood clotting times were within normal limits in most cases. Hence they did not consider it likely that vitamin K deficiency per se could be responsible for the hemorrhagic syndrome.

The role of toxic fungi in the hemorrhagic syndrome has been investigated by Forgacs and Carll (1955) and Forgacs et al. (1955, 1958, 1962). They stated that one of the paramount features of the hemorrhagic syndrome is the variability, both within and between affected flocks, in epizootiology, clinical symptoms, hematologic findings, course of mortality, and pathologic changes. They noted that these variations are strikingly similar to those observed among other hosts afflicted with known mycotoxicoses. Forgacs and Carll (1955) isolated various fungi from feed scattered in the litter of broiler houses where the hemorrhagic syndrome was enzootic. Some of these fungi, when cultured on a mixture of grains and subsequently dried, ground, and fed to one-day-old chicks, caused morbidity and mortality. At necropsy, hemorrhages were found in the subcutaneous tissue, skeletal muscles, heart, gastrointestinal tract, liver, and kidneys. Forgacs et al. (1958) reported attempts to produce the hemorrhagic syndrome in chickens under simulated field conditions. The chicks were placed on wood shavings and fed a broiler mash inoculated with a 0.5 per cent mixture of dry fungal substrate. The birds maintained on such litter manifested depres-

sion and diarrhea, and, on necropsy at the end of eight weeks, lesions similar to those of the hemorrhagic syndrome were found. The results of these studies indicate that the role of fungi in the hemorrhagic syndrome needs further investigation.

The widespread use of coccidiostats and the appearance of hemorrhagic syndrome occurred almost simultaneously. This observation prompted investigation into the role of coccidiostats in the hemorrhagic syndrome. Baker and Jaquette (1953), Cover et al. (1955), and Goldhaft and Wernicoff (1954) reported the occurrence of hemorrhagic syndrome in flocks that had not received sulfonamide medication. However, Gray et al. (1954) and Martheal and Velling (1961) indicated that in their cases of hemorrhagic syndrome the flocks had been treated with sulfaquinoxaline or other coccidiostats. In the author's examination of cases of hemorrhagic syndrome submitted to the diagnostic laboratory for the past ten years, most of the cases and particularly the severest cases have been associated with sulfonamide medication. That the condition is not a simple case of sulfonamide intoxication per se is indicated by the many flocks not showing hemorrhagic syndrome yet receiving the same amount of medication as affected birds.

Experiments have been conducted indicating that flocks can tolerate amounts of sulfonamides in excess of those used in feed as coccidiostats. Cuckler and Ott (1955) reported that the continuous administration of 0.05 per cent sulfaquinoxaline in the feed or of 0.025 per cent in water for as long as 12 weeks had no adverse effects on chickens. Gerry and Witter (1952) reported that histopathological examinations of tissues from 9-week-old birds fed 0.3 per cent sulfaquinoxaline in the mash for 3 weeks did not reveal any evidence of toxicity. However, the chickens fed this level of medication did not grow as well or make as efficient weight gains as the unmedicated controls. Sanger et al. (1956) reported that in their observa-

tions where certain drugs had been used, especially sulfonamides, the hemorrhagic syndrome suggested a manifestation of drug allergy

All cases of hemorrhagic syndrome have not been ascribed as being due to a single cause. It may be that similar clinical and pathological syndromes may be produced by different causes acting independently or simultaneously.

Control. In the light of our present knowledge, only certain precautionary measures can be suggested with no assurance that hemorrhagic syndrome will be prevented or cured. The use of coccidiostats, particularly sulfonamides, should be attended with caution in respect to dosage and duration of treatment. If there is gross evidence that mold is present in the feed hoppers or litter, corrective measures should be taken to eliminate this possible source of trouble. Although supplementary feeding of vitamin K in the form of alfalfa leaf meal or menadione bisulfate has been used in cases of hemorrhagic disease, there is no controlled evidence that this treatment has been successful.

Endocarditis. Vegetative endocarditis is rarely reported in the records of diagnostic laboratories. It probably would be found more frequently if the hearts of all birds necropsied were carefully opened. Kernkamp (1927) mentioned vegetative endocarditis as being associated with streptococcic peritonitis of chickens. Dauber and Katz (1943) reported vegetative endocarditis on the aortic and mitral valves associated with extensive pericarditis. The etiology of the pericarditis was undetermined and cultural attempts were not made. Most of the hearts affected with vegetative endocarditis were enlarged. On histological examination the vegetations were found to contain masses of bacteria and fibrin.

Povar and Brownstein (1947) described a large number of cases of valvular endocarditis observed during routine postmortem examination of birds dying from miscellaneous conditions on a large breed-

ing farm. Approximately 15 per cent of 551 females over 40 weeks of age had some degree of valvular endocarditis. Only 3 per cent of the birds between 10 weeks and 40 weeks of age were affected. It was noted that birds affected with chronic infections had a significantly greater incidence of valvular endocarditis than did birds dying of all other causes. Birds with salpingitis had the highest percentage of valvular endocarditis. Birds with hepatitis had the second highest percentage of heart lesions, and birds with lesions of bumblefoot ranked third in percentage of lesions.

They described the lesions as variable in size from small, punctiform, edematous nodules to yellowish, friable masses three-fourths of a centimeter in diameter. The smaller lesions lined the edge of the valves in a glistening row. The larger lesions were caseous and extremely friable. The semilunar valves of the pulmonary artery were most often affected followed by the right atrioventricular valves and the semilunar valves of the aorta in frequency. The left atrioventricular valves were affected with the lowest frequency but had the largest lesions. Cultures from the heart valve lesions yielded staphylococci and streptococci.

Gross and Domermuth (1962) reported the experimental production of endocarditis in chickens and turkeys by the intravenous inoculation of cultures of *Streptococcus faecalis*, *Staphylococcus aureus*, and *Pasteurella multocida* isolated from the livers of naturally infected birds. Bacteremia was followed by valvular lesions, and later infarcts were produced in the liver, spleen, and myocardium. The peak of mortality in birds with endocarditis occurred between the fifth and sixteenth day post inoculation.

DISEASES AFFECTING THE KIDNEYS

Cysts and agenesia. The kidneys occasionally have small cysts 5 mm. in diameter containing a clear amber-colored fluid distributed throughout the parenchyma. Rarely, a single large cyst may involve the kidney. It is not unusual to find agenesia

of one kidney in a healthy bird. The one remaining kidney apparently compensates for the added load and the bird is not unduly handicapped. The kidneys are frequently the site of tumors and inflammatory conditions associated with specific diseases. These conditions are discussed in their appropriate chapters in the text.

Avian nephrosis. Cosgrove (1962) reported his observations on a new syndrome in broilers occurring in the Delmarva Peninsula area. The condition has been termed "Gumboro disease" because of the prevalence of the disease in broilers in the vicinity of the town of Gumboro. The disease was first observed in 1957 and an increasing number of cases have been seen since that time.

Clinical signs. In a typical outbreak 10–20 per cent of the flock may be suddenly affected. An early sign is a watery, white diarrhea with soiling of the feathers in the vent region. This is followed by anorexia, depression, trembling, unsteady gait, prostration, and death. The mortality may range from 1 to 10 per cent. In the terminal stages, trembling of the neck and body is pronounced. The shanks show evidence of dehydration. Birds 2–15 weeks of age may be affected with most cases occurring at 5 weeks of age.

In a given group of birds the disease runs its course in 5–7 days. The disease spreads slowly from one pen to another. In some outbreaks the disease may affect only one pen. Outbreaks tend to reoccur on the same farm. The mortality ranges from 1 to 15 per cent with an average of 5 per cent.

Lesions. The most prominent and constant lesion is renal damage. In birds necropsied early in the course of the disease the kidneys may be nearly normal in color with only slightly visible tubules. In advanced stages of the disease the tubules and ureters are distended with urates and the kidneys are pale and enlarged. The degeneration and dysfunction of the kidneys is manifested by urate deposits on the serosal surfaces of the viscera in some birds. A catarrhal enteritis is present. There is

enlargement of the bursa of Fabricius which may have a white central core. The liver may have infarcts along the edges. Hemorrhages may be present in the leg and thigh muscles. The skeletal muscles show evidence of dehydration. Histopathological changes of the kidneys are cloudy swelling of the tubules. Winterfield and Hitchner (1962) indicated that both nephrosis and nephritis have been observed on microscopic examination. Blood studies indicate a low serum calcium and increased uric acid.

Etiology. Winterfield and Hitchner (1962) reported the isolation of two viruses which induced nephritis and nephrosis in chickens when inoculated in the eye. One virus was isolated in 1954 from the intestinal tract of a chicken with catarrhal enteritis. Other birds in the flock from which the original virus was isolated had intramuscular hemorrhages suggestive of hemorrhagic disease. The second virus was isolated from the kidneys of a 9-week-old bird which came from a flock with signs of nephrosis. This flock was vaccinated with infectious bronchitis vaccine at 1 week of age. When chicks were inoculated with either of the two virus isolates, mild respiratory symptoms were produced, mortality was low, and some birds had gross kidney lesions. By using serologic and cross-immunization studies, these isolates were determined to be related immunologically to known infectious bronchitis strains.

Gout. Although not of common occurrence gout has been observed in both young and mature turkeys and chickens (Jungherr, 1935; Schlotthauer and Bollman, 1931a). The predisposing factors are not always known but some cases have been associated with conditions that impose a stress on the kidneys such as a high protein diet, sodium bicarbonate intoxication, vitamin A deficiency, and bluecomb disease. The articular or visceral form may occur singly or in combination. Schlotthauer and Bollman (1931b) produced articular gout in turkeys by increasing the protein level of the feed to 40 per cent with the addition of horse meat and 5 per cent urea. Gout tophi appeared on the feet of those birds in which the blood values for uric acid were 15 mg. per cent for at least two weeks. In articular gout, urate deposits may occur on the articular surfaces and in the periarticular tissues (Fig. 39.19). Bullis and Van Roekel (1944) observed visceral gout in chicks less than 3–4 days of age. The losses were usually less than 5 per cent and the cause was unknown. In the visceral form, the kidney tubules are distended with urates and white deposits of uric acid crystals may be found on the surface of the viscera (Figs. 39.50 and 39.51). Lloyd *et al.* (1949) reported ex-

FIG. 39.49 — Gout in a mature hen. Urate deposits in toes, feet, joints, and tendon sheaths.

FIG. 39.50 — Visceral gout. Urate deposits in the kidneys of a chicken.

perimental production of articular gout involving the feet of young poults fed a 38 per cent protein ration (Fig. 39.52). The birds gradually recovered after the protein level was reduced to 20 per cent. The condition did not occur in groups fed a lower level of protein.

Snoeyenbos *et al.* (1962) reported naturally occurring gout in a flock of 400 eleven-month-old Broad Breasted White turkeys. About 20 per cent of the group were affected including both males and females. The flock was provided with adequate feed and water. The birds had been

eating a 20 per cent protein feed for 6 weeks. At necropsy, numerous tophi were observed in the periarticular tissues of the feet and uric acid crystals were present in the tendon sheaths and joints of the wings, hocks, and feet. Urate crystals and erosions were present on some of the articular surfaces. Serum uric acid levels were above 15 mg. per cent. Colchicine was fed to affected birds at a level of 0.4 mg. per pound of body weight per day for a week but this treatment failed to lower serum uric acid levels or alter the course of the disease. This dose was about 8 times the
FIG. 39.51 — Visceral gout. Urate deposits on the surface of the liver and heart.

FIG. 39.52 — Swelling of the foot and toes in a turkey poult affected with gout.

maximum dose necessary to control the disease in man. The flock was placed on a 15 per cent protein ration for 11 days and then returned to the original ration. One month after the first signs were noted, the flock appeared to have recovered except for 6 severely affected birds. Egg production and hatchability were normal.

REPRODUCTIVE DISORDERS

Cystic right oviduct. In the developing female chick two ovaries and two oviducts are present. As the bird matures the left ovary and oviduct become functional and the right ovary and oviduct remain immature. However, there have been reports of finding two functional oviducts in fowl.

Of common occurrence is a cystic right oviduct. This structure may vary in size from a small one-inch elongated cyst (Fig. 39.53) to a ballooned sac containing a pint of clear watery fluid. The small cysts are of little consequence but large cysts compress the vital organs. Ascites, the accumulation of fluid in the abdominal cavity, is colloquially termed "water-belly" by poultrymen. In addition to a cystic oviduct, ascites may be produced by pathological conditions involving the heart, kidneys, liver, and mesentery.

Cystic left oviduct. Goldhaft (1956) reported the occurrence of massive cysts in the left oviduct and the dorsal ligament of the oviduct in a flock of White Leghorn
FIG. 39.53 — Cystic right oviduct in a chicken.

pullets. Where cysts occurred in the oviduct the anterior and posterior portions of the oviduct were normal but the middle of the oviduct was a blind sac distended with over a pint of clear fluid in some cases. It was estimated that 5 per cent of a flock of 2,800 seven-month-old birds were affected with these cysts during the previous 30-day period. The cause of the high percentage of cysts in this flock was not determined. Hutt et al. (1956) also observed discontinuous cysts in the oviduct similar to those described by Goldhaft (1956). They postulated that discontinuity of the oviduct probably resulted from accidental degeneration of part or parts of the Mullerian duct during the development of the embryo. They also described another defect in which the anterior end of the oviduct was closed by cohesion of the lips of the infundibulum causing a cystic oviduct.

Atresia of the oviduct. Finne and Vike (1951) described hereditary atresia of the oviduct in the region of the isthmus. The layers looked normal but the yolks were discharged into the body cavity. Peritonitis developed and the birds usually died at 5 to 6 months of age shortly after coming into production.

False layer. The term "false layer" has been used to describe the bird which looks like a normal layer but in reality does not lay eggs. Hutt et al. (1956) described the ovulating nonlayer hen as a bird that has the external characteristics of a layer, visits the nest regularly, yet does not lay eggs, as verified by trap nest records. This bird has a normal appearing ovary and oviduct but the infundibulum fails to engulf the ovum after it has been ovulated. These birds are excessively fat and have liquid or coagulated yolk in the body cavity.

Low production as a sequel to infectious bronchitis. Broadfoot et al. (1954) reported that natural infection of chicks with infectious bronchitis during the first week of age may interfere with later egg production. Flocks 7 months of age that had bronchitis as chicks were laying only 50 per cent whereas birds of the same breed-

ing that did not have bronchitis as chicks were laying at a normal rate. The birds in the poor laying flock looked healthy and had the appearance of good layers. Trapnesting records of the flock for 14 days showed that 43 per cent of the birds visited the nests on three to five successive days without laying. Some of these birds visited the nest as many as three times in a single day. Postmortem examination of 26 of these birds revealed that the viscera was surrounded by a heavy layer of mottled oily fat. Cheesy yolks with roughened and pitted surfaces were found in the body cavity. The oviducts were not full size and many were less than 20 per cent normal size. The striking fact about these birds was that the ovaries were found to be fully active. In a subsequent report, Broadfoot et al. (1956) experimentally infected chicks of different ages with virulent bronchitis virus and vaccine strains of bronchitis. The results of these experiments confirmed their field observations that exposure to virulent bronchitis virus during the first week of age produced an increasing number of false layers at maturity, and chicks exposed to a mild vaccine strain of bronchitis virus did not experience an adverse effect on egg production at maturity.

Impacted oviduct. Occasionally an impacted oviduct is observed in which the oviduct is occluded by masses of yolk, coagulated albumen, shell membranes, and, in some instances, fully formed eggs. Large masses of yolklike material may be found in the oviduct and upon transection these masses have the appearance of concentric rings.

Internal layer. In some birds soft-shelled eggs or fully formed eggs may be found in the peritoneal cavity. This indicates that the yolk progressed normally through the oviduct to a certain point and then reverse peristalsis discharged the egg into the body cavity. A bird with a large accumulation of eggs in the peritoneal cavity may assume a penguinlike posture.

Egg bound. "Egg bound" is the term used to describe the condition where an egg is lodged in the cloaca but cannot be

laid. It may result from inflammation of the oviduct, partial paralysis of the muscles of the oviduct, or the production of an egg so large that it is physically impossible for it to be laid. Young pullets laying an unusually large egg are more prone to an egg bound problem. This condition may be relieved by inserting a lubricated finger into the cloaca and exerting pressure on the abdomen with the other hand. If expulsion of the egg is not possible in this way then the egg may be held in position at the vent opening and the shell can be broken with a sharp object and the contents and pieces of the shell removed. If the chicken has been egg bound for a considerable period of time before the condition is detected there is apt to be an eversion of the cloacal tissues after the egg is removed. The blood-stained tissues invite cannibalism and the bird should be placed in separate quarters until fully recovered.

Ovarian disorders. The ovary reflects the general health of the mature bird. Many infectious diseases and physiological disturbances immediately produce retrogressive changes in the ovary. The normal, yellow, turgid ovum may become wrinkled and the contents almost black with hemorrhage. At other times the yolk is coagulated or "cooked" in appearance. Discolored, pedunculated, and inspissated ova are the hallmark of pullorum disease. Cauliflowerlike growths from the ovary are indicative of lymphomatosis. Multiple cystic ova filled with clear fluid may occur occasionally.

Abnormal eggs and depressed production. Eggs differing in size and shape may be laid in any flock but in the average healthy flock there is remarkable uniformity of the eggs. There are a number of conditions which affect shell quality, internal quality, and rate of lay. Wilson (1949) found that environmental temperatures had a marked effect on the strength and thickness of the shell. As the temperature rises above 70° F., the blood calcium drops progressively; at 100° F. the shell averages about two-thirds the normal thick-

ness. This would explain why the eggshell is thicker and stronger in the winter months. Increased humidity also has an unfavorable effect on shell thickness but not as marked as increased temperature. Jull (1930) indicated that the production of soft-shelled eggs is most prevalent in the spring when production is at its peak. Respiratory diseases such as infectious bronchitis and Newcastle disease may affect the size, shape, shell texture, and internal quality of eggs (Gordeuk and Bressler, 1950; Biswall and Morrill, 1954).

Mann and Keilin (1940) reported sulfanilamide to be a very powerful inhibitor of the enzyme carbonic anhydrase. Since then several reports have appeared in the literature describing the inhibitory effects of certain sulfonamides on the formation of eggshells. Hinshaw and McNeil (1943) found that a single dose of sulfanilamide, 0.5 grain per pound of live weight, caused turkeys to lay eggs with very thin shells or eggs without shells the next day. When they fed 1.5 grains of sulfanilamide per pound of live weight to leghorn hens, the same result was produced. This inhibitory action of small dosages of sulfanilamide on the secretion of shell material was confirmed by Benesch et al. (1944), Gutowska and Mitchell (1945), and Tyler (1950). Scott et al. (1944) observed that in addition to thin shells, sulfanilamide also caused a bleaching of the pigment in brown eggs. Bankowski (1948) reported a decrease in egg production following sulfamerazine and sulfamethazine medication. Mehring et al. (1955) reported that two unsubstituted sulfonamides, Diamox and benzenesulfonamide, caused pullets to lay eggs with very thin shells or with no shells beginning with the first egg laid after the initial dose. Nicarbazin, a coccidiostat, may cause mottled yolks, loss of shell pigment, decreased egg size, and low egg production (Weiss, 1957; Baker et al., 1957). Arasan, a fungicide used in the treatment of seed corn, has been reported to cause misshapen and soft-shelled eggs, retarded production, and finally complete cessation of production (Waible et al., 1955; Johnson et al., 1955).

Trematodes and ascarids sometimes enter the cloaca and pass up the oviduct where they are swept along with the yolk and albumen and become encased by the shell.

Cloacitis. Cloacitis, or vent gleet as it is commonly known, is a chronic inflammatory process of the cloaca with a very offensive odor. A yellow diphtheritic membrane may form on the mucosal surface of the vent and urates and inflammatory exudate contaminate the skin and feathers beneath the vent. The disease is more common in laying hens than in males. A very small percentage of birds in a flock are affected at one time and the disease does not appear very contagious. The specific cause of this disease is unknown. Transmission experiments carried out by Gwatkin (1925) and Scherago (1925) were unsuccessful. Removal of affected birds is advised in commercial flocks. Valuable birds can be treated by cleansing the affected area and applying a broad-spectrum antibiotic in dust or ointment form.

Cage layer fatigue. The marked increase in the number of birds kept in cages during the past decade has given rise to a new problem. The condition, called cage layer fatigue, is characterized by inability of the birds to stand and marked fragility of the bones (Fig. 39.54). The bones are not soft but are exceedingly thin and break or splinter at the slightest pressure. In addition to paralysis, the rearing of birds in cages has created a marketing problem. The marked fragility of the bones results in fractures when the birds are removed from the cages and more injury occurs when the birds are subjected to the pounding of the picking machines in the dressing plants. The bone splinters become lodged in the meat, creating processing problems.

It has been observed that birds will recover in 4-7 days if removed from the cages and placed on the floor (Couch, 1955). Francis (1957) noted significant differences in the incidence of cage layer fatigue between various strains. During a 10-week observation period 0.65 per cent of one strain was affected compared to a high of 3.95 per cent in another strain. Eighty per cent of the birds recovered when removed from the cages. Couch (1957) stated that bone ash, blood calcium, and blood phosphorus values on selected early cases were all within the normal range which would differentiate the condition from rickets. According to Grumbles (1959) this condition occurs more often during the summer months in young pullets that are producing at a high rate and have a good feed efficiency ratio. The percentage af-

FIG. 39.54 — White Leghorn affected with cage layer fatigue showing characteristic squatting position.

fected will vary from 1 to 20 per cent. Fisher, quoted by Grumbles (1959), stated that in his experience, cage fatigue has not occurred when the calcium level of the diet was maintained at 2.5 per cent.

CONGENITAL AND INHERITED CONDITIONS

Congenital loco. Durant (1926, 1927) first noted this nervous disorder in newly hatched White Leghorn chicks. Subsequently, Knowlton (1929) conducted breeding trials and concluded that the defect was inherited as a simple Mendelian recessive. An apparently identical syndrome was reported in turkey poults by Cole (1957). After a thorough investigation of the genetic factors involved he concluded that the condition was an obligate postnatal lethal syndrome caused by the homozygous state of the recessive gene *lo*. Hatchability is not affected and the poults are in excellent physical condition. Symptoms manifested are opisthotonus, or sagging of the head and neck until the beak touches the floor. The birds can stand normally for only a few seconds at a time and then in-

voluntarily or in response to external stimuli they thrust themselves vigorously into a backward somersault. They lie on their backs or sides kicking aimlessly (Fig. 39.55). The anatomical defect responsible for this syndrome is unknown. The brain appears normal upon gross and microscopic examination. Affected birds die since they are unable to eat or drink.

Congenital alopecia. Congenital alopecia is occasionally encountered in newly hatched chicks. Certain avian hybrids develop a partial alopecia which is characteristic of the cross breeding.

Congenital opisthotonus. Caskey *et al.* (1944) described congenital opisthotonus occurring in chicks at hatching due to manganese deficiency in the maternal diet. The symptoms persisted at maturity even though adequate manganese was given. The progeny resulting from the mating of affected males and females did not manifest opisthotonus thus indicating it was not an inherited characteristic.

Cerebellar hypoplasia. Avian cerebellar hypoplasia and degeneration according to Winterfield (1953) is probably an inherited

FIG. 39.55 — Congenital loco in turkey poults. Affected birds manifest opisthotonus and thrust themselves over backward.

defect. The condition was first observed in 12-week-old pullets in 15 different flocks with 3 to 10 per cent becoming affected. Affected birds did not die and came into production at 6 months of age. Symptoms were weaving and bobbing of the head, and when the birds were excited they became ataxic. Gross pathology was confined to the cerebellum which was about one-fourth normal size. Neuronal degeneration was present in the cerebellar cortex and there was degeneration and disappearance of the Purkinje cells. In England, Markson et al. (1959) described a similar condition affecting Light Sussex pullets.

Crooked toes. Crooked toes may occur in young or adult birds. This condition should not be confused with "curly toe paralysis" which is caused by riboflavin deficiency. In the crooked toe condition the toes have a lateral curvature but the bird still walks on the plantar surface of the foot (Fig. 39.56). However, in "curly toe paralysis" the toes curl under and the bird walks on the dorsal surface of the toes. Birds with riboflavin deficiency have difficulty in walking and rest on their hocks when not trying to walk. In "curly toe paralysis" a histological section of the sciatic nerve will enable a positive diagnosis to be made.

The tendency for crooked toes is inherited and any birds so affected should not be used for breeding. Black et al. (1952) reported strain differences in the manifestation of crooked toe condition in chicks when brooded under the bright emitter type of infra-red lamp. Chicks from one strain manifested none of the abnormality whereas 100 per cent of the offspring from crooked-toed parents of another strain had crooked toes when brooded under infrared lamps. However, when the two stocks were reared under ordinary electrical heating, crooked toes did not develop in either strain. This is an example of the interactions which frequently occur between inheritance and environment. Rearing chicks on a smooth surface such as a newspaper will increase the number of cases of crooked toes if the birds carry this genetic defect. Crooked toes are under the influence of genetic factors; however, these genes express themselves differently in various environments.

Scoliosis. This condition commonly spoken of as wry neck is characterized by torsion and lateral curvature of the neck (Figs. 39.57 and 39.58). It is most commonly observed in birds of growing age

FIG. 39.56 — Crooked toe condition in a three-week-old chick.

FIG. 39.57 — Wry-neck condition in a young chicken.

FIG. 39.58 – Wry neck. Same chicken as Fig. 39.57 with neck exposed revealing torsion and lateral deviation.

and usually only an occasional bird in a flock is affected. Although birds with this affliction manage to eat and drink without too much difficulty it is generally best to remove them from the flock.

Coloboma of the iris. This condition is manifest as a unilateral or bilateral teardrop shape of the pupil or as a circular pupil with a defect in the iris. Wilcox (1958) presented evidence that the condition was inherited in White Leghorns by finding coloboma in 22 per cent of the offspring obtained from mating affected birds. Because of the dark pigmentation of the iris in chicks the defect was not readily discernible until six weeks of age. The defect was much more obvious when observed in bright light in which the iris was maximally constricted. In some of the offspring without coloboma, a pronounced bulging of the cornea occurred presumably from increased intraocular pressure in the anterior chamber of the eye. In one case bulging developed in an eye previously classified as coloboma. Another abnormality observed occasionally in this stock was a sunken eye, which was reduced considerably in size. Recognition of the existence of coloboma in chickens is important in making a differential diagnosis of ocular lymphomatosis. A histological examination of the eye would enable one to differentiate between these two conditions.

Poisons and Toxins

The literature contains many reports of acute and chronic poisoning of birds due to the ingestion of toxic substances, but the losses from these conditions are insignificant compared with the losses experienced from various other diseases. The majority of cases of poisoning are accidental or due to a poor system of management. When birds are confined to small units or the supply of natural food on the range is limited due to unfavorable weather conditions, they may consume any succulent food available regardless of its palatability or toxicity.

Losses in birds may be attributed to autointoxication, bacterial intoxication, and poisoning by drugs and chemicals, as well as by various phytotoxins, insects, and food constituents. Some of these agents are comparatively rare, and little is known

about them, but the more common ones have been investigated, and the toxic as well as the lethal dosages have been determined. In cases of poisoning in birds, positive diagnoses in most instances are made too late for effective treatment, but if the cause is definitely established, it may be removed and further losses avoided.

The body defenses which act to destroy the toxic action of poisons vary considerably in different animals. There is also a variation in the tolerance of certain species for toxic agents. As the result of extensive investigations, Sherwin and Crowdle (1922) found that the action in the bodies of fowls was similar to that of other animals regarding the detoxication of various poisonous substances.

AUTOINTOXICATION

Autointoxication may be defined as self-poisoning due to the absorption of the waste products of metabolism or of the products of decomposition within the in-

testine. In young chicks which are raised under artificial conditions, autointoxication is more frequently experienced as the result of injudicious feeding practices. The feeding of bulky foods rich in crude fiber which may occlude the digestive tract may prevent proper elimination and cause the absorption of decomposed contents of the intestines. Chicks which are raised in confinement and are supplied with chopped green feed often consume quantities of coarse fibrous stems which obstruct the intestinal tract. This condition occurs most frequently in young poults which are raised in confinement and supplied with green feed containing short pieces of fibrous stems. Large numbers of poults may be lost in a short time following such feeding procedures. The use of hay chaff for litter in poultry houses frequently results in the ingestion of indigestible fibrous material which may cause obstruction of the intestinal tract.

The symptoms observed in birds suffering from autointoxication include loss of appetite, increased water consumption, and depression, followed by weakness and prostration. Nervous symptoms typical of a generalized toxemia may appear shortly before death.

Occasionally sudden death occurs among apparently healthy turkeys and is caused by the consumption of large numbers of grasshoppers without any appreciable amount of other food being taken at the same time. Death is caused by the hard parts of the grasshopper, particularly the spined legs which irritate the mucosa of the digestive tract and frequently puncture the walls of the crop and intestines. Nongallinaceous birds are apparently not affected in this manner.

BACTERIAL TOXINS

Although the losses in birds attributed to bacterial toxins are not considered to be of great economic importance, they occasionally result in heavy losses in individual flocks. The only organism of this type which is important in the consideration of poultry diseases is *Clostridium*

botulinum. No significant lesions are found in botulism, and a positive diagnosis is based upon demonstration of the organism and its toxin.

MOLDS AND FUNGI

Molds and fungi frequently attack grains and forage crops in the field and in storage when conditions are favorable for the development of these organisms. They frequently produce toxins which are poisonous to mammals and birds, and in some instances have caused considerable losses. As a rule, birds are less susceptible to poisoning by molds or fungi than are the common species of domesticated animals. Moldy grains have long been considered as dangerous for stock feed, but they are invariably fed until losses occur. The appearance of the grain is no index as to its toxicity. Some of the worst-looking grains may prove to be nontoxic, while brighter and better-appearing grains may be extremely poisonous. Chickens have been fed moldy corn infected with species of Diplodia, Aspergillus, Mucor or Rhizopus, Penicillium, and various bacterial organisms without any unfavorable results. Scabby barley heavily infested with *Gibberella saubinetii* has been fed to fowls without apparently affecting their health or egg production. Wheat damaged by the so called stinking smut was used quite successfully as a poultry feed, although it is generally admitted that the feeding value of such grain is impaired by the action of the smut.

Even though the practice of feeding salvage grains as well as those infected with molds and fungi is quite common, extreme care should be taken in the selection of the grain constituents, and only feed of good quality should be used as poultry feed.

Brazilian groundnut poisoning (*Aspergillus flavus* toxin). In England during 1960, Blount (1961) reported that at least 500 cases of turkey "X" disease were diagnosed and indicated it was estimated that more than 100,000 turkeys died. Intensive investigations by various British workers,

Sargeant and O'Kelley (1961) soon made it apparent that this was a new disease. A feeding trial reported by Blount (1961) produced 100 per cent mortality in 25 poults between 2 to 3 weeks of age and this was the first evidence that proprietary feeds were causing the losses. Subsequent investigation revealed that Brazilian groundnut meal was the one ingredient present in all the toxic feeds. It was discovered that the toxic principle was aflatoxin, a toxic metabolite produced by strains of Aspergillus flavus contaminating the peanut meal (Sargeant et al., 1961). Samples of groundnut meal from Africa and India also found to be toxic by Carnaghan and Sargeant (1961). These investigations led to the discovery that strains of Aspergillus flavus are among the commonest fungal contaminants of cereal grains and the possibility exists that these grains could be a source of toxin. The first report of Brazilian nut poisoning in North America was by Archibald et al. (1962) who reported the disease in Canadian chickens.

Signs and lesions. Turkeys are generally affected at 4 to 6 weeks of age but losses may occur up to 16 weeks of age. Death usually follows within a week after symptoms are noticed. Affected birds will eat litter and there is a gradual loss of appetite. The poults are lethargic, the wings droop, and the feathers are ruffled and broken. Occasionally, nervous symptoms are present and the birds may die in a state of opisthotonus with the legs extended backwards. Mortality is variable but usually is high with 50 to 90 per cent loss not uncommon (Blount, 1961). Chickens fed diets similar to those which kill turkeys, pheasants, and ducklings have retarded growth but low mortality.

The primary lesions in poults are enteritis and nephritis. The liver may have congestion, petechial hemorrhages, or pale necrotic areas. Blount (1961) reported that the blood may be watery and fail to clot normally.

Ducklings are more susceptible to afla-

toxin than turkeys, pheasants, or chickens and this sensitivity makes them the bird of choice when testing feed for toxicity. Clinical signs are manifested by diminished feed intake and poor growth. A conspicuous change sometimes observed in young white-skinned ducklings is lameness and a purple discoloration of the feet and legs caused by subcutaneous hemorrhage. Young ducklings develop ataxia and convulsions shortly before death and manifest opisthotonus. It should be noted that opisthotonus is characteristic of the terminal stage in duck virus hepatitis.

Internal lesions vary according to survival time and age of the birds (Asplin and Carnaghan, 1961). Ducklings dying at one week of age have slightly enlarged puttycolored livers and pale, swollen kidneys. Petechia are present in the kidneys and pancreas. Older ducklings have a pale reticulated network throughout the liver and this is accompanied by atrophy and cirrhosis. Nodular hyperplasia of the liver is found in chronic cases. Ascites and hydropericardium may be present along with a subcutaneous transudate.

Histopathology. The most prominent histopathological changes in turkeys as reported by Wannop (1961) were degeneration of the liver cells and bile duct hyperplasia. Similar hepatic changes were observed in ducklings (Asplin and Carnaghan 1961). The pancreas had diffuse areas of acinar degeneration. The kidneys had congestion of the tubular sinusoids and degeneration of the proximal convoluted tubules. In 3- to 4-month-old chickens, lymphoid hyperplasia occurred particularly in those areas where parenchymal cell regeneration was seen. By 4 months of age multiple circumscribed areas of lymphoid hyperplasia were found scattered throughout the liver (Asplin and Carnaghan, 1961). Pancreatic and renal changes were similar to those in ducklings.

A positive diagnosis of this disease would necessitate the demonstration of aflatoxin in the feed. At present, means of testing for this toxin are beyond the scope of the

average diagnostic laboratory. Biological testing could be performed by feeding the suspect feed to ducklings.

Ergot. Ergot poisoning is occasionally responsible for extensive losses in poultry. Ergot is the sclerotium of the fungus *Claviceps purpurea* which infects the seed-bearing heads of maturing rye and other grains (Fig. 40.1). In European countries where rye is commonly used as poultry feed, ergotism is frequently encountered. Ergot is distasteful to chickens and if other feed is available they will not eat it. In acute poisoning the comb becomes wilted and cyanotic. The birds become depressed and do not eat but have abnormal thirst accompanied by diarrhea. General debilitation is followed by convulsions, paralysis, and death. In chronic cases the comb, wattles, and toes may become discolored and necrotic and may slough. Internal lesions consist of enteritis in conjunction with degenerative changes in the heart, liver, and kidneys. Chickens will make a prompt recovery when the source of ergot is removed.

DRUGS AND CHEMICALS

The poisoning of poultry by drugs and chemicals is most frequently due to accident, carelessness, or the injudicious use of these products as medicinal agents.

Ammonium chloride. This chemical, while not commonly used as a medicinal agent, sometimes has been administered in an effort to prevent ascites or the accumulation of fluids in the abdominal cavity of birds. The nontoxic dose reported by Gallagher (1919) was 15 to 45 grains; the lethal dose was found to be 60 grains.

The clinical symptoms manifested in ammonium chloride poisoning are loss of appetite, depression, progressive weakness, coma, and death. No characteristic lesions can be demonstrated

Arsenic. Arsenical preparations are extensively used in the control and extermination of rodents and insects. When considerable amounts of these arsenical compounds are ingested by birds, toxic reactions may result which frequently terminate fatally. Van Zyl (1929) states that birds are more resistant to arsenic poison-

FIG. 40.1 — Ergot. These black, hard, spindle-shaped masses are the sclerotia of the fungus *Claviceps purpurea* which infects the seed of maturing rye.

FIG. 40.2—Arsenic poisoning in a duck. Hemorrhages in the myocardium and yellow-green necrotic areas in the liver.

velopments are retarded. According to Nunn (1907), when mercury enters the circulation it is not directly eliminated from the body, but it is deposited in most of the tissues, chiefly the liver and kidneys. The lesions found in birds as the result of mercurial poisoning resemble those characteristic of a generalized toxemia. Various degrees of gastroenteritis may be observed throughout the digestive tract with or without distinct hemorrhagic areas. Considerable amounts of greenish gelatinous exudate in the alimentary canal may be sufficient to color the ingested food material. The mucous membranes frequently become necrotic and exfoliate. The kidneys are usually pale in color, showing degenerative changes, and often are studded with minute white foci. The liver shows evidence of fatty degeneration. The abdominal cavity frequently contains a thick viscid fluid greenish in color.

Geese seem to be quite susceptible to poisoning with calomel. A single dose of 2 grains or more may cause death in less than 24 hours. The symptoms and lesions produced in geese are similar to those found in other birds. However, the degenerative changes found in the heart, liver, and kidneys are much more severe

and may account for the rapid and fatal reaction of calomel in geese. Figure 40.3 shows the extensive degenerative changes in the region of the glomeruli of the kidney, and Figure 40.4 shows the formation of crystals in a necrotic focus of the kidney. These changes were observed in the kidneys of experimental geese which were given 2-grain doses of calomel.

Boric acid. Boric acid poisoning is very rare in birds. The practice of using chemicals in the preservation of canned foods in order to inhibit the growth of putrefactive organisms resulted in the addition of boric acid for this purpose. Gallagher (1924) reported that canned string beans to which boric acid was added at the rate of 9 grams per quart were toxic to chickens. The clinical symptoms described were loss of appetite, diarrhea, depression, and progressive weakness, followed by coma and death. The lesions produced were severe gastroenteritis, the mucosa of the crop becoming thickened, necrotic, or gangrenous. Degenerative changes in the kidneys were quite extensive.

Copper poisoning. Copper sulfate and Bordeaux mixture are perhaps the most common copper compounds used in agriculture, the former as a medicinal agent

FIG. 40.3 — Kidney of a goose, showing degenerative changes in region of glomerulus. ×320.

and the latter as an orchard spray. In poultry practice copper sulfate, also known as bluestone or blue vitriol, has occasionally been recommended for the medication of drinking water. If sufficient amounts of this chemical are ingested, fatal intoxication is frequently observed. Gallagher (1919) found that 20 grains of the crystalline salt or 15 grains in solution was the toxic and lethal dose for the fowl.

Pullar (1940a) reported the minimum lethal dose in grams per kilogram of body weight to be 0.9 copper sulfate crystals, 0.3 to 0.5 copper sulfate when mixed with twice its weight in sodium chloride, and copper carbonate 0.9. Both copper sulfate
FIG. 40.4 — Calomel poisoning in goose, showing crystals in necrotic foci of kidney. ×320.

and copper carbonate in quantities of 1.0 to 1.5 grams per kilogram of body weight were considered the minimum lethal dose for pigeons, while that for several species of ducks ranged from 0.4 to 0.9 grams. Pullar (1940b) considered the maximum daily intake of copper carbonate tolerated by birds to be 0.06 gm. per kilogram of live weight for fowls and 0.029 for domesticated mallard ducks. No toxic effects were noted from copper sulfate 1 to 4,000 in drinking water for fowls or domesticated mallard ducks.

According to Lander (1926a), the salts of copper in the stomach form albuminates which are quite soluble and rapidly absorbed. They are conveyed to the various tissues by the blood stream and deposited chiefly in the liver, lungs, and kidneys. The elimination of these products in the bile and urine is rather slow. Clinical symptoms of copper poisoning in fowls depend largely on the amount of the toxic agent absorbed. In mild cases a slight depression may be observed, followed by recovery. In fatal cases, a primary stimulation and activity may be noted, followed by severe depression and weakness. Coma, convulsions, and paralysis may occur before death. The lesions consist of catarrhal gastroenteritis accompanied by the secretion of a greenish seromucous exudate. Coagulation necrosis of the mucous membranes of the lower esophagus and crop are often observed. Hemorrhages are frequently found in the mucosa of the intestines. Degenerative changes in the liver and kidneys may be quite severe.

Cresol poisoning. Bullis and Van Roekel (1944) reported on injury and mortality in chicks caused by exposure to fumes from coal-tar creosote oil. Bressler et al. (1951) studied the effect of salt and carbolineum in the experimental production of ascites in turkey poults. Subsequently, West (1957) reported on disinfectant poisoning in chicks. Bierer et al. (1963) studied the effect of feeding 1 per cent coal tar and other disinfectants to chicks for a two-week period.

Under natural conditions, cresol poisoning in chicks occurs most commonly at 3 to 6 weeks of age. The affected chicks are depressed, weak, and have a tendency to huddle. The flock is generally uneven in size and has ragged feathering. Respiratory distress is manifested by rales, gasping, wheezing, and extension of the head and neck. Chicks affected with anasarca may waddle or walk stiff-legged.

The lesions are variable depending upon the severity and duration of the condition. The subcutis on the ventral portion of the body is infiltrated with a yellow transudate. The breast muscles are pale in color. Clear, amber-colored fluid may fill the abdominal cavity. A yellow fibrinous layer may cover the liver. The liver may be enlarged and mottled in early cases or shrunken and cirrhotic in older cases (Fig 40.5). The spleen is pale and small. The kidneys are usually swollen and pale. Hydropericardium is present and the heart may be pale and enlarged. The lungs are often edematous or have areas of hepatization. Fluid and mucus may be present in the trachea. Bullis and Van Roekel (1944) observed blood in the mouth and trachea of some chicks. West (1957) observed that the bone marrow was pale and contained more moisture than normal. He also indicated that the odor of coal tar was detected in the internal tissues of three cases. Bierer et al. (1963) noted a depressed growth in chicks fed a coal-tar disinfectant. He did not observe ascites and edema but but the experiment was terminated in two weeks and sufficient time may not have elapsed for lesions to appear.

West (1957) reported mortality varying from 2 to 56 per cent. He indicated that morbidity and mortality probably depend upon several factors, e.g., the concentration of the toxic agent, overcrowding, type of floor, quantity of litter, prevailing weather conditions, and ventilation.

Further injury may be prevented by moving chicks to new quarters. If this is not possible every effort should be made to improve the ventilation, and the old litter should be removed. Carbolineum

FIG. 40.5 — Cresol poisoning. The liver is gray, shrunken with rounded edges. Ascitic fluid and coagula (arrow) in body cavity.
should be used with caution, and the house should be heated and ventilated for several days to dissipate the toxic vapors before the chicks are brooded.

In making a differential diagnosis of cresol poisoning the possibility of salt poisoning, "toxic fat," crotalaria poisoning, and alimentary exudative diathesis must be considered.

These syndromes resemble one another in their clinical manifestations and it is exceedingly difficult for the diagnostician to establish a specific diagnosis. As the etiology of these conditions place responsibility and liability on different parties it becomes mandatory that supportive evidence can be offered in defense of a diagnosis. In those conditions where the responsibility rests with the flock owner, such as cresol poisoning, admission of guilt is more readily elicited by indirection rather than by accusation. The diagnosis of the other syndromes is discussed under their respective headings.

Cyanides. Hydrocyanic acid poisoning may arise not only through the use of the acid and its salts, but through the consumption of certain species of plants which under certain circumstances generate sufficient hydrocyanic acid to cause fatal cases

of toxemia. The highly toxic properties of these compounds make them quite effective in the extermination of rodents, birds, and plant parasites.

Birds are seldom poisoned by cyanides except through accident or carelessness. As a rule, they do not select cyanogenic plants for food except in rare cases when there is no other green feed available. Calcium cyanide is extremely toxic for birds. This compound is used extensively to destroy large numbers of undesirable birds such as sparrows or starlings. This preparation is distributed by dusting machines at night while birds are at roost. The inhalation of the calcium cyanide results in the destruction of the birds in a very short time. Winchell (1925) reported the successful use of calcium cyanide in the destruction of large numbers of domesticated fowls condemned as control measures in an outbreak of European fowl plague. One pound of this compound was sufficient to destroy 2,000 birds within 1 or 2 minutes.

Gallagher (1919) found the toxic dose of potassium cyanide to be 1/10 to 1/2 grain, while the lethal dose was considered to be from 1 to 2 grains. The symptoms develop soon after the consumption of

the toxic substance. The bird usually loses its sense of balance, drops to the floor in a comatose condition, and dies in a very short time. The action of cyanides in large doses is so rapid that characteristic lesions are not well developed. The comb and wattles appear cyanotic; the internal organs become congested; the blood is dark and has an oily appearance; bubbles of gas may be seen in the cavities of the heart. Characteristic odors resembling those of bitter almonds can be detected in the blood and congested organs.

Lead. The commercial preparations of lead which may be responsible for lead poisoning include the oxides and carbonates of lead, lead acetate, lead arsenate, and metallic lead. The oxides and carbonates are used in paint preparations. Lead acetate is used in commercial and medicinal products. Lead arsenate is incorporated in orchard and garden sprays while metallic lead, especially in the form of shot, has been responsible for lead poisoning in fowls and game birds. Large numbers of ducks die each year from ingesting lead shot that contaminate shooting preserves and hunting grounds. In an effort to decrease the number of pellets eaten, attempts have been made to develop shot from an alloy that would gradually disintegrate in the alkali marshes. Most of the lead compounds are comparatively insoluble in water but may become more soluble in acid or alkaline solutions. Lead salts in contact with digestive fluids may form albuminates and other more soluble compounds which are readily absorbed and distributed throughout the tissues by the blood stream. Lead compounds may be deposited in various amounts in the liver, kidneys, bones, and nerve and muscle tissue. Elimination of lead from the tissues is slow and is effected through the bile, urine, salivary, mucous, and cutaneous secretions.

Species. Lead poisoning has been diagnosed in wild mallard ducks, domestic ducklings, Canada geese, guinea fowl, pigeons, and chickens (Wetmore, 1922; Jones, 1939; Wickware, 1940; Stiles, 1940;

Rae and Crisp, 1954; Adler, 1944; Costigan, 1940; Hanzlik and Presho, 1923; Salisbury and Staples, 1958; and Shillinger and Cottam, 1937).

Signs and lesions. Costigan (1940) observed leg weakness and leg paralysis in guinea fowl poisoned by ingesting lead shot. Salisbury and Staples (1958) reported lead poisoning in chicks caused by feeding a grit composed of "frit," an ingredient used in the manufacture of enamelware. Analysis of the "lrit" revealed that it contained 32 per cent lead oxide. Four hundred chicks died out of a flock of 600 during the first two weeks of age. They reported that the most consistent lesions of lead poisoning in the chicks were submucosal hemorrhage and necrosis of the gizzard lining. Experimental poisoning of adult White Leghorns was followed by loss of weight, cessation of egg production, and green diarrhea in later stages. The birds had severe anemia but no evidence of stippling was found on blood smears. All birds had necrosis of the gizzard lining. Johns (1934), in a study of lead poisoning in ducks, considered the stippling of red blood cells as characteristic of a dying cell, and that the selective affinity of lead salts for immature red blood cells caused their early destruction.

Coburn et al. (1951) reported that they were unable to find evidence of stippling in blood cells due to lead poisoning in any avian species. These workers did observe poikilocytosis and anisocytosis in ducks experimentally poisoned with lead nitrate. Abnormal red cell shapes included dumbbell, bottle, oat, sickle, and teardrop forms. In chickens that are anemic from lead poisoning, enucleated erythrocytes may be found in blood smears (Fig. 40.6).

Toxic levels. Wetmore (1922) reported that the usual number of shot found in dead waterfowl was 15 to 40. The maximum number of shot recorded was 150, and the average was 25. Hanzlik and Presho (1923) observed clinical symptoms in pigeons 8 to 10 days after the introduction of lead shot directly into the crop.

FIG. 40.6 — Lead poison-
ing. Blood smear from a
chicken. Note the enu-
cleated, spindle-shaped
erythrocyte and the tear-
drop-shaped erythrocyte.
They considered the minimum lethal dose
to be 0.16 gram of metallic lead per kilo-
gram of body weight. Coburn et al. (1951)
determined the critical daily dosage of
lead to be between 6 and 8 mg/kg of body
weight when lead was given as an aqueous
solution of lead nitrate. At the higher
level the survival period was about 4 weeks.
McIntosh and Staples, quoted by Salisbury
and Staples (1958), failed to produce any
gross evidence of lead poisoning in fowl
by feeding single massive doses of red
lead and white lead in amounts up to 1,000
mg/kg of body weight.

Diagnosis. The signs and lesions of lead
poisoning are not pathognomonic and sup-
portive evidence is needed before a posi-
tive diagnosis can be made. Finding metal-
lic lead in the digestive tract in conjunc-
tion with a high lead content in the liver
or bones would establish a positive diagno-
sis. Adler (1944) investigated lead poison-
ing in Canada geese and found there was
no correlation between the amount of lead
in the leg bones and the number of shot
found in the gizzard. He stated that the
amount of lead found in the leg bones is
a measure of the duration of exposure to
the lead, as only a small portion of the

daily intake of lead is stored, the rest
being excreted. He did find, however,
that there was a correlation between the
lead content of the liver and the number
of shot present in the gizzard. From these
findings he concluded that the best organ
for chemical analysis to confirm a diagno-
sis of lead poisoning was the liver. A high
lead content in the liver would indicate
that the lead was recently ingested whereas
a high lead content in the bones would in-
dicate chronic poisoning.

Naphthalene. Naphthalene formerly was
frequently used in the form of moth balls
as a protection against lice and mites in
nests. This preparation is fairly volatile
and gradually decreases in volume on ex-
posure to air. When the moth balls be-
come small they may be readily ingested
by fowls. The loss of 40 fowls in a flock
of 400, caused by naphthalene poisoning,
was reported by Hudson (1936). The
clinical symptoms associated with this
form of poisoning include congestion of
the comb and wattles, abnormally bright
eyes, greenish-black diarrheal excrement,
progressive paralysis, and death. Death
usually occurs within 3 days following the
first appearance of diarrhea. The lesions

consist of severe catarrhal gastroenteritis with necrotic areas in the mucous membrane of the crop. The liver is congested and greatly enlarged, with numerous small necrotic foci. The strong characteristic odor of naphthalene can be detected in the contents of the crop and gizzard.

Nicotine sulfate. Nicotine, the highly toxic alkaloid of tobacco, has been used for many years by nurserymen and gardeners for the control of insects. According to Carpenter (1931), the development of the commercial "Black Leaf 40," a standardized 40 per cent solution of nicotine sulfate, made it possible to standardize the dosage and obtain more efficient results in the treatment of internal parasites of poultry. Apparently mature fowls tolerate greater doses of nicotine sulfate than do mammals or other animals. Various commercial preparations containing nicotine sulfate and other constituents, including kamala, have been used with varying degrees of success in controlling intestinal parasites. Bleecker and Smith (1933b) reported toxic reactions in birds treated internally with "Black Leaf 40." They (Bleecker and Smith, 1933a) also reported the toxic dose of this preparation to be from 0.5 to 1.0 cc. In some cases birds receiving a toxic dose became depressed and prostrated and died in a short time. Parker (1929) found that baby

chicks were quite susceptible to poisoning with nicotine sulfate. Doses of 0.2 cc. in various concentrations were given with the following results: an 8 per cent solution killed all treated chicks; 6 per cent solution was fatal to 70 per cent; 4 per cent solution resulted in the loss of 50 per cent; and 3 per cent solution, though producing a toxic reaction and coma for about 15 minutes, resulted in very few deaths.

The application of nicotine sulfate in the form of "Black Leaf 40" on the roosts of the hen house when fowls go to roost has been quite effective in controlling external parasites. According to Carpenter (1931), nicotine is highly volatile at 100° to 105° F. and is volatilized by the body temperature of the fowl. Cases of severe intoxication have been reported from the improper use of this product. Proper ventilation of the poultry house prevents the possible accumulation of vapors sufficient to produce toxic reactions.

The symptoms observed in nicotine poisoning include severe depression, retarded respiration, cyanosis, and coma followed by death. The lesions usually observed are as follows: congestion of the lungs and liver, ecchymoses of the lungs and heart, congestion of the nictitating membranes, dilatation of the pupil (Fig. 40.7), and a dark cyanotic condition of the blood.

FIG. 40.7 — Nicotine sulfate poisoning in chickens, showing dilatation of the pupil.

15 mg. per kilogram of live weight. The repeated ingestion of sublethal doses may result in chronic toxemia.

Postmortem examination reveals various degrees of congestion with the accumulation of some serous fluid in the pericardial sac as well as in the abdominal cavity in some cases. Enteritis is usually limited to the upper part of the small intestine. A characteristic pungent odor of phosphorus can be detected in the contents of the crop and gizzard especially in birds which have ingested large doses.

Nitrates. The nitrates of potassium and sodium have been known to produce poisoning in poultry, the general character of which is similar to that of sodium chloride poisoning. Sodium nitrate is commonly used in the form of Chile saltpeter as a fertilizer and may be mistaken for sodium or magnesium sulfate. In attempted medication of fowls, such errors have occurred with fatal results. Guberlet (1922) reported the lethal dose to be from 60 to 70 grains for the average fowl, smaller doses causing digestive disturbances accompanied by diarrhea.

The clinical symptoms most frequently observed are excessive thirst, anorexia, vomition, diarrhea, retarded heart action, subnormal temperature, and cyanotic appearance of comb, wattles, and skin. Muscular weakness develops into progressive paralysis followed by coma and death. In some cases convulsions appear shortly before death. The lesions include varying degrees of gastroenteritis, frequently of a hemorrhagic nature. Degenerative changes may be observed in the heart, liver, and kidneys. In peracute cases the lesions are less distinct.

Potassium permanganate. This chemical compound is frequently used as an antiseptic in drinking water for poultry but is decidedly toxic if administered in greater amounts than recommended for therapeutic use. Mature fowls are apparently not injured by consuming a 1:500 solution of potassium permanganate as drinking water for several weeks. Gallagher (1919) reported the toxic dose to

be 30 grains. He also reported that an experimental fowl died in less than 24 hours following the administration of the toxic dose. No clinical symptoms were observed prior to death. The lesions consisted of a severe cauterization of the crop wall. The submucosa and skin on the lower surface of the crop were blackened. Extensive blood clots were found in the crop where the tissue came in contact with the chemical crystals. All the other organs were normal. The potassium permanganate apparently did not leave the crop, the caustic action of the chemical compound being localized in the tissues with which it came in contact.

Sodium bicarbonate. Years ago it was a common practice for poultrymen to "flush" their flocks with various chemicals in the drinking water, one of which was sodium bicarbonate. Pathologists in diagnostic laboratories observed that chicks with lesions of visceral gout often had a history of receiving sodium bicarbonate as a flush. Subsequent investigation revealed that overdosing with sodium bicarbonate caused nephritis and visceral gout (Delaplane, 1934).

Witter (1936) reported toxic reactions but no mortality in 2-week-old chicks which were given an 0.6 per cent solution of sodium bicarbonate. However, a level of 1.2 per cent sodium bicarbonate caused toxic reactions in 2 days and mortality by the fourth day. Chicks 6 to 8 weeks of age which were given a 2.0 per cent sodium bicarbonate solution became sick in 2 days and began dying by the third and fourth days. Administration of a 2.4 per cent solution to yearlings produced toxic symptoms and death in five days.

Clinical signs included depression, weakness, increased water consumption, and watery droppings. The primary lesion occurred in the kidneys which became pale and swollen initially, followed by marked distension of the tubules and ureters with urates. Urate deposits were found on the epicardium and surfaces of liver and lungs.

Jungherr (1935) reported that single doses or repeated small doses of sodium bi-

carbonate may cause visceral gout. He also stated that visceral gout may occur in 2-day-old chicks that had not received feed or medication of any kind. Bullis and Van Roekel (1944) observed visceral gout in chicks 3 to 4 days of age that had not received sodium bicarbonate. Losses in these cases were usually less than 5 per cent. They also stated that excess sodium bicarbonate fed to chicks would produce visceral gout (Fig. 40.8).

Scrivner (1946) reported upon the effect of various concentrations of sodium bicarbonate in the drinking water of day-old poults. Levels of 0.1 per cent sodium bicarbonate and below were nontoxic when given for 18 days. Sodium bicarbonate at concentrations of 0.3, 0.5, and 0.6 per cent produced 20, 60, and 70 per cent mortality, respectively, in 2 to 3 weeks. It should be noted that the lesions in the dead poults were subcutaneous edema and ascites. None of the dead poults had visceral gout whereas the reports of sodium bicarbonate

poisoning in chicks describe gout as one of the principal lesions.

Other sodium compounds. Scrivner (1916) studied the effect of various sodium compounds on day-old turkey poults when administered in the drinking water at a concentration of 0.75 per cent. Administration of sodium citrate killed 19 out of 30 poults in 22 days. Lesions produced were subcutaneous edema and ascites. Sodium iodide administered for 5 days killed 100 per cent of the poults, 2 of which had lesions of ascites and subcutaneous edema. Sodium sulfate administered for 15 days killed 11 out of 31 poults with lesions of ascites and subcutaneous edema. Sodium hydroxide, administered at a concentration of 0.1 per cent in the drinking water for 21 days killed 2 poults which had ascites and subcutaneous edema. From the foregoing it is apparent that sodium compounds other than NaCl and sodium bicarbonate may be toxic for birds and produce lesions of ascites and edema.

FIG. 40.8 — Sodium bicarbonate poisoning. Five-day-old chick with urate deposits over the viscera and muscles.

Sodium chloride. It has been shown that most species of domestic fowl such as the turkey, chicken, duck, and pigeon are susceptible to salt poisoning. Young birds are more susceptible than mature birds which is probably the result of young birds consuming more feed in relation to body weight. Salt poisoning could arbitrarily be classed as acute or chronic. The acute cases would be those in which the birds consumed large amounts of salt in a short period of time. This could happen when birds were accidentally exposed to large amounts of salt, such as rock salt used in chilling brine, fish brine, or mixed with sand for highways. Gallagher (1919) reported 2.5 drams of this salt to be the toxic dose for chickens. The chronic cases of salt poisoning are more common than the acute and occur where there is salt in the drinking water or excess salt in the feed. Bigland (1950) reported on field cases of salt poisoning in turkey poults and found that in some instances the feed contained an amount in excess of 1 per cent salt over what the manufacturer intended. In addition, some of the water samples contained salt. He also found that the salt content in the feed hoppers was higher than in feed taken from the bag. Apparently, the salt by virtue of its specific gravity and physical characteristics gravitates to the bottom of the feed hopper. Losses started at 8 to 9 days of age with a daily mortality of 1 to 3 per cent continuing to 14 to 18 days of age. Total losses amount to 10 to 20 per cent.

The clinical symptoms include loss of appetite, severe depression, and progressive paralysis, followed by respiratory failure and death. In poults at necropsy, Bigland (1950) found anasarca, ascites, hydropericardium, cardiac hypertrophy, edema of the lungs and enteritis in the duodenum with edema of the intestinal wall. Increasing the salt in the diet causes a marked increase in water consumption and this was noted in experiments by Krakower and Goettsch (1945) and Paver et al. (1953). The additional stress placed upon the kidneys by increased salt and water intake

is reflected in enlargement of the kidneys with glomerular hypertrophy.

Young poults are much more susceptible than older turkeys. Bressler et al. (1951) noted that considerable mortality in young poults was produced when 0.9 per cent or higher levels of salt were added to the ration. Ewing (1947) observed that a 2 per cent level of salt produced 38 per cent mortality in turkey poults. In one trial, Scrivner (1946) fed 2.5 per cent salt in the mash and produced 40 per cent mortality in poults at 7 days of age accompanied by lesions of edema and ascites. However, Roberts (1957) using turkeys of 8 to 31 weeks of age found that salt levels up to 6.0 per cent in the ration increased the water intake but did not affect the growth and development. A reduction in weight gain was noted where 6.0 and 8.0 per cent salt was fed but no mortality occurred. Scrivner (1946) reported that feeding 2.0 per cent sodium chloride in the water and 0.5 per cent salt in the feed to day-old poults produced depression in 48 hours and 100 per cent mortality in four days. There was no edema or ascites. When the concentration of salt in the water was reduced to 1 per cent with 0.5 per cent in the feed all poults died in five days with lesions of ascites and edema. Lowering the salt concentration in the water to 0.5 per cent in addition to feeding 0.5 per cent salt in the mash caused 80 per cent mortality in 10 days with lesions of subcutaneous edema and ascites.

Paver et al. (1953) found no harmful effect in feeding day-old chicks salt levels ranging from 0.98 to 3.25 per cent in the mash. Levels of salt above 3.5 per cent did cause mortality in chicks. They found that a gradual increase in the salt concentration of the diet fed to chickens over one month of age from 2 per cent to 50 per cent interfered greatly with growth but was not necessarily fatal. It was postulated that this was due to the lower food requirements of adult birds in relation to live weight and possibly increased renal efficiency in older birds.

Gordon et al. (1959) reported the pro-

duction of a condition resembling "toxic fat" disease in 2 to 6 per cent of 4-week-old chickens fed purified diets containing 20 per cent blood meal, 2 per cent corn oil, and 0.88 per cent sodium chloride. Symptoms and lesions were not produced in chickens fed similar diets containing 30 per cent blood meal and 22 per cent corn oil. When ether-extracted blood meal was fed with the high level of NaCl no edema resulted. Supplementation of isolated soybean protein diets with high levels of NaCl resulted in edema only in chickens fed diets low in fat. It was concluded that there is an ether-soluble factor present in blood meal which disturbs salt regulation of the young chicken. In addition, high levels of fat can counteract the edematous effects of a high dietary NaCl level

Shaw (1929) reported that less than 5 grams were nontoxic for ducks weighing 600–800 grams, while larger doses were lethal. Torrey and Graham (1935) reported four consecutive doses of 5 to 6 grams of salt were fatal to half-grown Pekin ducks. However, the ducks tolerated doses of 1 to 2 grams of sodium chloride daily for 29 days. The clinical symptoms of toxicity were depression, loss of appetite, incoordination, progressive weakness, prostration, and death. Lesions varied from a mild congestion of the duodenum to severe enteritis accompanied by nephritis.

Edwards (1918) investigated the toxicity of sodium chloride for pigeons and reported that feeding more than 3 grams per kilogram of body weight produced toxic reactions and above 3.3 grams was fatal. The symptoms and lesions were similar to those in other birds. According to Buckley et al. (1939) there is no antidote for sodium chloride poisoning. However, every effort should be made to provide the birds with readily accessible clean fresh water and a salt-free diet.

Kamala. Kamala must be regarded as a poison even though it is used as an anthelmintic for the removal of tapeworms in poultry. It is a powerful irritant in the gastrointestinal tract. Care must be used in the administration of kamala in order to avoid toxic reactions. Following flock treatment with kamala, the egg production invariably is reduced for some time. Hall and Shillinger (1926) considered a 15 grain dose as an effective anthelmintic for mature fowls. Turkeys are less tolerant to kamala than chickens according to the report of Beach (1930). Hawn (1933) found kamala was neither a safe nor an efficient anthelmintic for turkeys. Cram (1928) warns against the use of kamala in birds affected with complicating diseases because of resulting high mortality.

Strychnine. Strychnine is a powerful toxic alkaloid occurring in the seeds of certain species of the Loganiaceae. It is readily absorbed from the digestive tract into the blood stream and is a powerful stimulant to the central nervous system. Its elimination from the tissues is slow, thus intensifying the cumulative action. Toxic doses produce tetanic spasms, paralysis, respiratory failure, and death. Strychnine is used extensively in the control of rodents. Accidental strychnine poisoning occasionally occurs in animals and birds consuming poisoned baits. Fowls apparently are more resistant to strychnine than mammals. According to Heinekamp (1925), the toxic dose in fowls depends largely on the quantity and nature of the crop contents, the absorption of the toxic agent being inversely proportional to the amount of food in the crop and directly proportional to its fluidity. Gallagher (1919) regarded 0.08 gram per kilogram of body weight as the lethal dose for chickens.

Sulfonamides. Sulfonamides were among the first of the so-called "wonder drugs" to emerge following World War II. Their success in the treatment of human diseases led to experimentation in the field of veterinary medicine. The therapeutic level and toxic level of some sulfonamides may impinge on one another and caution is needed in regard to dosage and duration of treatment. The small amount of the drug used in proportion to the bulk of the

the feed makes thorough mixing and distribution throughout the feed difficult. The ready availability and indiscriminate use of medications by poultrymen may lead to cases of intoxication. Levine (1939) in studying the effect of sulfanilamide against coccidiosis found that concentrations of 0.2, 0.3, and 0.4 per cent by weight of mash fed for a period of two weeks was definitely toxic for chickens. Farr and Wehr (1945) fed sulfamerazine to chickens and produced necrosis of the liver and spleen as well as retarded weight gains. Levine and Barber (1947) found hemorrhagic infarcts, necrosis and swelling of the spleens in chickens following the feeding of three sulfa drugs. Delaplane and Milliff (1948) reported that laying pullets which were fed sulfaquinoxaline in the mash at a level of 0.25 per cent for a period of eight to ten days rapidly declined in egg production, became droopy, weak, anemic, and eventually died. Davies and Kendall (1953) and Davies (1954) found that sulfaquinoxaline added to the drinking water in a concentration of 0.0645 per cent produced a toxic effect after treatment for only 5 days.

Yacowitz, et al. (1955) reported that the feeding of 0.1 per cent sulfaquinoxaline in the presence of 3–5 per cent alfalfa and 5 mg. of menadione per pound of feed resulted in the occurrence of a hemorrhagic syndrome in chicks. Hemorrhages closely resembled those encountered in field cases of hemorrhagic disease. The feeding of iodinated casein and penicillin appeared to increase the toxicity of sulfaquinoxaline. The whole blood clotting time was increased but the prothrombin time was normal.

Marthedal and Velling (1961) indicated that macroscopic changes were produced in five to eight-week-old chickens in four days following the administration of 0.05 per cent sulfaquinoxaline in the drinking water. From these reports it is apparent that the various sulfonamides may be toxic under certain conditions.

Signs. Toxicity is manifested in growing birds by ruffled feathers, depression,

and a pale or icteric color of the tissues about the head. Farr and Jaquette (1947) noted that birds treated with sulfamerazine in the mash at levels higher than 0.25 per cent made poorer weight gains due to the unpalatability and toxic effect of the drug. In laying flocks, toxicity is manifested by a marked drop in egg production. Edema and hemorrhage of the wattles may occur (Fig. 40.9). Scott et al. (1944) studied the effect of feeding sulfanilamide to birds in production. They indicated that sulfanilamide in the diet would cause decreased production, thin shells, rough shells, and loss of pigment in the shell. In controlled studies they found that the addition of 0.008 to 0.5 per cent sulfanilamide to the diet caused an immediate effect on shell quality. Egg production practically ceased at levels above 0.25 per cent. It was also determined that blood calcium levels were not depressed by sulfanilamide feeding. The thinness of the shell could not be attributed to premature expulsion of the egg as it remained in the shell gland for the normal length of time.

Gross lesions. Levine and Barber (1947) and Delaplane and Milliff (1948) reported that spleen lesions varied from hemorrhagic infarcts to small whitish foci (Fig. 40.10). In a few instances more than half the spleen was a white necrotic mass. The liver was frequently involved with greyish-white nodules about 1 mm. in diameter

FIG. 40.9 – Sulfonamide poisoning in an adult chicken. Note depressed attitude and swollen hemorrhagic wattles.

FIG. 40.10 — Hemorrhages in myocardium and small white granulomas in the spleen due to sulfonamide intoxication.

scattered throughout the tissue (Fig. 40.11). Similar greyish-white nodules and petechiae occurred in the kidney. Nodular lesions were also present in the myocardium and lungs. Farr and Jaquette (1947) noted that the spleen was the organ most frequently affected in sulfonamide intoxication. Delaplane and Milliff (1948) also found subcutaneous hemorrhages. Yacowitz et al. (1955) reported that lesions following the feeding of sulfaquinoxaline were watery blood, yellow fatty bone marrow, and hemorrhages in the thigh and breast muscles (Fig. 40.12). Hemorrhages were present in the heart, and the liver and intestine contained numerous petechial and ecchymotic hemorrhages (Fig. 40.13).

Histopathology. Caseation necrosis, giant cells, lymphocytic and eosinophilic infiltration were observed in the liver by Dela-
FIG. 40.11 — Sulfonamide intoxication in a chicken. Small granulomas in the liver (arrow), and a pale reticulated network along the edges of the liver.
FIG. 40.12 — Sulfonamide poisoning. Hemorrhages in the breast muscle of a chicken.

plane and Milliff (1948). In the absence of caseation there was hyperplasia of the connective tissue stroma. Nearly every follicle of the spleen contained multinucleated or giant cells. Some follicles had caseation necrosis and infiltration of eosinophils. The lungs had small circular tuberclelike areas composed of a caseous center surrounded by giant cells. Eosinophils were numerous in the center of

nodules that were not caseated. Lymphocytes and neutrophiles infiltrated the periphery of the nodular areas. The kidneys had hemorrhages and nodular areas composed of lymphocytes, granulocytes, and giant cells.

Alpha naphthyl thiourea. This preparation, commercially known as ANTU, which was recently developed as a rodenticide and is one of the most effective agents
FIG. 40.13 — Sulfonamide poisoning. Punctate hemorrhages in the mucosal surface of the intestine of a chicken.

for this purpose, is also highly toxic for domesticated animals and poultry. While there is much critical work to be done in determining the toxicity and lethal dosages of this product, Anderson and Richter (1946), through their experimental work with chickens, found that young chicks are quite susceptible to poisoning by this preparation. It is apparently less toxic for older birds. Chicks ranging in age from 3 to 5 weeks and fed 2 per cent to 3 per cent ANTU in mash showed toxic reactions in a short time. Half of these birds were dead in 18 hours. Most of the survivors which were fed plain mash recovered and those which continued to be fed on the toxic ration ate very little and died within 4 days. The clinical symptoms include depression, loss of appetite, listlessness, incoordination, weakness, prostration, and death. Well-defined pathologic lesions were not developed in all the poisoned birds. There was evidence of edema in the lungs and excessive quantity of fluid in the pericardial sac. Some cases showed evidence of fatty degeneration of the liver and kidneys.

Pullets averaging 1½ pounds were given doses up to the quantity to be found in 6 ounces of 2 per cent poisoned mash. Some died, and the survivors lost weight and would have been unprofitable birds if raised to maturity. Pulmonary edema, fatty degeneration of the liver and kidneys, and in some cases degeneration of the heart constituted the principal pathologic changes.

Sodium monofluoroacetate. This chemical compound, commonly designated as "Compound 1080," is one of the most effective rodenticides recently developed. It is effective in the extermination of rodents but is also toxic for domesticated animals and birds. Cottral et al. (1947) determined that the minimum lethal dose for chickens is about 14 mg. per kilogram of body weight and that repeated sublethal dosages will produce death in a short time. The clinical symptoms include restlessness, followed by a definite heart acceleration and increased respiration. Sublethal dosages

frequently produce a definite blanching of the comb and wattles, while heavier dosages will induce congestion and cyanosis of those appendages. As the toxemia progresses, the birds become weak and comatose. Some cases develop nervous symptoms and convulsions prior to death. The pathologic changes observed in this type of poisoning include distention of the pericardial sac with clear straw-colored fluid, hemorrhages in the cardiac tissue as well as on the endocardium, severe degeneration of the heart tissue, dark tarlike color of the blood, and large quantities of serous straw-colored fluid in the lungs and thoracic cavity. The liver appears dark in color, and the gallbladder is distended with bright green, watery bile. Degenerative changes in the kidneys may occur in some cases as well as a mild enteritis. The toxic action is primarily on the heart, and no effective treatment for this condition is known at the present time.

DDT (dichloro-diphenyl-trichloroethane). Dry DDT crystals and the water-dispersible preparations used in reasonable quantities as indicated for their use in insect control are incapable of causing toxic reactions in domesticated poultry. From the results of experimental studies, it would appear that great quantities of 5 per cent to 10 per cent DDT preparations would have to be ingested, inhaled, or dusted upon the bird to cause an unfavorable reaction. This would be a far greater quantity than that to which poultry is likely to be exposed under normal conditions. According to Kingscote and Jarvis (1946), the oil preparations are regarded as more dangerous, but not sufficiently so as to exclude their use if reasonable care is exercised. Their primary use is for controlling gnats, flies, and some intermediate hosts of poultry parasites. McNeil and Hinshaw (1947) reported that water emulsions were more effective than kerosene emulsions and safer to use. There apparently was no advantage in using concentrations greater than 2 lb. per 100 gal. of water. The amount recommended is 5 gal. per 500 sq. ft., resulting in the dis-

persion of about 100 mg. of powder per square foot.

The clinical symptoms observed in DDT poisoning include dyspnea, rapid breathing through the mouth, rapid blinking of the eyelids, muscular spasms, progressive incoordination, prostration, and death. Young birds may die in a short time without showing any well-defined clinical symptoms. There are no characteristic gross pathologic changes in the internal organs except the heart, which frequently shows petechial hemorrhages on the base. The majority of the birds show no specific postmortem lesions which can be of diagnostic value.

Arasan poisoning. Arasan [tetramethylthiuram disulfide (TMTD)], a fungicide used in the treatment of seed corn, was reported toxic to hens and chickens by Johnson et al. (1955), Waible et al. (1955) and Schumacher and Heuser (1956). The major symptoms observed in laying hens include misshapen and soft-shelled eggs, retarded production, and finally completely arrested production. Heuser and Schumacher (1956) reported a drop in production from 70 per cent to 10 per cent in 3 days after feeding a ration containing 33 per cent of Arasan-treated corn. In chicks, reduced growth and development as well as feed conversion efficiency are first observed, followed by hock disorders, inability to stand, and greatly increased mortality.

This product is extremely toxic, and such low levels as 7.5 parts per million of the compound in poultry rations will produce toxic reactions. The similarity of Arasan toxicity symptoms in hens with those produced by mild outbreaks of infectious bronchitis or Newcastle disease makes field diagnosis difficult. Seed corn may be treated with TMTD levels as high as 750 to 1,000 p.p.m., and such levels would make it practically impossible to dilute corn sufficiently to prevent toxic effects in poultry rations. According to Swanson et al. (1956), low levels of Arasan-SFX (75 per cent TMTD) resulted in a reduction in eggshell thickness and

firmness in albumen. At levels above 100 p.p.m., practically no hard-shelled eggs were produced.

Dieldrin. Carnaghan and Blaxland (1957) reported mortality in wild pigeons and pheasants presumably caused by the ingestion of seeds treated with dieldrin. As circumstantial evidence strongly suggested that the birds were eating treated seed, controlled experiments were carried out to determine the toxicity of various chemicals used in seed treatment.

Grain dressings containing organo-mercurials and gamma benzene hexachloride were found to be nontoxic to pigeons and pheasants. The feeding of wheat treated with dieldrin caused mortality in pigeons and pheasants. The administration of washings from 1½ oz. of dieldrin-treated grain proved fatal to adult pigeons. Deaths occurred between 4 and 10 days after administration of the toxic product.

The first symptoms manifested were a listlessness and a "hunched up" attitude. The birds did not maintain an even flight and lost their balance when lighting. Before death, nervous symptoms became pronounced and were characterized by rapid lateral movements of the head with slight tremor of the head and neck. There was constant blinking of the eyelids. Death occurred during a violent convulsion. At necropsy the liver and kidneys were congested. The gizzard lining was degenerated and hemorrhages were present on the surface of the underlying muscle.

Chlordane. Rosenberg and Tanaka (1950) showed chlordane to be definitely toxic to growing chickens. The tolerance of chicks to chlordane poisoning apparently increases progressively in different age groups. The addition of 0.25 per cent chlordane to the ration caused deaths as early as the first and second days in the 7-day-old group. Deaths were recorded after 2 days in the 21-day-old chicks; in 4 days in the 63-day-old birds and in 8 days in the 112-day-old group. All experimental chicks died within 17 days on the ration. Chlordane killed all 7-day-old chicks when fed at levels ranging from

0.10 to 0.25 per cent. The ration containing 0.05 per cent chlordane killed only 66.6 per cent of the chicks. The primary lesions found in all of the fatal cases were in the heart. Excessive quantities of fluid were found in the pericardial sacs; there were enlargement and distortion of the heart as well as engorgement of the coronary vessels.

The toxicity of chlordane to laying pullets was reported by Rosenberg *et al.* (1950). The experimental birds were highly resistant to chlordane poisoning. None of the birds receiving 0.05 or 0.15 per cent chlordane died during a 28-day test, and those receiving 0.25 and 0.5 per cent survived without mortality for 27 and 21 days, respectively. The birds fed 0.5 per cent chlordane completely ceased egg production and went into a molt; feed consumption decreased as did the body weight. Shriveling and cyanotic combs were observed. The group receiving 0.05 per cent of the drug was only slightly affected, continuing to lay nearly as well as the controls, and showed no clinical symptoms. Gross lesions observed in dead birds receiving the lethal doses consisted of heart lesions similar to those described in chicks.

Post (1951) compared the toxic effect of chlordane and toxaphene in pheasants and Chukar partridges. He determined that the toxic level of chlordane was 200 mg. per kilogram of body weight for pheasants and Chukar partridges. The maximum survival time for the pheasants was 56 days at the lower level of drug decreasing to 10 days when a level of 5,000 mg. per kilogram of body weight was given. Partridges died much more acutely than the pheasants with the shortest survival time being 2 hours and the maximum survival time 72 hours.

The minimum lethal dose of toxaphene was 200 mg. per kilogram of body weight for pheasants. Death occurred within 20 days when the minimum toxic level was fed and within 4 hours when levels of 5,000 mg. per kilogram were fed. The minimum lethal dose for partridges was 50 mg. per

kilogram of body weight. Some birds died within 2½ hours after administration of the drug and maximum survival time was 5 days. Poisoning by toxaphene and chlordane produced similar signs and lesions.

Lindauc. Bootes (1962) reported poisoning in a group of 200 turkey poults following the use of lindane in the litter. Approximately 300 grams of an insecticide powder containing 10 per cent lindane was sprinkled over the litter in a 9' × 9' brooder house. About 30 minutes after the application of the insecticide the poults stopped eating and began to squeak noticeably. Shortly thereafter, many of the birds showed signs of nervous derangement, manifesting opisthotonus, flapping of the wings, tetanic spasms of the muscles, and finally lapsing into a coma before death. At necropsy the only lesion was a slight edema in some poults. Within twenty-four hours 75 poults had died. Although the poults were moved to clean litter at the end of twenty-four hours, losses continued for a week and a total of 170 in the original group of 200 eventually died.

Malathion. Gaafar and Turk (1957) studied the toxicity of Malathion for chickens. They determined the LD_{50} of Malathion for 3-week-old chickens to be between 200 and 400 mg. per kilogram of body weight and for yearlings between 150 and 200 mg. per kilogram of body weight. Almost all of the poisoned birds recovered if they survived the first 16 hours. The signs of Malathion toxicity in the poisoned groups were drowsiness, incoordination, reluctance to move, resting on their hocks, excessive salivation with mucus hanging from the beaks, cyanosis of the skin, diarrhea, blood-tinged brownish droppings, coma, and death. At necropsy the principal change was congestion and discoloration of the heart muscle. Many birds had a marked dilatation of the subcutaneous blood vessels. These workers also reported that no signs of toxicity resulted when chickens were dusted at weekly intervals for four weeks with a 4 per cent Malathion powder.

Golz and Shaffer (1955) reported that there was no evidence of toxicity in chickens after they were fed mash containing 100 and 1,000 p.p.m. of Malathion for ten weeks. At a level of 5,000 p.p.m. of Malathion in the mash or an average consumption of 450 mg. per kilogram of body weight per day these investigators found that chickens showed definite signs of toxicity such as retarded growth, poor feathering, soft droppings, weakness of the legs, and paralysis.

Chlorinated hydrocarbon. McCune et al. (1962) reported hydropericardium and ascites in chicks fed a chlorinated hydrocarbon. Investigation of this compound was prompted by the observation that chicks reared in a battery freshly painted with an epoxy-resin paint developed ascites and hydropericardium similar to the lesions found in the "toxic fat" syndrome. Various fractions of the paint were mixed with the mash and it was found that the major toxic product was chlorinated biphenyl which was added to the paint as a plasticizer.

Feeding 0.04 per cent biphenyl in the feed produced symptoms and mortality starting at 3 weeks of age and reaching major proportions during the fourth week. Affected chicks had labored respiration and rales. At necropsy the abdominal cavity was distended with fluid and hydropericardium was present. The crops of some birds contained bloody fluid. The kidneys were swollen and pale in most chicks but in the advanced stages many were hemorrhagic. Some livers were enlarged and mottled in appearance. The lungs were commonly hydropic and hemorrhagic. A yellow gelatinous transudate was frequently found under the skin and within the body cavity.

Thiophosphate poisoning. A commercial thiophosphate spray (Diazinon) used for insect control proved to be highly toxic for White Pekin ducks. The youngest birds, 8 and 15 days old, suffered 100 per cent mortality 1 hour after the spraying operations were completed. The mortality of the older birds, 22 to 36 days of age,

was 50 per cent in 5 hours and an additional loss of 25 per cent within the next 24 hours.

The only clinical manifestations observed were inability to stand and tremors of the head and neck. Pathologic tissue changes were confined to acute congestion of the lungs. According to Dougherty (1957), diagnosis by lesions or clinical laboratory tests is difficult if not impossible.

The lethal dose per os for Malathion, a less toxic thiophosphate preparation, is 1,100 mg. per kilogram and for Diazinon is 14 mg. per kilogram in White Pekin ducklings under experimental conditions. The intratracheal lethal dose is 600 mg. per kilogram for Malathion and 6 mg. per kilogram for Diazinon. Insecticides considered safe for chickens or other gallinaceous birds may be highly toxic for other species.

Carbon monoxide. Severe losses in chicks and turkey poults may be caused by carbon monoxide poisoning, primarily due to poorly ventilated brooders or the result of defective coal or oil heating units. Adequate ventilation of brooders and housing facilities is an important factor in poultry management. Accumulation of carbon monoxide may prove fatal to entire units of young birds before the condition is discovered. The symptoms of acute carbon monoxide poisoning include restlessness, drowsiness, stupor, labored breathing, and incoordination. As the toxemia progresses, the birds gasp, fall, and lie on their sides with heads thrown back. They commonly develop spasms or convulsions prior to death. Many acutely affected birds recover when removed to fresh air. In subacute cases, the feathers may appear rough, the appetite is diminished, and evidence of nutritional disturbances is manifested by retarded development and growth. Stiles (1910b) found that 0.04 to 0.05 per cent carbon monoxide is sufficient to produce definite toxic reactions. The principal lesion observed in acute carbon monoxide poisoning is the bright cherry-red color of the lungs and blood. The

only from about July first to the middle of August. He reported losses in mature fowls following the ingestion of black locust leaves. The toxic material produces a severe hemorrhagic enteritis, followed by depression, paralysis, and death in 12 to 24 hours.

Corn cockle. The corn cockle (*Argostemma githago*) is a weed which grows in wheat fields throughout the world. The seeds of this plant are highly toxic. The whole cockle seed is very unpalatable and is usually avoided by birds, but in ground grain mixtures it may be consumed in sufficient quantities to produce a fatal toxemia. Quigley and Waite (1931) found the toxic dose to be about 0.2 per cent of the body weight and the minimum lethal dose 0.25 per cent of the body weight of fowls. Heuser and Schumacher (1941) reported that 5 per cent of the ration or 0.3 per cent of the body weight was toxic for chickens 6 to 10 weeks old. They found that a tolerance to the poison is frequently developed so that 0.4 to 0.5 per cent body weight could be consumed without materially affecting the growth. Ten per cent of the ration or 0.8 per cent body weight was lethal to some of their experimental fowls.

The clinical symptoms observed are a decided decrease in the respiration and heart rate, caseous lesions on the mucous membranes of the mouth, and diarrhea, the severity of which depends on the amount of toxic feed consumed. The lesions include yellow caseous exudate on the lining of the crop and varying degrees of gastroenteritis. Accumulations of clear amber fluid under the serosa of the digestive tract and in the pericardium, hemorrhages, and congested areas on the heart may be observed. Various degrees of congestion may be encountered together with degenerative changes in the liver.

Cottonseed meal. The active principle of cottonseed products which is toxic to both animals and birds is gossypol. Cottonseed meal has been used as a protein supplement in stock feed for many years, and if properly used in a mixed grain ration is a valuable and economic protein supplement. Excessive quantities, however, produce toxic effects often terminating in death. Kaupp (1933) studied the toxic properties of cottonseed meal for poultry. He concluded that toxic effects were soon observed in birds consuming 1 ounce of cottonseed meal daily or its equivalent in gossypol. Clinical symptoms of generalized toxemia appear with loss of appetite, cyanosis, and emaciation, followed by death in a few days after the appearance of the first clinical symptoms. The lesions include cyanotic appearance of the comb and wattles, varying degrees of gastroenteritis, and degenerative changes in the liver and kidneys.

Coyotillo. Losses in poultry by the consumption of the fruit and seed of the coyotillo plant (*Karwinskia humboldtiana*) have been reported. This plant is indigenous to southwestern Texas and Mexico. Marsh and associates (1928) reported that the clinical symptoms of this form of poisoning do not appear for several days and may appear as late as 3 weeks after the ingestion of the toxic substance. The toxic dose for chickens was found to be 0.3 per cent or more of the live weight, fed as dried fruit or seed. Symptoms of generalized toxemia appear, followed by progressive paralysis and death.

Crotalaria seed. The toxicity of certain species of crotalaria seeds for the chicken, quail, and dove was reported by Thomas (1934). Turkeys appeared to be more resistant to their toxins. However, crotalaria poisoning was not a serious problem until the introduction of mechanical pickers for corn and soybeans and the intensive use of crotalaria in the Southeast to increase the humus and nitrogen content of the soil (Kelley *et al.*, 1961; Smith and Osborne, 1962). Although there are hundreds of species of crotalaria, Smith and Osborne (1962) reported only a few are toxic for poultry. *Crotalaria spectabilis* appears to be the most toxic species for poultry, but *C. giant striata* was found toxic by Kelley *et al.* (1961), and Emmel (1937b) found *C.*
FIG. 40.15 – Crotalaria spectabilis seeds. Note smooth glassy seed coat and mitten-shaped appearance. ×4.

retusa toxic for chickens The small seeds are black or greenish brown with a smooth surface and have a characteristic mitten shape (Fig 40.15). A toxic alkaloid known as monocrotalin was extracted from Crotalaria spectabilis seed by Thomas et al. (1935). Under experimental conditions, Kelley et al. (1961) found that 1 per cent of C. spectabilis in the diet of day-old chicks killed all the chicks by 4 weeks of age. Studies by Bierer et al. (1960) showed that 0.2 of a pound of Crotalaria specta-

bilis seeds per ton of feed (0.01 per cent) was toxic for chickens.

Caylor (1961) found that 0.05 per cent Crotalaria spectabilis in the feed lowered production after 4 weeks and had a pronounced effect by 6 weeks. At a 0.1 per cent level, production practically ceased by 6 weeks. These results showing the effect of Crotalaria sp. on egg production were confirmed by Harms et al. (1963). They also observed that the inclusion of 64 Crotalaria spectabilis seeds per pound of feed for 9 weeks did not cause mortality in pullets.

Poisoning may occur in the acute or chronic form, terminating fatally in from 1 day to several months. Affected chicks become droopy, inactive, and have ruffled feathers. There is a tendency for the birds to huddle, and feed consumption decreases. Growth is retarded and the birds are stunted and inactive (Fig. 40.16). Birds with accumulations of abdominal fluid manifest a ducklike attitude when walking. In mature birds the comb and wattles are pale and egg production gradually drops with a corresponding increase in mortality.

The type and extent of the lesions vary with the duration of the condition and the age of the birds. Young birds may have subcutaneous edema and ascites. Hydropericardium may be present occasionally but is not a prominent lesion. Early in the course of the disease the liver is

FIG. 40.16 – Crotalaria spectabilis poisoning. Note stunting of the chick on the right compared with normal chick on the left.

FIG. 40.17 — Crotalaria spectabilis poisoning in a 2-week-old chick. The visible lobe of the liver is yellow and atrophied and the other lobe is covered by ascitic fluid.

swollen and mahogany colored but later becomes atrophied and cirrhotic (Fig. 40.17). Mature birds may die acutely from massive hemorrhage from the liver. Lesions described by Emmel (1937a) were numerous petechiae in the serous membranes and visceral fat (Fig. 40.18). The liver is

FIG. 40.18 — Hemorrhages of the epicardium and myocardium in acute Crotalaria spectabilis seed poisoning in a chicken. (Emmel, Jour. A.V.M.A.)

mottled and the kidneys show evidence of nephritis. Simpson et al. (1963) reported that the most prominent lesions in poults were focal or diffuse hemorrhages visible on the surface of the liver and extending into the parenchyma. Hemorrhages were also present on the epicardium and in the pectoral musculature.

Simpson et al. (1963) found at necropsy of pullets that had been fed Crotalaria-contaminated diets for nine weeks that the walls of the pericardial sac and air sacs were thickened. The lungs were edematous and the wall of the proventriculus was thickened. The livers were either dark and swollen or atrophied, knobby, and grayish tan. The spleens were swollen and pulpy.

Histopathological changes reported by Kelley et al. (1961) and Simpson et al. (1963) are most prominent in the liver. There is a fibrous thickening of the liver capsule and vacuolation or granular degeneration of the hepatic cells. Productive tissue changes are present in the region of the portal triad associated with bile duct hyperplasia and increased connective tissue. Occlusion of the small branches of the portal veins is caused by swollen endothelial cells and subendothelial edema. The kidneys may have interstitial edema,

dilatation of Bowman's space, and hyaline casts in some tubules. In the spleen there is a depletion of the splenic corpuscles and necrosis of persistent germinal centers. Occasionally there is a lymphocytic interstitial myocarditis and separation of myocardial fibers by edema. Hypoplasia of the bone marrow is found in chicks.

In young birds, the lesions produced by Crotalaria poisoning resemble those produced by "toxic fat," salt poisoning, cresol poisoning, and alimentary exudative diathesis. Tissues from affected birds and the suspected feed sample can be analyzed for the presence of monocrotalin, the toxic alkaloid in *Crotalaria spectabilis* seed. In acute cases of poisoning the presence of the characteristic mitten-shaped seeds in the crop or gizzard aid in making a diagnosis.

Daubentonia seeds. The Daubentonia (*Daubentonia longifolia*), also called the Sesbania, is a native of Mexico but was introduced to the southern states as an ornamental shrub. The seeds of this plant are readily eaten by poultry and are extremely toxic According to Shealy and Thomas (1928), the ingestion of as few as nine seeds will cause death in birds. The first clinical symptoms observed are a staggering gait, accompanied by drooping of the wings. Depression, general debility, and unthriftiness soon become apparent. The comb becomes cyanotic, and the head may hang over to one side Muscular twitching, diarrhea, emaciation, and extreme weakness are followed by death in 24 to 72 hours after the appearance of the first symptoms. The lesions include severe gastroenteritis with ulceration of the proventriculus and gizzard together with degenerative changes of the liver.

Death camas. The death camas belong to the genus Zygadenus, and the members of this genus, according to Marsh *et al.* (1915), generally conceded to be poisonous are *Z. glaberrimus, Z. intermedius, Z. mexicanus, Z. nuttallii, Z. paniculatus,* and *Z. venenosus.* Niemann (1928) reported an outbreak of poisoning in the domestic fowl due to the ingestion of *Z. nuttallii.*

This plant is not very palatable and is only eaten by fowls on the range in the early spring and late fall when other green feed is comparatively scarce. Experimental feedings of 5 to 10 grams to chickens produced marked clinical symptoms in 12 hours, including salivation, incoordination, muscular weakness, and diarrhea, followed by prostration and death. No definite lesions are associated with this type of poisoning. A strong, penetrating, disagreeable odor from the internal organs was noted, and muscular atrophy was observed. The mesenteric and abdominal blood vessels appeared congested. The lumen of the digestive tract was noticeably diminished in size.

Glottidium seed. *Glottidium vesicarium* (Jacq.) Harper is quite common along the coastal plain from North Carolina to Florida and Texas, having been introduced from the West Indies. The seeds of this plant are toxic for poultry. Under ordinary conditions fowls do not select these seeds as food but if underfed may consume sufficient quantities to be toxic. Emmel (1935) produced toxic effects by experimental feeding of *G. vesicarium* seeds to fowls. The clinical symptoms in acute poisoning are prostration, and cyanotic appearance of comb and wattles accompanied by diarrhea. In chronic cases the feathers become ruffled, copious yellow diarrhea persists, and the birds may become emaciated. The combs appear light in color and become scaly. The most characteristic lesions observed include necrotic enteritis, necrotic areas in the lining of the gizzard, and degenerative changes in the liver and kidneys.

Vetch seed. Reports of toxicity as the result of feeding large quantities of vetch seed to chickens are recorded in the literature. Little reliable information can be secured on the toxic principles of the vetches from the reports published either in this country or abroad. Numerous incidents of poisoning, commonly referred to as "lathyrism," are recorded in which birds show severe central nervous disturbances including spasmodic convul-

sions, paresis, and death following the use of large quantities of Lathyrus peas in the feed. Stockman (1931) regarded the nature of this toxic reaction highly controversial. Anderson and his associates (1925) indicated that the seed of *Lathyrus sativus* is not toxic unless contaminated by seeds of a variety of vetch, *Vicia sativa* L., var. *angustifolia*. Horvath (1915) reported that the vetchling (*Lathyrus cicera*), when fed as a sole food, seemed to exert a toxic effect on hens, resulting in a loss of weight. No characteristic pathologic lesions were produced. Harper and Arscott (1962) reported that the seed of common vetch, *Vicia sativa*, was toxic and lethal when fed at levels of 20 to 40 per cent in practical type rations to poults and chicks. At the 30 per cent level, 70 per cent mortality occurred in the poults and 100 per cent occurred in the chicks within one to four weeks after feeding the toxic mash. Autoclaving the ground vetch seed for 8 hours reduced toxicity and significantly improved growth. The seed of hairy vetch, *Vicia villosa*, was less toxic for poults and chicks. Several varieties of vetch seed contain a cyanogenic glucoside, "vicianin," which is decomposed by an enzyme (vicinase) into hydrocyanic acid, benzaldehyde, and a disaccharide (vicianose). It is possible that large quantities of such feed could cause considerable loss in a flock of birds.

Milkweed. Two of our common species of milkweed, *Asclepias tuberosa* and *A. incarnata*, contain the bitter glucoside asclepidin, which apparently is toxic to animals and birds. Pammel (1911) includes *A. vestita* and *A. mexicana* in the list of toxic species of the milkweed family. Campbell (1931) reported serious losses in poultry caused by the consumption of the narrow-leaved, whorled milkweed, *A. mexicana*. Experimental investigations indicated that all parts of the plant are toxic. Pammel (1917) reported milkweed poisoning in chickens resulting in the loss of approximately 500 birds. Stiles (1912) reported extensive losses in turkey poults resulting from the consumption of whorled milkweed (*Asclepias gale-*

ordes). Poultry, as well as other species of livestock, are not likely to eat milkweed except when it is the only succulent feed available.

The clinical symptoms may vary considerably, depending on the quantity of the toxic material eaten. The first symptom observed was lameness which developed rapidly into complete loss of muscular control. The neck became twisted and the head drawn back. The affected birds often lay on their sternums or sat on their hocks alternately extending and retracting their heads at frequent intervals. This condition did not seem to be a true paralysis but appeared to be an overstimulation of the motor nerve centers with complete loss of coordination. At times the birds would fall over and struggle, with violent convulsive movements of the legs. In some instances the symptoms gradually subsided, followed by recovery. In fatal cases the symptoms became progressively worse, followed by prostration, coma, and death. No characteristic lesions were found upon necropsy.

Nightshade. The black nightshade (*Solanum nigrum*) is a common weed in yards and poor pasture land. The immature fruit of this plant contains the alkaloids solanin and solanidin which are toxic to man and animals. The toxicity of the plants is believed to be influenced by the soil, climate, and degree of plant maturity. Hansen (1925) reported fatal poisoning in chickens and ducks attributed to black nightshade. The clinical symptoms include incoordination, prostration, paralysis, and death. The pupils of the eyes may be dilated. No characteristic lesions are reported except evidence of severe toxemia.

Lily of the valley and oleander. The flowers, leaves, and stems of the lily of the valley (*Convallaria majalis*) and the leaves of the oleander (*Nerium oleander*) were reported by Bartosi (1939) to be poisonous for geese, ducks, and hens. The lily of the valley flowers were found to be lethal to geese in doses of 15 grams and to ducks in doses of 12 grams. Doses of 50

grams produced only a mild enteritis in mature chickens.

The dried leaves of the oleander plant of the previous season's growth proved fatal to geese in 24 hours after the ingestion of 6 grams. The lethal dose for ducks was found to be 3 grams. The young leaves of this plant proved fatal to hens in doses of 15 grams. Hinshaw reported losses in turkey poults within 24 hours as the result of eating young shoots of oleander. The postmortem examination of the poults showed hemorrhagic enteritis. (See chapter on Diseases of the Turkey.)

The clinical symptoms of oleander poisoning include general depression, weakness, diarrhea, accelerated heart rate, impaired vision, muscular incoordination, and in some instances paralysis of the wings. Various degrees of gastroenteritis and liver degeneration occur in fatal cases.

Potatoes. Under certain conditions the potato (Solanum tuberosum) is poisonous to domesticated animals and poultry. Greened tubers, produced by exposure to light, and young potato sprouts contain considerable amounts of the alkaloid solanin which is highly toxic Analyses have shown that the solanin content of the sprouts and peelings is higher than that of the interior of the tuber. Hansen (1927) reported several outbreaks of poisoning in poultry resulting from the ingestion of potato sprouts. Losses occurred within a few hours after the consumption of the toxic sprouts. Temperton (1944) reported losses in ducks as the result of eating either cooked or uncooked sprouted potatoes. This type of poisoning is similar to that of poisoning by other plants of the nightshade family. However, where large amounts of potatoes are fed to poultry, it is advisable as a safety measure to cook green or sprouted potatoes and to discard the residual water. From the standpoint of nutrition, raw potato starch is poorly digested by poultry, and cooking will result in a more efficient utilization of this type of feed.

Tobacco. The tobacco plant (Nicotiana

tobacum L.) contains the toxic alkaloid nicotine. Hunter and associates (1931, 1934) reported that growing chicks over 3 weeks of age can tolerate as much as 0.06 per cent nicotine in the ration without any toxic reaction. The feeding of the same nicotine levels in the form of ground cigar clippings having only 0.86 per cent nicotine content retarded the growth and development of chicks, causing some losses. Toxic doses of tobacco produce similar reactions to those of nicotine sulfate poisoning.

Algae. Certain types of algae, including the Microcystis aeruginosa, which grow abundantly in lakes under certain conditions, may become concentrated in localized areas by the action of strong winds blowing the surface of the water in one direction for a number of days. Great quantities of algae are deposited on the banks and in the shallow waters along the shore line. The disintegration of this material produces toxins which are responsible for the loss of various species of wildlife as well as domesticated animals and birds. This condition has frequently been called "water bloom." Fitch and his associates (1929) reported losses of livestock from this cause in Minnesota. Brandenburg and Shigley (1947) reported this condition in North Dakota. It has also been reported in northern Iowa and in parts of Canada. It usually occurs in the latter part of July, August, and September. The exact nature of the toxin is not known at the present time. Apparently, the toxin is an intermediate product of disintegration, as these toxic properties disappear during the latter stages of decomposition.

The toxicity of this material is directly proportional to the concentration. Some waters taken from the shores of lakes are extremely toxic to birds and animals. Under experimental conditions, oral dosages of 10 cc. to 30 cc. will produce death in mature ducks and chickens in 10 to 45 minutes. The toxin is thermostable and is affected little, if any, by boiling. The

symptoms include restlessness, twitching of muscles, nervous manifestations, spasms, convulsions, paralysis, and death. These clinical manifestations resemble strychnine poisoning in many respects. The postmortem lesions include generalized cyanosis; dark, tar-colored blood; liver congested and dark in color; heart dilated and distended; muscles also congested and dark in color. No characteristic hemorrhages are observed. Ashworth and Mason (1946) described in detail the symptoms and lesions associated with algae poisoning in laboratory animals.

Because of the highly toxic nature of this material and the rapidity with which it acts, there are no therapeutic measures effective. Poultry should be restricted to areas free from toxic material.

Nontoxic algae may be responsible for considerable losses in young chickens. The mature birds are seldom affected, but the young chicks which wade out along the shore line and feed on insects alighting on the floating scum or masses of algae, invariably swallow various amounts of this material. This scum becomes lodged in the nostrils as well as the digestive and respiratory passages, causing strangulation and suffocation. Symptoms characteristic of strangulation are observed. Postmortem examination reveals obstruction of the nostrils and respiratory passages as well as those of the digestive tract.

Losses of poultry associated with the ingestion of algae should be investigated at once. The toxicity of algae can be determined readily by injecting 2 cc. or more of a sample filtered through gauze, intraperitoneally into laboratory animals or chickens. Toxic material will produce typical clinical symptoms in a short time and death within an hour or so. A prompt determination of toxicity may prevent serious losses to all species of livestock.

INSECTS

Insects of various kinds annoy poultry and act as intermediate hosts for poultry parasites, but only a few of those eaten by birds are considered poisonous. Only one insect is described which, if eaten in sufficient numbers, produces a severe toxic reaction in chickens, i.e., the rose chafer.

Rose chafer. Rose chafers (*Macrodactylus subspinosus*) are abundant during the latter part of May and June, and early July in Canada and the eastern United States extending as far west as Colorado. The toxic properties of this insect for chickens have been reported by Bates (1916), Gallagher (1920), and Lamson (1916, 1922). Fatal cases of poisoning in young chickens of various ages have been recorded, but mature fowls are seldom killed. Chickens will feed ravenously upon these insects if available, and 15 to 20 rose chafers are sufficient to kill a chicken 1 week old, while birds about 3 weeks of age show a toxic reaction after eating 25 to 45 of these insects. A fatal reaction usually results in 21 hours, or the birds gradually recover. Watery extracts made from crushed rose chafers proved toxic when administered to chickens. Lamson was of the opinion that the poisonous principle is a neurotoxin which has a direct effect on the heart action.

The clinical symptoms include drowsiness, incoordination, weakness, prostration, convulsions, and retraction of head and neck over the back of the affected chicken. Death usually occurs in less than 21 hours subsequent to eating rose chafers or from ½ to 1 hour after the appearance of the first symptoms. The postmortem examinations fail to show characteristic lesions other than injection of the blood vessels of the heart in some cases.

MISCELLANEOUS FOOD POISONS

Selenium. Toxic reactions from eating grains grown in certain limited areas, due to specific toxic mineral constituents, have been reported by Franke and associates (1931) in parts of South Dakota. The so-called alkali disease was found to be due to the high selenium content of the grain grown in that locality. Losses of livestock from selenium poisoning were reported

by Moxon (1937). Studies at the South Dakota Experiment Station indicated that toxic grains fed to laying hens at levels which contained 15 p.p.m. of selenium resulted in reduced weight, caused a decided reduction in egg size, and practically destroyed the hatchability. According to Poley and associates (1937), the feeding of 5 p.p.m. of selenium did not appreciably affect the hatchability even though some evidence of selenium poisoning was apparent.

Toxic fat syndrome. During the fall of 1957, severe outbreaks of a new disease syndrome characterized by ascites, hydropericardium, and subcutaneous edema occurred in broilers in the central and southeastern United States. Schmittle et al. (1958) and Sanger et al. (1958) reported on clinical observations and laboratory findings. They determined that certain samples of fat or feed containing this fat would produce the edematous condition when fed to chickens. Wannop and Chubb (1961) in Great Britain reported a syndrome characterized by ascites and hydropericardium in broilers. They indicated that fat had been added to the feed. Alexander et al. (1962) reported that the source of the toxic factor was traced to specific lots of feed grade animal fats containing a residue from some fat-processing operations. They further indicated that it was believed that the residue contained either a contaminant, or, in the course of the fat processing, a new compound was formed which was toxic for chicks. Investigation by Friedman (1962) indicated that some vegetable fat sources may yield fatty acids contaminated with the chick edema factor.

Signs. Clinical signs may appear as early as 3 weeks of age and are manifested by dyspnea, ruffled feathers, droopiness, paleness, stunting, and sudden death. Some of the chicks may have a waddling, unsteady gait or a penguinlike posture. Blood counts reveal a marked anemia, and Simpson et al. (1959) reported erythrocyte counts as low as 800,000 per cubic millimeter. In blood smears, immature erythrocytes can be

seen. Mortality as high as 90 per cent has been reported.

Lesions. Birds in the advanced stages of the disease have large, fluctuating, distended abdomens containing clear straw-colored fluid with large fibrinous clots (Fig. 40.19). Subcutaneous edema occurs in the region of the breast, abdomen, and thighs. The most consistent lesion is a greatly distended pericardial sac filled with amber-colored fluid (Fig. 40.20). The heart is slightly enlarged and the myocardium is pale. Occasionally, petechiae may be present in the myocardium. Hemorrhages may occur in the skeletal muscles but are not a constant feature of the disease. The crop contents may be bloody and the buccal cavity, beak, and head region may be blood stained. The lesions in the liver are variable depending upon the duration of the condition. A removable layer of yellow coagulated serum may cover the surface (Fig. 40.21). In the early stages the liver is enlarged and mottled with irregular, diffuse, lighter-colored areas resembling fatty change interspersed with red streaks or patches. In chronic cases, the liver is shrunken, nodular, firm, and has a nut-

FIG. 40.19 — Toxic fat syndrome. Severe ascites in a 7-week-old chicken.

FIG. 40.20 — Toxic fat syndrome. Marked distension of the pericardial sac with fluid.

meg or bronze color. The kidneys are pale, swollen, with occasional hemorrhage occurring beneath the capsule of the anterior lobes.

Effect on pullets and layers. Dunahoo *et al.* (1959) studied the effect of toxic fat in the rations of laying hens and pullets. Pullets receiving a diet containing 5 per cent toxic fat from the twelfth to the fourteenth week of age came into production two weeks later than the controls.

Their rate of production was 20 per cent below that of the controls and hatchability was decreased. Pullets receiving 5 per cent toxic fat in the ration for 61 days did not come into production. The growth rate of these pullets was depressed by feeding toxic fat. Sixty-seven per cent of the birds receiving toxic fat for the full growing period died during the course of the experiment. Birds that died before laying age frequently had hydropericardium,

FIG. 40.21 — Toxic fat syndrome. Ascitic fluid in peritoneal cavity and a fibrinous layer over the surface of the liver.

whereas this lesion was rarely present in birds of laying age. Other lesions were ascites, enlarged and ruptured livers, and pale, swollen kidneys. Laying birds fed 5 per cent toxic fat in the ration practically ceased production in 2 weeks time. The hatchability of eggs from birds fed toxic fat was very low. Production was only slightly improved 6 weeks after the feeding of the toxic fat had been discontinued.

Effect on cockerels. Allen and Lalich (1962) reported testicular hypoplasia in cockerels following prolonged feeding of toxic fat at a level of 0.25 per cent in the diet. The rate of growth was not appreciably affected when this concentration of toxic fat was fed. Despite the testicular hypoplasia, the manifestation of such secondary sex characters as comb size and body conformation was not delayed. Toxic fat at levels of 0.5 and 1.0 per cent in the feed caused testicular hypoplasia in conjunction with ascites and hydropericardium. Whereas, when the level of toxic fat was reduced to 0.25 per cent, ascites and hydropericardium were markedly reduced but retarded testicular development was found consistently.

Other species. Simpson et al. (1959) indicated that clinical cases occurred in turkeys as well as chickens but Sanger et al. (1958) stated that according to all reports the disease was confined to chickens. Edgar et al. (1958) fed 4 per cent toxic fat to ducks and turkeys for 6 and 11 weeks respectively but failed to produce any pronounced signs or lesions of the disease.

Histopathology. Simpson et al. (1959) and Sanger et al. (1958) described the histological changes found in the toxic fat syndrome. Liver lesions consisted of areas of focal necrosis, cellular degeneration, and numerous petechiae. Bile duct proliferation was evident and there were accumulations of crystallized bile salts in the bile ducts. In advanced cases there was destruction of nearly all the liver cells which was accompanied by fibrosis and infiltration of heterophiles and lymphocytes. Heart lesions were myocardial degeneration and separation of the muscle fibers, with focal

hemorrhages, and lymphocytic infiltration. The kidneys had interstitial edema and enlarged glomeruli that were bloodless due to the proliferation and swelling of the endothelial cells. Vascular lesions in most tissues were an endotheliosis consisting of proliferation and hypertrophy of the endothelial cells of arterioles. Hyaline casts and fibrin were present in some kidney tubules.

Studies on the toxic factors. Ott et al. (1961) described a chick assay procedure for the edema-producing factor in toxic fat. Detectable hydropericardium was produced by feeding 7 parts of pure edema-producing factor per billion parts of diet in a 20-day feeding period. Mortality was caused when 64 or more parts of the pure factor were present per billion parts of diet. On the basis of comparative assay results it was concluded that the concentration of the pure factor in the toxic fat standard was approximately 0.5 p.p.m. After a 21-month holding period, the toxic fat was calculated to be 72 per cent as toxic as it was initially. This comparatively small loss in the activity of the chick edema factor indicates it is very stable in toxic fat.

Wootton et al. (1962) reported the isolation of three hydropericardium-producing factors from a toxic fat. Two of the compounds were isolated in a pure form. Investigation indicated they possessed a high melting point and high molecular weight. It was also determined that they were crystalline compounds containing six chlorine atoms per mole and appeared to have an aromatic nucleus.

Diagnosis. In making a differential diagnosis of the toxic fat syndrome it would be necessary to eliminate the possibility of cresol poisoning, salt poisoning, crotalaria poisoning, and exudative diathesis.

Cresol poisoning is only of sporadic occurrence in an occasional flock. A careful history of the case would reveal that a cresol disinfectant had been used prior to housing the flock.

Salt poisoning caused by excessive amounts of NaCl in the feed or water

could be detected by analysis of these dietary components for their salt content. Sanger *et al.* (1958) indicated that the extreme liver necrosis found in the toxic fat syndrome was not found in salt poisoning.

Crotalaria poisoning would be more likely to occur in those regions where crotalaria is grown and therefore would tend to be regional in occurrence. Feed suspected of containing *Crotalaria spectabilis* could be analyzed for the toxic alkaloid monocrotalin.

The paucity of reports describing naturally occurring cases of exudative diathesis would indicate that this condition is rarely seen in the field. The marked liver changes found in cases of toxic fat poisoning have not been described for vitamin E deficiency. In field cases of exudative diathesis, Thompson and Smith (1953) described muscular dystrophy of the skeletal muscles and myopathy of the gizzard muscle. In addition, microscopic examination of the brain revealed cerebral edema and hemorrhage. Ascites and marked hydropericardium, a constant feature of the toxic fat syndrome, are not mentioned as prominent changes in exudative diathesis. Controlled feeding trials using supplementary vitamin E would determine whether this vitamin was involved in the disease in question.

If the conditions resembling toxic fat syndrome can be eliminated, then a presumptive diagnosis can be made on the basis of history, signs, and gross and microscopic lesions. If fat still remained from the lot that was used in the suspect feed a bioassay determination could be performed by feeding this fat to day-old chicks. The development of hydropericardium and ascites following the feeding of the suspect fat would indicate its toxicity.

Protein poisoning. Protein poisoning in poultry may be both quantitative and qualitative. Jull (1930) points out the harmful effects of excessive protein in the ration. The clinical symptoms caused by excessive amounts of protein are those of generalized toxemia including depression, leg weakness, prostration, and coma, followed by death. This problem is primarily one of management, and losses from this cause can be prevented by using properly balanced rations.

Birds may also be poisoned by the ingestion of proteins of poor quality such as partly decomposed foods. Decomposed proteins frequently prove toxic if fed in sufficient amounts. It is believed that the products of disintegration are responsible for the toxic reaction, which is not necessarily associated with bacterial toxins produced as in the case of botulism.

Feeds of various kinds, whether they are proprietary feed mixtures or some ingredient of home mixed rations, are often suspected of being responsible for poultry losses. Quigley and Waite (1931) reported that investigation on numerous samples examined over a period of 3 years failed to show any toxic reaction in actual feeding trials. Various other reports indicated that comparatively few feeds suspected of being poisonous proved to be so when examined.

The losses in poultry as the result of poisoning from any cause are exceedingly small compared to the losses attributed to infectious diseases, parasites, and other causes. Positive diagnosis of poisoning depend entirely upon the discovery of the poison in the bird by chemical analyses or by the detection of a specific poison in the food supply.

Diseases of the Turkey**

Dietary Diseases

The turkey responds differently to many of the nutritional factors than does the chicken, and for this reason the requirements are often different. Likewise, the pathological changes seen when these factors are lacking may vary from those seen in the chicken under similar conditions. Only the pertinent facts and differences are given in this section. For more complete information on the nutritional requirements of birds, the reader is referred to the sections on nutrition and vitamin requirements, and to textbooks on turkey

rearing such as Marsden and Martin (1955).

A number of vitamins are known to be needed by turkeys. They are especially important in the starting ration because poults have a higher requirement for some of the vitamins than do baby chicks.

Most vitamins required by turkeys are present in the commonly used feedstuffs, and it is not necessary to purchase them in purified form or in expensive proprietary mixtures. Vitamins A, D, and G (riboflavin) are most likely to be deficient in turkey rations. Table 41.1, compiled by Kratzer (1958), summarizes the symptoms of vitamin deficiencies, the amounts required for normal growth, and the principal sources of the vitamins required by turkeys.

VITAMIN A DEFICIENCY

Sources of vitamin A activity for turkey rations include fish oils, alfalfa meal, yellow corn, fresh greens, and dry vitamin A

TABLE 41.1
Vitamin Requirements of Turkeys (Kratzer, 1958)

Vitamin	Signs of Deficiency	Amount Recommended Per Pound of Feed	Best Sources
A *	Poults—poor growth, unsteady gait, watery eyes, inner eyelid cloudy and partially drawn, white exudate from eyes and sinuses, pustules in mouth and esophagus, white flaky exudate in bursa of Fabricius, high mortality Breeders—loss in weight, unsteady gait, watery eyes, inner eyelid cloudy and partially drawn, white exudate from eyes and sinuses, pustules in mouth and esophagus, poor egg production, poor hatchability with an increase in abnormal embryos	Poults, 4,000 U.S.P. units. Breeders, 4,000 U.S.P. units.	Fresh greens, alfalfa meal, fish oils, commercial concentrates, and synthetic vitamin A.
D₁ *	Poults—rickets characterized by poor growth, leg weakness, enlarged hocks, crooked keel, beaded ribs, soft bones and beak, high mortality. Breeders—low egg production, low hatchability, soft-shelled eggs	Poults, 600 I.C. units. Breeders, 600 I.C. units	Fish oils, activated animal sterols
E *	Development of enlarged hocks in poults fed special rations may be prevented by vitamin E Poor hatchability in breeders Embryos from deficient hens show eye disorders	Poults, 6 I.U. Breeders, 20 I.U.	Fresh greens, grains, alfalfa meal, and commercial concentrates.
K	Blood fails to clot normally Small injuries cause excessive bleeding	Practical rations contain adequate amounts.	Fresh greens, alfalfa meal, and synthetic vitamin K.
Thiamine B₁	Poor growth, emaciation, weakness, inability to stand, and death in poults	Poults, 1 milligram.	Grains, grain by-products, oil cake meals, and synthetic thiamine.
Riboflavin *	Poor growth, leg weakness, low hatchability in breeders	Poults, 2 milligrams. Breeders, 1 8 milligrams.	Milk products, liver meal, fresh greens, alfalfa meal, yeast, fermentation products, synthetic riboflavin.
Pantothenic Acid *	Poor growth, high mortality, and dermatitis at corners of mouth of poults Poor egg production and hatchability in breeders	Poults, 6 milligrams. Breeders, 8 milligrams.	Yeast, molasses, liver meal, milk products, alfalfa meal, wheat bran, fermentation products, synthetic pantothenic acid.
B₆ group	Poor growth, uncoordinated movements, convulsions, high mortality, and poor hatchability in breeders.	Poults, 2 milligrams.	Grain, grain by-products, soybean oil meal, milk products, yeast, alfalfa meal, animal products.
Niacin *	Poor growth, inflammation of the mouth, poor feathering, and perosis	Poults, 35 milligrams Breeders, 15 milligrams.	Wheat and wheat by-products, yeast, liver meal, fish meal, meat scraps, synthetic niacin.
Biotin	Poor growth, dermatitis, perosis, high mortality in poults Poor hatchability.	Exact requirement unknown.	Fresh greens, alfalfa meal, soybean oil meal, cane molasses, grain, grain by-products.
Folic Acid	Poor growth, cervical paralysis, mild anemia, high mortality. Poor hatchability in breeders.	Poults, 0 5 milligrams. Breeders, 0.4 milligrams.	Fresh greens, alfalfa meal, liver meal, wheat bran, soybean oil meal, synthetic folic acid.

(table continued on next page)
FIG. 41.1 — A 5-week-old poult and a 6-week-old chick, both showing typical signs of vitamin A deficiency. (Hinshaw, Univ. of Calif.)

observed an outbreak of the disease, in a breeding flock, which resulted from feeding dehydrated alfalfa meal low in carotene. In addition to the typical symptoms described by Hinshaw and Lloyd (1934), hatchability of eggs laid by the flock was greatly reduced and poults that did hatch suffered a heavy mortality. The breeders recovered except for blindness, hatchability of eggs increased, and poult mortality decreased after the flock was given high potency vitamin A oil.

Necropsy findings. Lesions are confined principally to the upper digestive tract and to the head. They consist of swollen caseated glands (pustules) in the posterior part of the mouth (Figs. 41.2 and 41.3), the upper esophagus, and the crop, and an involvement of the sinuses of the head (Figs. 41.4 and 41.5). The bursa of Fabricius, an accessory pouchlike organ present only in young poults, located dorsal to the rectum and having an opening into the cloaca, is usually filled with a white, flaky exudate. Urate deposits on the intestines, heart, and lungs, and swollen kidneys filled with urates, common in chickens suffering from vitamin A deficiency, have not been observed in turkeys.

By means of chemical tests available in many diagnostic laboratories, it is possible to determine if turkeys have adequate storage of vitamin A in their bodies. These tests are based on the determination of pro-vitamin A or vitamin A in the livers and may prove an aid in differentiating

FIG. 41.2 — Portion of esophagus of a turkey hen, showing pustular lesions in vitamin A deficiency. (Hinshaw, Univ. of Calif.)
FIG. 41.3.—(A) Floor of mouth and pharyngeal region of a 40-day-old turkey that died from vitamin A deficiency. (B) Some of a 45-day-old chick; note the large number of pustules in B as compared with A. The specimens are typical for the two species. (C) Sagittal section of bursas of Fabricius and caseous plugs characteristic of vitamin A deficiency in young turkeys and chickens; the left bursa was from a poult; the right, from a chick; the middle specimens are typical caseous plugs from bursas taken from chicks. (Hinshaw, Univ. of Calif.)

avitaminosis A from diseases showing similar clinical signs.

Control and prevention. Control and prevention consist of furnishing sufficient vitamin A in the ration. This can be supplied by large amounts of bulky feeds such as fresh greens and alfalfa meal. (See

FIG. 41.4.—Turkey hen showing typical signs of a vitamin A deficiency. Taken 87 days after being on a deficient ration. The hen died 3 days after the picture was taken. (Hinshaw, Univ. of Calif.)

Tables 41.1 and 41.2.) According to the National Research Council, both poults and mature turkeys should receive 4,000 units of vitamin A per pound of feed. It should be noted that the vitamin A of fish oils tends to diminish after the oil has been mixed in the mash, and that when alfalfa meal is stored its vitamin A content decreases, especially in warm weather.

RICKETS (VITAMIN D DEFICIENCY)

Rickets is caused by failure to receive a proper balance of vitamin D_3 and minerals. Vitamin D_3 is also necessary for egg production and hatchability. A lack of it contributes to the development of crooked breast bones. This vitamin is present in certain fish oils. It is also supplied by direct sunlight, which changes certain substances in the skin to vitamin D_3. Vitamin D_3 is of great importance to poults, which have a high requirement.

Signs. Leg weakness, awkwardness of gait, softness of the beak and leg bones, and ruffled, unkempt feathers are characteristic of this condition. The affected poults fail to gain weight and finally die if the balance of minerals and vitamin D_3 is not cor-

FIG. 41.5 – An extreme case of sinusitis in a turkey hen suffering from vitamin A deficiency after being fed for 8 months on a ration containing a low level of vitamin A. The picture on the left (A) is a sagittal section of the head shown on the right. (B) Note the massive accumulation of the whitish-yellow caseous exudate typical of sinusitis as associated with vitamin A deficiency in turkeys. (Hinshaw, Univ. of Calif.)

rected. Vitamin D deficiency in breeders causes lowered egg production, lowered hatchability of eggs laid, and an increase in soft-shelled eggs.

According to Scott et al. (1932), poults receiving a diet deficient only in vitamin D_3 will develop signs in 18 to 20 days, and 100 per cent mortality will occur within 30 days after hatching.

Necropsy findings. Softness of the bony

structures and beading of the ribs are the most common necropsy findings. A definite diagnosis depends on a chemical analysis of the bones or blood or upon the "line" test for rickets.

Prevention and control. There are several forms of vitamin D, some of which are very effective for the prevention of rickets in rats, but not in chicks and poults. For this reason, a source of vitamin

TABLE 41.2
EXAMPLES OF VITAMIN A CONTENT IN FEEDSTUFFS (ASMUNDSON AND KRATZER, 1951)

Feedstuff	Approximate Units of Vitamin A Per Pound	Per Cent in Ration To Supply 4,000 Units Per Pound	Amount in Pounds Per Ton of Ration
Dry "A" concentrate (4,000 A per gram)	1,816,000	0 22	4.4
Fish oil (2,250 A per gram)	1,021,500	0 39	7.8
Alfalfa meal	67,000	6	120 0
Fresh green leaves	45,000	9	180.0
Yellow corn	3,100	50 per cent would supply only 1,500 units	

D_3 such as fish oil should be tested with chicks before use in turkey feeding. Poults need several times as much vitamin D in their feed as chicks (see Table 41.1). The International Chick Unit (ICU) based on vitamin D_3 is now used as the standard unit for poultry feed formulas. The recommended allowance for turkeys is 600 ICU for both poults and breeders. The requirements for poults are several times greater than for chicks, so chick rations should not be fed to poults without adjusting the vitamin D_3 level.

Biologically tested fish oils of guaranteed vitamin D_3 potency are the only oils that are suitable for supplying turkeys with vitamin D_3. Fish oils that have no guarantee of potency may or may not contain adequate vitamin D. Vitamin D_3 activated sterols may be substituted for fish oils (see Table 41.1). Dry products containing synthetic vitamin D_3 or feeding oils are the supplements commonly used in turkey rations. Vitamin D_3 is more stable than vitamin A, but its stability is affected by many of the conditions affecting vitamin A, and care must be taken to avoid adding it to premixes unless it is properly stabilized (Grau *et al.*, 1956).

It is a good practice to add vitamin D_3 to the ration of the breeding flock to insure an adequate storage in the egg for development of the embryo and for starting the poult after it is hatched. Since sunshine cannot be depended upon during the brooding season, fish oil should be a regular part of the ration until the poults are put on the range. Whether or not it should then be continued depends on the amount of sunshine available. A proper balance of minerals, especially calcium and phosphorus, is also essential in preventing rickets.

DIETARY DERMATITIS

Patrick *et al.* (1941, 1943) found that biotin is an antidermatitis factor for turkeys. Niacin and pantothenic acid deficiencies (Kratzer, 1958) may also cause mouth inflammation, which must be differentiated. This deficiency disease may be seen in the field, but other forms of dermatitis are also common and must be considered in making a diagnosis. Very little is known regarding the other types of dermatitis (see Miscellaneous Diseases).

Signs. The clinical signs of dietary dermatitis in poults consist of a sore mouth and encrustations at the corners of the mouth; diarrhea, resulting in an inflamed encrusted vent; thickened eyelids that tend to stick together; ragged feathers; and a listless, unthrifty appearance. In advanced cases the feet may also be involved (Fig. 41.6A and B). Growth is very slow, and mortality is high.

Pantothenic acid (filtrate factor) is sometimes spoken of as the "chick antidermatitis vitamin." Dermatitis of a mild form is seen in poults fed a diet deficient in this ration, according to Kratzer and Williams (1948). Such poults grow more slowly than normal and suffer a heavier mortality than chicks fed the same deficient diet.

Prevention of dietary dermatitis consists in supplying adequate amounts of the vitamins concerned. The important sources of these and amounts needed are given in Table 41.1.

PEROSIS (Slipped Tendon, Hock Disease, Spraddle Legs)

Perosis (Figs. 41.7, 41.8, and 41.9) may cause considerable loss to turkey growers if not prevented by use of a properly balanced ration. Jukes (1940) and Evans *et al.* (1943) have shown that this condition in turkeys is associated with an improper balance of calcium, phosphorus, manganese, and choline in the ration. According to Patrick *et al.* (1943), biotin is also an antiperosis factor, and according to Briggs (1946) and Jukes *et al.* (1947), niacin is necessary to prevent it. Lack of manganese is probably the most common cause.

This disease should not be confused with a similar condition of newly hatched poults which is also called "spraddle legs." This latter condition is caused by one of a number of factors including faulty in-
FIG. 41.6 — (A) A 29-day-old turkey after 17 days on a deficient diet. Note the encrusted eyelids, mouth, and nostrils. The feet did not show lesions at the time this picture was taken. (B) Legs and feet of two 3-week-old turkeys. The ones on the left are from a poult fed a deficient ration from hatching time. The others are from a poult fed a normal ration. Note the dryness of the skin of the legs and the marked ulceration of the foot pads in the affected specimen. (T. H. Jukes.)
FIG. 41.7 — Perosis. Note thickening, shortening, and distortion of the perotic legs on the left as compared with the normal legs on the right. (T. H. Jukes, Jour. of Nutr.)
FIG. 41.8 — Leg bones (2, 4, 6) from a perotic 4-week-old turkey poult receiving a ration deficient in choline, compared with leg bones (1, 3, 5) from a normal poult. Note the shortening, thickening, and distortion of the bones caused by choline deficiency. (T. H Jukes, Jour. of Nutr.)

FIG. 41.9 — An advanced case of slipped tendon in a mature turkey. Note the rotation of the right leg at the hock joint. (Hinshaw, Univ. of Calif.)

cubation, improper diet in breeding stock, and faulty structure of hatching trays. Staphylococcosis should also be differentiated from this type of deformity.

Signs. The signs seen in this disease are bowed or badly twisted legs due to improper calcification of the tibia and metatarsus, especially at the hock joints. This deformity allows the tendon of Achilles to slip from its groove. In turkeys the metatarsus often turns at a right angle, giving the name "spraddle legs" to the condition. Occasionally, the femorotibial joint is affected. There is usually enlargement and flattening of the hock joint, and sometimes the entire shank.

Prevention. There is no cure for the disease after it reaches the deformity stages. According to Asmundson and Kratzer

(1951), a poult ration containing from 0.8 to 1.0 per cent phosphorus and 1.8 to 2.0 per cent calcium may be relied upon to provide enough calcium and phosphorus for bone formation and at the same time prevent perosis under ordinary conditions.

Hopper feeding of limestone grit to growing turkeys is not recommended as this practice is unnecessary and dangerous since it upsets the mineral balance of the ration. If grit is to be supplied, it should be of an insoluble type. A summary of the sources of the vitamins needed to prevent perosis and the amounts needed are given in Table 41.1.

MISCELLANEOUS DEFICIENCIES

A number of other deficiencies may occur in turkeys, and the reader is referred to the section on nutrition and vitamin requirements for details. References to a few are given below.

Lysine deficiency in poults is characterized by a white bar appearing on the feathers of bronze and other dark-feathered breeds. Descriptions of this deficiency disease have been reported by Fritz et al. (1947), German et al. (1949), Kratzer et al. (1950), and Grau et al. (1958).

This is the only amino acid studied to date which produces any easily recognized symptom except poor growth. Figure 6.1 shows the effects of a deficiency of this amino acid on the feathers.

Scott (1950), 1951a and b) described a deformity in poults characterized by a swelling of the tibiometatarsal joint associated with a failure in retention of creatinine. This swelling frequently appeared in 2-week-old poults and recurred when the poults were 14 to 16 weeks of age. Retention of creatinine was increased by enriching the ration with vitamin E and inositol. This condition should not be confused with staphylococcosis. The deficiency could, however, predispose poults to staphylococcosis. An enlarged hock condition associated with an isolated soybean protein has been described by Hunt and McGinnis (1959). This condition was prevented by washing the protein concentrate

with water (60° C.) or by addition of all vitamins at a 15-fold increase over the basic level.

Riboflavin deficiency causes poor growth, leg weakness, and poor hatchability of eggs. Table 41.1 and Chapter 3 should be consulted for additional information. Figure 7.12 illustrates the deficiency.

A deficiency of folic acid causes poults to develop a type of cervical paralysis which usually results in death, according to Richardson *et al.* (1945) and Jukes *et al.* (1947). Signs of this deficiency are described in Chapter 7. Figure 7.17 illustrates the cervical paralysis seen.

For the effects of various mineral deficiencies the reader is referred to Chapter 6. A number of papers have been published recently on the effects of zinc deficiency in turkeys. Good reviews on this subject will be found in reports by Supplee *et al.* (1961) and Sullivan (1961a and b).

Fungus Diseases

Fungus diseases, due to molds and yeasts, may cause considerable mortality in turkeys. The most important are aspergillosis, favus, and candidiasis. For an excellent bibliography on avian mycosis see Chute et al. (1962). For a comprehensive review on mycotoxicosis see Forgacs and Carll (1962). See also Chapter 18.

ASPERGILLOSIS (Brooder Pneumonia, Mycotic Pneumonia, Pneumomycosis)

Aspergillosis, more commonly known as brooder pneumonia, is caused principally by *Aspergillus fumigatus*, although other molds of the same genus may be responsible. *A. fumigatus* is widely distributed in nature and is pathogenic for many animals, including man. In young poults kept on contaminated litter, it produces pneumonia with heavy mortality. Infected older birds may suffer from pneumonia or air-sac infection.

Aspergillosis has been reported in turkeys by Lignières and Petit (1898), Balfour (1911), Schlegel (1915), Durant and Tucker (1935), Hinshaw (1937), Witter and Chute (1952), Moore (1953), and Raines et al. (1956). The outbreak reported by Durant and Tucker occurred in wild turkey poults reared in captivity. The disease appeared at 5 days of age and reached a maximum mortality at 15 days. When the epizootic subsided at the end of 3 weeks, only 200 of the 785 poults remained alive. Moore reported ophthalmitis as a common symptom in outbreaks observed by him, and Raines et al. described encephalitis as a common manifestation in an outbreak of 18-day-old poults. Van Heelsbergen (1929) gives a detailed description of an outbreak investigated by Schlegel. The description given below, taken from Hinshaw (1937), is essentially the same as described by Schlegel and is based on the writer's experience with the disease.

Signs. The signs depend on the location of infection. Lesions in the mouth, trachea, or bronchi produce hoarseness, heavy breathing, and sometimes rattling in the throat. As the disease progresses, dullness, labored breathing, and emaciation may be seen. Death probably results from either toxemia or asphyxiation. The mortality varies but is usually greater in brooder poults than in older birds.

Necropsy findings. Diagnosis is readily made in advanced cases. The lungs and air sacs are the principal seats of infection, but the process may extend into the peritoneal cavity or into the air passages of the bones (Fig. 41.10). The kidneys, liver, and spleen may be affected by direct contact from the air sacs. Yellow, semiliquid, or caseated masses in the air sacs and lungs, with buttonlike ulcers attached to the mucous membranes, are common. In the early stages these ulcers appear as round, yellowish-white masses attached to the membrane. In advanced cases a greenish mold turf may be seen over the surfaces of the infected areas and in the convex depressions of the ulcers, especially in the air sacs.

In cases of ophthalmitis, described by Moore (1953), the primary involvement was in the vitreous humor and the adjoining tissues. In one bird he observed the presence of mycelia in the crystalline lens.

In encephalitis aspergillosis described by Raines et al. (1956), torticollis and lack of equilibrium were observed. The brains of such cases contained necrotic foci 1–2 mm. in diameter in both the cerebellum and cerebrum. Hubben (1958) has reported meningoencephalitis in both turkeys and ducks. A mycotic encephalomalacia has

FIG. 41.10 — Lungs of turkey showing typical caseous nodules seen in the early stages of aspergillosis. Note also irregular lesion with center darkened by aerial hyphae of the fungus, denoted by the arrow. (Hinshaw, Univ. of Calif.)

been described by Jungherr and Gifford (1944).

Final diagnosis depends on identification of the mold. The fungus can be readily demonstrated by microscopic examination of specimens that have been treated with 10 per cent sodium or potassium hydroxide and by culturing on suitable media. A careful examination of the surface of the buttonlike lesions will often reveal aerial hyphae, and seedings from these will usually insure a pure culture. See also the section on Mycotoxicosis.

Prevention, control, and treatment. Careful selection of mash, grain, and litter is essential in preventing this disease. Access to musty, moldy strawstacks should be avoided.

Improperly kept drinking fountains used for dispensing milk have been found to be a source of infection. One outbreak was associated with contaminated milk cans. The inside of the lids of the cans used for transporting milk was found to be covered with a fine mold growth; the owner had washed and scalded the cans daily but thought it unnecessary to clean the lids. The storage barrels for the milk were also heavily infected.

The areas around feed hoppers and watering places are fertile fields for the growth of molds. Unless a permanent yard

system is used, frequent moving of feed troughs and watering places is advisable. Placing feed containers and watering fountains on screened elevated platforms helps to prevent turkeys from picking up molds that develop in such places. Drainage is advisable for areas where water is liable to stand after rains.

Control is best accomplished by removing the cause. A careful search should be made for mold in the litter, the feed, and the feed and water containers. Daily cleaning and disinfection of feed and water utensils will aid in eliminating the infection. Spraying of the ground around the containers with chemical solutions may be advisable if it is impossible to change feeding areas frequently. In outbreaks, a 1:2,000 solution of copper sulfate in place of all drinking water may be used to aid in preventing the spread through this means, though it should not be relied upon as a preventive to be used continually. The antifungal antibiotics as preventives for this disease should be considered.

The deep-seated nature of the respiratory form of the disease renders treatment of little avail. *Extreme care should be used in handling and disposing of sick birds because of the possible danger of transmitting the disease to the attendant.*

MYCOTOXICOSIS

Mycotoxicosis is a poisoning of the host which follows the entrance into the body of toxic substances of fungal origin. A large number of fungi are capable of producing toxins and the reader is referred to Forgacs and Carll (1962) for a comprehensive review.

Peanut (ground nut) meal poisoning (Turkey X Disease). After the review by Forgacs and Carll (1962) was written and in the process of publication, a serious disease of turkeys which was causing enormous losses on British turkey farms was reported. This disease affecting all ages was called Turkey X Disease by Blount (1961) and was subsequently found to be caused by a toxin produced by *Aspergillus flavus* (Sargeant *et al*, 1961). The source was contaminated peanut (ground nut) meal used widely in British animal feeds. Over 500 British turkey farms were affected in 1960 and losses in excess of 100,000 turkeys were reported.

Other pertinent references on these outbreaks and subsequent reports on research on the disease in turkeys include the following. Asplin and Carnaghan (1961), Lancaster *et al* (1961), Siller and Ostler (1961), Wannop (1961), Allcroft and Carnaghan (1962), and Nesbit *et al* (1962). Chickens and ducks were also found to be susceptible, and ducklings were found to be the laboratory animal of choice for detecting toxicity of suspected toxin-containing feeds. Blount *et al* (1963) found differences in susceptibility of different strains of ducklings used for assay. It should be emphasized that other animals are also susceptible to this toxin (Clegg, 1962) and that *A. flavus* can contaminate other substances used in animal feeds (Richmond *et al*, 1962). Toxins from other species must also be considered (Forgacs and Carll, 1962).

Signs. The signs of the disease as described by the various investigators include death without observed signs, depression, unsteady gait, stiffness of the muscles, and torticollis. Falling over backwards was also observed.

Necropsy findings. On necropsy, typical lesions of the kidneys include membranous glomerulonephritis and hyaline droplet nephrosis. The liver shows a very severe hepatic necrosis and excessive bile production. Marked catarrhal enteritis especially in the duodenum is characteristic.

Treatment. No specific treatment has been suggested. Forgacs *et al*. (1963) have, however, reported on the antimycotoxic activity of 8-hydroxyquinoline under laboratory and simulated field conditions with a number of mycotoxins. The British outbreaks have stimulated a large number of investigations aimed at producing fungus-free sources of peanuts used for production of meal for use in animal feed rations.

Hemorrhagic syndrome. Although this well known condition in chickens and especially in broilers (Forgacs *et al.*, 1958, 1962) has not been reported in turkeys, the possibility of finding it in turkeys should not be overlooked.

FAVUS

Favus is a chronic skin disease caused by a fungus, *Achorion gallinae*, and characterized by whitish areas on the exposed skin parts of the body (Fig. 41.11). It is not a commonly occurring disease. *Since man is susceptible, care should be taken to prevent transmission if an outbreak occurs*. The disease is generally mild and sporadic in nature. It may exist in a flock for several months, but few losses directly traceable to it are experienced.

Signs. The white powderlike spots which characterize the disease usually appear first around the beak. Thence they spread to the wattles, dewlap, and snood, and in extreme cases to the feathered portions. The fine pinpoint white spots finally coalesce and may cover a considerable area. As the fungus spreads and grows, a piling up of the threads occurs, and a thick, crustlike area may result.

Prevention, control, and treatment. Removal and disposal of all infected birds is recommended. It is well to move the flock to new quarters when practicable. After removal of infected individuals, the

FIG. 41.11 — Favus. An unusual case affecting the entire carcass. (L. D. Bushnell.)

premises must be thoroughly cleaned and disinfected.

Treatment should be attempted only in very valuable birds. Fungicidal ointments and antifungal antibiotics may be of value, but no experimental information on their efficacy is available. A mixture of 6 parts of glycerine and 1 part of iodine applied locally is recommended by van Heelsbergen (1929) for the infected parts of the head. Beach and Halpin (1918) reported that a formalin-vaseline ointment rubbed thoroughly into the lesions cured 50 out of 52 cases treated.

CANDIDIASIS (Mycosis of the Crop, Moniliasis, Thrush)

Candidiasis is a disease of the upper digestive tract of both chickens and turkeys caused by yeastlike organisms belonging to the genus, Candida. Jungherr (1933a) was probably the first in the United States to observe the disease in chicks; Gierke (1932) has reported an outbreak of a thrushlike disease occurring in turkeys in California during the summer of 1932; and Hinshaw (1933) has described the results of studies on several outbreaks in turkeys and chickens. A review on the disease as it now exists in turkeys and chickens in California is recorded by

Mayeda (1961). Hart (1947) reported the disease in turkeys and other fowl in New South Wales. Blaxland and Fincham (1950) and Jordan (1953) have reported the existence of the disease in Great Britain. Wickerham and Rettger (1939), in a taxonomic study of Candida species from various sources, included several strains isolated by Hinshaw from turkeys and chickens. These proved to be Candida albicans and were indistinguishable from species isolated from man. Jungherr (1933b, 1931) found in later studies that C. albicans and C. krusei and Oidium pullorum n.sp. were the yeastlike fungi most frequently isolated from chicks. Of these he considered C. albicans and O. pullorum of etiological importance. A soluble endotoxin, toxic for mice, was isolated from C. albicans by Salvin (1952). As far as is known, the influence of this endotoxin on the disease in fowl has not been investigated.

Jungherr (1933a) was able to transmit the disease in chicks by feeding fecal material from diseased chicks and by injecting pure cultures of C. albicans. The average period of incubation under experimental conditions was 31 days. Hinshaw (1933) was able to transmit the disease from turkeys to turkeys, chickens, and rabbits. He observed that the disease is one

associated with poor management, where unsanitary surroundings prevail and debilitation is prevalent. Under such conditions the use of antibacterial antibiotics in feed or drinking water could result in an increase in *Candida albicans* in the digestive tract. This in turn could influence the incidence and severity of the disease. The relation of *Candida* sp. to pendulous crop is discussed in the section on that disease.

Signs. As most of the outbreaks observed have been complicated with some other pathologic condition, specific signs have been difficult to determine. More or less constant clinical signs, however, are listlessness, loss of appetite, tendency to stand around with heads drawn back on *the shoulders*, and a sunken appearance of the chest. The eyes and sinuses appear sunken and the heads haggard. Candidiasis must be differentiated from the disease formerly described by Jungherr (1927) as a mycosis of the crop of turkeys but now known to be caused by a Trichomonas. (See Trichomoniasis of Upper Digestive Tract.)

Underwood (1955) has described the use of a panendoscope as aid in diagnosing the disease. This instrument is inserted into the crop via the mouth and esophagus and permits visual examination of the mucous membrane for lesions.

Necropsy findings. The crop has been the most common seat of infection. Fungi have also been demonstrated in scrapings from the mouth, infraorbital sinuses, upper and lower esophagus, proventriculus, gizzard, and intestines. Cultures of the causative organism have been obtained from all of these organs and in addition from a lung abscess and from a skin abscess.

In the more acute cases, as well as in the milder cases, there is seen a catarrhal to thick mucoid exudate with a tendency to form a pseudomembrane. Soft, raised, whitish-yellow ulcers having a roselike appearance and scattered over the surface, at times coalescing to form a solid mass of piled-up exudate (Fig. 41.12) characterize the more chronic cases. These lesions have been variously described by turkey growers and others as having a "turkish-

FIG. 41.12 — (A) Crop of a turkey suffering from candidiasis (moniliasis). (B) Enlarged section of A; note the raised, piled-up exudate which tends to form roselike masses. (Hinshaw, Univ. of Calif.)

towel-like" or "curdy" appearance. In early or mild cases the mucous membrane may appear parboiled. The lesions are easily scraped from the surface, leaving the mucous membrane abraded and injured.

In most cases the crops either are empty or contain a small amount of thick slimy exudate. Cultures of the fungus are readily obtained in nearly pure state by washing off the surface exudate and planting a fairly deep scraping on suitable media.

Prevention, control, and treatment. Because of the nature of the disease and its frequent association with other diseases common in crowded quarters and in flocks suffering from some form of malnutrition, sanitation and proper diet are important factors in control. Removal of birds to clean and thoroughly disinfected quarters, together with the daily cleaning and disinfection of feed and water containers, has helped to reduce losses.

According to Underwood et al. (1956), copper sulfate either in the feed or in drinking water (1:1,000 and 1:1,500) has little effect on C. albicans or the disease in experimentally produced cases in chicks and poults. Yacowitz et al. (1959) reported successful prevention of Candidiasis in chickens by the addition of an antifungal antibiotic, Nystatin (Mycostatin-Merck), at a minimum level of 152 mg. per kilogram of ration for a period of 4 weeks. Kahn and Weisblatt (1963) obtained similar results. Wind and Yacowitz (1960) successfully treated crop mycosis with mystatin (Mycostatin-Squibb) by dispersing it in drinking water at levels of 62.5 to 250 mg. per liter with sodium lauryl sulfate (7.8 to 25 mg. per liter) for a 5-day period.

If antibacterial antibiotics are being used in an infected flock for nutritional purposes, their removal may aid in reducing the Candida flora.

Bacterial and Viral Diseases

The common diseases of turkeys caused by bacterial and viral agents are included in this section. The reader is referred to standard textbooks on bacteriology if descriptions of the causative organisms are desired. For discussions on fowl plague, fowl coryza, ornithosis, equine encephalomyelitis virus in birds, Newcastle disease, and other diseases seldom seen in turkeys,

the reader is referred to the sections on diseases of chickens.

BOTULISM*

Botulism is caused by toxin produced by an anaerobe, Clostridium botulinum. Of the types of botulinic toxins poisonous to man and animals, only A and C are

* See also Chapter 15.

known to affect fowls. The toxins are produced by the microorganism while growing in such substances as decomposing food, dead carcasses, and wet grain, and are transmitted to birds when the contaminated products are eaten. Coburn and Quortrup (1938) described an outbreak of botulism in turkeys caused by the type C organism. The outbreak occurred in a flock of 1,400 turkeys which were ranging on a 20-acre stubble field. About 50 turkeys were sick at the time of the investigation, and an additional 50 had died the previous week. The source of the toxin was found to be a shallow, stagnant pool of water in the stubble field. Filtered water samples from it were shown to contain the type C toxin by tests on white mice. *Clostridium botulinum* (type C) was also isolated from the soil taken from the water hole.

Signs. The most common clinical sign is complete paralysis of the neck, which gives the disease its name, "limberneck." The birds sit with their heads and necks on the ground or extended over the back (Fig. 41.13), often in a comatose condition. In turkeys the feathers do not shed so readily as in chickens affected with the disease.

The turkeys in the outbreaks described by Coburn and Quortrup (1938) manifested evidence of cyanosis of the head, posterior paralysis, and dyspnea, but only a few showed paralysis of the nictitating

membrane, a symptom usually considered pathognomonic. Some of the sick turkeys recovered spontaneously.

Necropsy findings. Coburn and Quortrup described the following postmortem findings: petechial hemorrhages on the auricular pericardium, hyperemia of the duodenal mucosa, and cloaca distended with urates. Thus the gross pathology would make one suspicious of fowl cholera.

One should look for evidence of spoiled food in the crop and for the presence of fly maggots, which are suggestive of the consumption of spoiled food. Diagnosis depends on the history obtained and on the symptoms and necropsy findings, but finally on the demonstration of the toxin or causative organism.

Prevention, control, and treatment. Every effort should be made to prevent turkeys from obtaining foods that might harbor the botulinus organism. Spoiled canned vegetables should never be given, for they are liable to contain botulinus toxin.

When the disease appears, all the birds should be moved to a new feeding ground and, if necessary, fenced to prevent access to spoiled food. Sick birds should have plenty of shade. Their crops can be drained and flushed out with warm water with the aid of a rubber tube and a funnel. Large doses of mineral oil or castor oil may help to get rid of the toxin in birds that have not gone into coma. The cause of the trouble should be traced and recurrence prevented. In valuable birds polyvalent (mixed) botulinus antitoxin may be used.

Persons handling turkeys suffering from botulism should keep in mind that the botulinus toxin may affect man. Careful washing of the hands after care of the birds is suggested as a precautionary measure.

ERYSIPELAS*

This disease, caused by the swine erysipelas organism *Erysipelothrix insidiosa (rhusiopathiae)*, was first reported in tur-

FIG. 41.13 — Typical posture in botulism of turkeys. (Hinshaw, Univ. of Calif.)

* See also Chapter 15.

keys by Jarosch (1905). The first report of an outbreak in the United States was made by Beaudette and Hudson (1936) in New Jersey. Since 1936 it has been diagnosed in various sections of the United States (Hudson, 1949). Reference is made to Chapter 15 as to how the disease affects other birds.

Most of the outbreaks reported in the literature have been confined to one farm with no recurrence the following year. In some areas, however, particularly in northwestern United States, the disease is now enzootic, and recurrence on the same farm is common. Swine and sheep, reported to be important factors in transmission in some areas, do not appear to be the sources in the Northwest. Fish meal has been suggested as a possible source of this infection (Grenci, 1943). The outbreaks have usually occurred in turkeys approaching the market age, and males have appeared to suffer the heaviest losses. Rosenwald and Dickinson (1941) have, however, diagnosed the disease in poults from a few weeks of age to maturity.

Signs and mortality. The disease manifestations are primarily those of a septicemia. The mortality in an outbreak studied by Beaudette and Hudson (1936)

was high, 200 of a flock of 500 dying in 9 days. Often, the first indication of the presence of the disease is the finding of dead birds which appear to be in good condition.

The clinical signs are listlessness, drooping tails and wings, and sometimes yellowish green diarrhea. Swelling of the joints of the legs has been noted, but this is not a constant sign. Affected birds tend to remain aloof from the remainder of the flock. These sick birds crouch; the heads often appear cyanotic, and nasal catarrh is a common sign. Swelling of the snood, as illustrated in Figure 41.14, is characteristic of this disease, but similar swellings are also seen in outbreaks of fowl cholera. Erysipeloid lesions commonly appear on the face, involving the major portion of the eyelids and area posterior to them (Fig. 41.15). The other areas of the skin most often affected are the wattles and breast. In acute outbreaks many of the individuals develop varying degrees of skin necrosis. Vegetative endocarditis may cause listlessness and loss of body flesh of a number of birds in a flock several weeks after the acute stage. The effect on the appetite seems to vary in different outbreaks, though most investigators agree that feed

FIG. 41.14 — Erysipelas. Swollen snood which is, according to Rosenwald and Dickinson, pathognomonic for the disease may also be seen in outbreaks of fowl cholera. (Rosenwald and Dickinson, Am. Jour. Vet. Res.)

consumption is lowered. Recovery in acute cases may be complete in a week or 10 days.

Temperatures as high as 109.6° F. have been noted in field outbreaks of the disease in turkeys, but rise in temperature has not been consistent with clinical signs. Adult turkey hens artificially infected with E. insidiosa have not shown uniformly marked increase in temperature. One such bird (19 weeks of age), given 0.8 cc. of 24-hour broth culture, became ill in 48 hours and did show a continued rise in temperature until it reached 110.6° F. on the fourth day after inoculation. On the day of its death (the sixth after inoculation) the temperature was 109.8° F. Another bird, which became visibly ill in 48 hours but recovered within 2 weeks, showed only a slight rise in temperature during the period of visible symptoms. A third turkey hen showed an increase from 104.9° F. on the day before inoculation to 108.8° F. on the sixth day after inoculation. Its temperature gradually subsided though the bird itself developed a chronic type of the disease and was finally killed in an emaciated condition after 4 weeks.

Necropsy findings. Diffuse hemorrhagic areas of various sizes are common in the breast muscles. The skin of the breast may develop purple-colored, irregular-shaped blotches, commonly referred to as "erysipelas blush." Diamond skin lesions so common in the chronic disease of swine are seldom seen in turkeys, but one such case is described by Peterson and Hymas

(1950). The nasal passages are usually filled with thick mucus; the livers are enlarged, congested, and friable. Catarrhal enteritis is evident, with some reddening of the mucosa of the large intestine. In most cases the spleens are enlarged, mottled, and friable, hemorrhages sometimes appearing. Other lesions occasionally found are hemorrhages in the pericardium, congestion of the kidneys and lungs, and, rarely, browning of the lung tissue. Vegetative endocarditis involving the bicuspid and tricuspid valves is often seen in chronic cases (Fig. 41.16). Stiles (1946) considered the absence of pus in affected joints and other structures as characteristic of the disease.

Diagnosis. The marked hemorrhagic condition of the skin and fascial and muscular tissues of the breast is the most significant finding at necropsy according to most investigators. Diagnosis must be confirmed by isolation of the causative organism. Differentiation from fowl cholera is necessary because of the similarity of the two diseases. The use of mice and pigeons for inoculation tests is recommended, as is the use of anti-swine-erysipelas serum for neutralization tests in the inoculated test animals. Mice or pigeons given either the pure cultures of the organism or tissues from erysipelas cases die within 21 to 96 hours. Similarly infected animals protected with 0.5 cc. of antiserum do not become sick.

FIG. 41.16 — Erysipelas. Vegetative endocarditis on the tricuspid valves as well as on one of the bicuspid valves in the left side of a turkey's heart. (E. M. Dickinson.)

Another aid to diagnosis is to stain blood or liver smears by Gram's method. The characteristic Gram-positive rods (which decolorize easily, however) are usually grouped in interlacing bundles. The individual organisms are slender, slightly curved, and show characteristic granules. It is possible to isolate the causative organism from the bone marrow of turkeys which have been dead as long as 2 weeks. Jerstad and Dickinson (1956) suggest that because of the persistence of the causative agent in bone marrow, only the shank of a dead bird needs to be shipped to a laboratory for diagnosis.

Prevention, control, and treatment. Since the disease is common in swine and sheep in the United States, turkeys should be kept away from swine and sheep herds in areas where erysipelas is known to exist. It is also unwise to use turkey ranges where the disease has previously occurred. For this reason unnecessary moving of the sick flock to clean range should be avoided.

Grenci (1943) isolated *E. insidiosa* from two samples of fish meal, a common ingredient of turkey feed. Therefore, as a preventive measure, this product should be thoroughly sterilized before being used in turkey feed.

Numerous reports on the use of anti-swine-erysipelas serum and antibiotics have been published. Beaudette and Hudson (1936) found that serum from recovered turkeys protected mice against infection. Lindenmayer and Hamilton (1942) found that 5.0 cc. of formalized serum from sick turkeys had protective value when injected intramuscularly into exposed turkeys. Inconsistent results have been reported on the use of anti-swine-erysipelas serum in sick flocks.

Dickinson (1958) states that treatment of visibly sick birds with penicillin and immediate use of bacterin for all birds is preferable to the use of antiserum.

Recent research on bacterins and antibiotics for prevention and control of the disease in turkeys has yielded encouraging results. Adler and Spencer (1952), Dickinson *et al.* (1953), Moynihan and Stovell (1954), Jerstad and Johns (1954, 1957), and Boyer and Brown (1957a, b) have reviewed the literature on methods of prevention and control and have given their own research results. Jerstad and Dickinson (1956) recommend routine vaccination of flocks of turkeys at 8 to 10 weeks of age in areas where the disease is a yearly problem. The formalized aluminum hydroxide adsorbed bacterin described by Adler and Spencer (1952), Dickinson *et al.* (1953), Jerstad and Johns (1954), and Cooper *et al.* (1957 a, b) is recommended to protect the birds to market age. An initial dose of 2 ml. intramuscularly or subcutaneously is recommended for young birds.

Large toms or breeders can be given 4 ml. booster injections at 16 weeks of age for additional protection. Although intramuscular injections were recommended in the original reports of these investigators, Dickinson (1958) states that intramuscular injections in the breast muscles may result in an inflammatory reaction which may be evident at market time if birds are slaughtered too soon after injection. To avoid this possible reaction, which may cause rejection of carcasses by inspectors, Dickinson suggests that older birds, especially, be injected subcutaneously in the neck about 1 to 2 inches below the skull (Fig. 41.17).

For control of the disease in an outbreak, Jerstad and Dickinson (1956) suggest giving all visibly sick birds penicillin and immediately injecting the entire flock with bacterin. They recommend injection of 0.5 ml. (200,000 units) of aqueous procaine penicillin G or crystalline penicillin G potassium or 1.0 ml. (300,000 units) of aqueous mixture of dibenzylethylenediamine dipenicillin G (150,000 units) and procaine penicillin G (150,000 units). Treatments should be repeated if necessary. Oil diluent preparations are not recommended for advanced cases because of slow action. Also they are difficult to use in cold weather.

Boyer and Brown (1957a, b) reported on the efficacy of oral therapy with antibiotics for control of erysipelas. Procaine penicillin in drinking water at 1,200 mg. per gallon, or in feed at 600 gm. per ton and aureomycin at 100 gm. per ton of feed plus soluble aureomycin in water at 1,000 mg. per gallon proved effective when used under summer conditions. In winter, slightly larger doses were necessary to get equivalent results due to difference in water and feed intake. These authors concluded that from the standpoint of experimental results and cost procaine penicillin is the most practical and efficient antibiotic to use for erysipelas control.

The existence of different antigenic strains of E. insidiosa as well as the possibility of the occurrence of both avirulent and virulent strains is discussed by Truszczynski (1961). These observations, along with those of Raines and Winkel (1956) that antibiotic resistant strains may exist, emphasize the need for continual examination of strains isolated from field outbreaks in order to give accurate advice on control measures.

McCulloch and Fuller (1941) found that household lye (sodium hydroxide) in dilutions of 1:200 to 1:500 is an effective disinfectant against E. insidiosa. Phenol, liquor cresolis and related disinfectants, tincture of iodine, triethanolammoniumlauryl sulfate, and household soaps were moderately effective, but formalin was ineffective.
FIG. 41.17 — Older birds should be injected subcutaneously in the neck region as illustrated. (E. M. Dickinson.)

Caution. Since the causative organism of this disease is pathogenic for man, extreme care should be taken when handling infected birds or tissues. Erysipeloid cases caused by contact with diseased turkeys have been reported by Stiles (1916) and Bivins (1919). At least three additional cases (unpublished) have been reported to Hinshaw.

FOWL CHOLERA*

Fowl cholera, caused by Pasteurella multocida, results in severe economic losses to turkey growers in certain areas. It was first described by DeVolt and Davis (1932), who reported an outbreak in a flock of 175 turkeys in Maryland where there was a 17 per cent mortality. Moynihan and Bankier (1945) have reported the disease in Canada, and Smith and Field (1944) described an outbreak in England. In the writer's experience, the

* See also Chapter 11

disease has been most prevalent in turkeys of about marketable age (6 to 8 months). In many outbreaks chickens have been shown to be the source of the disease, but it may also be carried by adult turkeys.

Signs, course, and mortality. In many respects the clinical signs of fowl cholera resemble those seen in fowl typhoid outbreaks. They include increased thirst, loss of appetite, listlessness, yellow or greenish-yellow, watery diarrhea, and a rise of 2° to 3° F. above normal temperature. The heads appear blue to purplish and have a haggard, drawn appearance. A slimy to gelatinous exudate in the mouth and nostrils is common. The breast muscles become congested, and the skin appears pinkish. Swelling of the snood, similar to that seen in outbreaks of erysipelas (Fig. 41.14) is characteristic in males. Paralysis of the legs and swollen joints are noted in both males and females which develop the chronic type of the disease.

The course of the disease causes acute, heavy losses occurring within a few days, followed by intermittent losses. Symptoms may not be observed before death. In less acute cases the birds linger for several days before dying. Very few sick turkeys recover. Losses vary from a few birds to over half of the flock.

Necropsy findings. The necropsy findings in turkeys are typical of those in chickens, though generally more pronounced. The breast muscles are congested, and the crop usually contains considerable food having a very sour odor. The heart is often enlarged, and the pericardium may be thickened and covered with a whitish-yellow exudate. Petechiae are commonly found over the surface of the pericardial sac, the muscles of the heart, and the adjacent tissues. The pericardial sac may be filled with a yellowish fluid containing whitish-yellow flakes. The liver is enlarged, friable, often salmon colored, and may contain many minute whitish abscesses that give it a mottled appearance. The spleen may be enlarged or show no alteration.

The blood vessels of the mesentery and intestines are usually engorged. The intestines lack tone and often show considerable evidence of hemorrhage, especially in the duodenum. The contents range from a semiliquid to a mucoid consistency. The feces are yellow to yellow-green.

The gizzard seldom contains much food, but the contents present have a peculiar sour odor. The mucous membrane peels readily, and the muscle of the gizzard appears more red than normally. Considerable gelatinous exudate may be present in the proventriculus, and the mucous membrane denuded.

Pneumonia is a characteristic finding. Various stages of lung involvement, from congestion to complete hepatization, are seen. In such cases, the pleural cavity contains a surplus of fluid, or the air sacs may be filled with a semisolid, yellow caseous mass. Similar caseous deposits may be found throughout the abdominal cavity, and such lesions must be differentiated from aspergillosis. In the latter condition the characteristic nodules and "button ulcers" serve as differentiating lesions.

There is a fetid odor to the body cavities and the digestive tract contents of birds suffering from fowl cholera. This odor, difficult to describe, is that of advanced putrefaction and is recognized after experience with a few cases. Isolation of the causative organism is the final means of diagnosis.

Prevention, control, and treatment. Sanitation and hygiene play an important role in prevention. Turkeys should be kept segregated from all fowl that have suffered from the disease. Adult carriers are responsible for the yearly recurrence of the disease on some ranches, and depopulation for a season may be necessary. There is no evidence that the disease is transmitted through the egg, but it is not a good plan to keep for breeding purposes turkeys that have recently suffered from the disease. Complete segregation of the breeding and brooding units or sale of the entire adult flock before any poults are hatched are

recommended as preventive measures on ranches where the disease has existed.

Skidmore's (1932) observations on the common housefly as a possible carrier emphasize the need for keeping turkeys well isolated from chickens or other fowl that might be suffering from the disease, and for prompt destruction of all diseased birds. Wild birds must be considered possible transmitters of the disease. The type of Pasteurella which caused an outbreak studied at the California station (unpublished data) proved to be identical to the one isolated from quail by Hinshaw and Emlen (1943). Burning or the use of a disposal pit instead of burial of dead birds is recommended; otherwise the diseased carcasses, a source of infection, may be dug up by dogs and other animals.

Immunization. Recent researches designed to improve bacterins for use in prevention of fowl cholera have yielded promising results. Pertinent references on this subject include the following: Heddleston and Hall (1958), Heddleston and Reisinger (1959, 1960), Heddleston (1962), Boyer and Brown (1963), and Dorsey (1963a, b).

The current recommendation, based on Heddleston and his co-workers' findings, is to use one of two bacterins. One of these is a water-oil emulsion formalized suspension of *P. multocida* (Heddleston and Reisinger, 1959), and the other is a formalized aluminum hydroxide adsorbed bacterin (Heddleston and Reisinger, 1960). Because of the existence of at least two immunogenic avian types of *P. multocida* (Heddleston, 1962; Dorsey, 1963a), it is recommended that a bivalent bacterin be used. Boyer and Brown (1963) compared bivalent and monovalent bacterins for turkeys and obtained somewhat better results with a bivalent type, but did not get complete protection with either one.

The use of bacterins for prevention of fowl cholera should be confined to those areas where the disease is an economic factor in production. Furthermore, only bacterins which have been proved to be of immunogenic value should be used. Determi-

nation of the immunogenic types of *P. multocida* which are responsible for losses from fowl cholera in a community is suggested. The use of bacterins containing these types will give greater assurance of protection against the disease.

Since much research on the immunization of turkeys is in progress, the reader is urged to continually search the current literature for new advances.

Treatment with drugs. Alberts and Graham (1948) employed sulfamerazine in an experimentally produced outbreak of fowl cholera in turkeys and in a naturally occurring outbreak in adult turkeys. Treated mash containing 0.5 per cent of the drug or 0.5 grain per pound of body weight given orally twice daily prevented losses from the disease during the period of treatment but failed to prevent recurrence of the disease. Their findings suggested sufficient retention of sulfamerazine in the body after discontinuing treatment to suppress *P. avicida* for 2 days after the course of therapy. At the California station sulfamethazine given at the rate of 0.3 per cent in the mash for a period of 3 days definitely reduced losses if given early in an outbreak. The drug did not, however, prevent a recurrence of the disease, nor were carriers eliminated. No evidence of immunity was noted following intermittent treatments over a period of several weeks. Sulfamethazine in amounts greater than 0.3 per cent affected egg quality in laying flocks of turkeys. Peterson (1948) found that 1:2,000 to 1:4,000 dilution of sulfaquinoxaline in drinking water stopped losses in field outbreaks.

McNeil and Hinshaw (1948) found that streptomycin administered in dosages of 150,000 micrograms (25,000 per kilogram of weight) prevented mortality in turkeys artificially infected if treatment was given before or at the same time as inoculation of *P. multocida*. When treatment was delayed 6 to 24 hours or when smaller dosages were given, mortality was prevented, but many chronic cases and carriers developed. Penicillin was ineffective.

Richey and Morgan (1957) found that both chloramphenicol (Chloromycetin) and sulfaquinoxaline reduced losses from fowl cholera if given at the onset of the disease or soon thereafter. Chloramphenicol was given at the rate of 1.0 gm. per pound of feed or 0.2 gm. of chloramphenicol suspension injected intramuscularly. Sulfaquinoxaline was used at the rate of 1.5 gm. per 10 pounds of feed or at the rate of 15 fluid ounces per gallon of water.

FOWL POX[*]

Fowl pox, a disease of the unfeathered parts of the birds' bodies, is characterized by the formation of pustules and scablike processes. It is caused by a filterable virus, pathogenic for chickens as well. Brunett (1933) tested fowl pox viruses of chicken, turkey, and pigeon origins and reported that the turkey strain was pathogenic for chickens, but not for pigeons. All three strains produced lesions in turkeys, but only the chicken and turkey strains produced immunity.

Tietz (1933) reported that turkeys were not susceptible to the strain of pigeon pox viruses used by him. Hinshaw's experience

has been more like that of Tietz, though very slight swellings of the feather follicles have been noted. Coronel (1934), Brandly and Dunlap (1938), and Beaudette and Hudson (1941) published evidence to show that there is a distinct strain of turkey pox virus which differs from both the chicken and pigeon types. Field observations made by Hinshaw suggest that such is the case.

Matheson *et al.* (1931) reported transmission of fowl pox by mosquitoes, and later Brody (1936) published a comprehensive report on subsequent investigations. These investigators found that one species of mosquito (*Aedes aegypti*) was still able to transmit pox 41 days after

* See also Chapter 26.
FIG. 41.18—Fowl pox in turkeys. Taken 3 weeks after lesions first appeared. (Hinshaw, Univ. of Calif.)

an initial infective meal. Blanc and Caminopetros (1930) in an earlier paper reported transmission by *Culex pipiens* 58 days after feeding on infected birds.

Signs and necropsy findings. The first indication of pox is the appearance of minute yellowish eruptions on the dewlap, snood, and other head parts. They are soft and, in this pustular stage, easily removed, leaving an inflamed area covered with a sticky serous exudate. The corners of the mouth, the eyelids, and the oral membranes are commonly affected. The lesions enlarge and become covered with a dry scab or a wartlike mass of yellowish-red or brown color (Figs. 41.18 and 41.19). The number of lesions depends on the virulence of the disease. In young poults, the head, legs, and feet may be completely covered with pustules. The disease may even spread to the feathered parts of the body (Fig. 41.20).

Brandly and Dunlap (1938) reported two cases in 3-week-old poults in which the foot pads and foot webs were involved. Large wartlike processes developed which made it difficult for the poults to walk. Except for a lesion of the mouth in one poult, the disease was confined to the feet (Fig. 41.21). In these instances the infection was apparently introduced when the owner "toe punched" the poults for identification purposes.

Males often suffer more than females from the disease, probably because of their inclination for fighting, which spreads the infection through small lacerations.

The mouth parts, the tongue, the esophagus, and occasionally the crop may be covered with masses of soft, yellow cankers closely adhering to the mucous membranes (Figs. 41.19 and 41.22). These yellow, diphtheric ulcers of fowl pox must be differentiated from the small, deep-seated, irregular, diphtheric ulcers or cankers often seen in the mouths of turkeys and not associated with typical head lesions. These cankers are common in turkeys that have been vaccinated against fowl pox or that have recovered from an outbreak. Their cause is not known.

Frequently during the breeding season

FIG. 41.19—Fowl pox lesions in mouth and esophagus. (Hinshaw, Univ. of Calif.)

atypical cases of fowl pox appear in adult turkeys which have been vaccinated with chicken pox vaccine several months previous In these outbreaks, which usually involve only a small percentage of the birds, the mucous membranes of the eyes and the mouth are the principal parts affected. Externally, no lesions in the eyes may be visible, but when the inner surfaces of the lids are examined, soft yellow diphtheric ulcers will be found to be the cause of the increased lacrimation and inflammation of the eye. Typical yellow cankers described above characterize the mouth lesions. There are no internal lesions that are characteristic of the disease.

FIG. 41.20 — Fowl pox lesions on the skin of breast of an adult turkey hen. The head parts were also severely affected. (Hinshow, Univ. of Calif.)

FIG. 41.21 — Fowl pox lesions in the foot pads accidentally introduced during toe marking operations. (Dept. of Anim. Path. and Hyg., Univ. of Ill.)
FIG. 41.22 — Fowl pox lesions in the mucous membrane of the crop of a turkey. Lesions covered the head and extended from the mouth to the crop in this bird. (Hinshow, Univ. of Calif.)

The finding by Pilchard *et al.* (1962) that serum from turkeys hyperimmunized against fowl pox virus show neutralizing activity may prove of value in differential diagnosis. It is of interest also that they were able to demonstrate the presence of fowl pox virus (viremia) in the serum of the inoculated turkeys for at least two weeks after disappearance of visible skin lesions.

Ophthalmitis caused by *Aspergillus fumigatus* (Moore, 1953) and keratoconjunctivitis described by Bierer (1956) must be differentiated from ophthalmitis caused by fowl pox virus.

Course and mortality. There is a marked difference in the severity of cases of fowl pox in turkeys and, consequently, variations in the course of the disease. Whereas mild cases may clear up in 2 or 3 weeks, severe outbreaks often last for 6, 7, or even 8 weeks. The canker or mouth types take longer to clear up. In such cases, starvation is the cause of death. Blindness often occurs after the closing of the eyes by severe infection of the eyelids. When the eye is involved, a yellowish cankerlike lesion develops on the mucous membrane of the lid.

The flock mortality is usually low, most of the losses being caused by blindness or starvation. Setback in development and loss in weight are of greater financial importance in the growing flock than the loss by deaths. As outbreaks commonly occur a few days or weeks before market time, it is often necessary to postpone killing the birds for several weeks. If the flock escapes an outbreak before market time, the disease sometimes appears in the breeding birds and causes severe losses through lowered egg production and poor fertility.

Prevention. Vaccination with live-virus vaccine, together with the usual sanitary program, is the recommended method for preventing fowl pox in turkeys. *The problem differs from that in chickens* because in the latter the effect of the disease and vaccination on egg production must be considered in the preventive program, while in the former a meat-producing bird only is involved. Healthy turkeys respond to vaccination, when virus of chicken origin is used, with little or no systemic disturbance such as sometimes follows vaccination of chickens. Vaccines made from turkey strains of virus cause more severe reactions than those made from chicken types, but the duration of immunity is no greater. Pigeon type vaccines produce little or no immunity in turkeys and should not be used.

Attention is called to the possibility of stimulation of parthenogenesis in turkey eggs following the use of live-virus fowl pox vaccines (Olsen, 1956, 1962; and Olsen and Poole, 1962).

Need for vaccination. Fowl pox is so widespread in most turkey-growing areas that yearly vaccination of all turkey flocks is good insurance.

The disease is probably carried to new areas by mosquitoes, birds, visitors, animals, used feed sacks, and the introduction of new stock. Turkey growers who do not vaccinate should keep a constant watch for the first appearance of lesions and should immediately obtain advice on the best plan of control.

Age for vaccination. The correct age to vaccinate turkeys will depend on the locality. In some areas it has been found necessary to vaccinate them by the end of June, regardless of age, because the prevalence of mosquitoes at that season spreads pox rapidly to all susceptible birds. There are considerable data to indicate that healthy turkeys can be vaccinated at any age. Dunn and Sherwood (1933) have successfully vaccinated day-old turkeys. Many growers have vaccinated successfully at 6 or 8 weeks of age; the majority, however, at 10 to 12 weeks. Extreme care must be taken, when vaccinating young poults, to prevent the vaccine from getting on parts of the body other than the area to be treated. Sometimes a careless operator, after spilling vaccine, holds the poult's head with his contaminated hand. The young, tender skin is so susceptible that a severe case of generalized pox may follow.

As it requires from 4 to 8 weeks for the vaccination lesion (take) to disappear completely, turkeys should be vaccinated at least 8 weeks before market time.

Vaccines of chicken pox origin will produce immunity for about 6 months. It may, therefore, be advisable to revaccinate all birds which are to be kept for breeders 6 or 7 months following the first vaccination. In order to be sure that such birds are no longer immune, it is a good plan to revaccinate a sample (100 birds) of the flock. If after a week the majority of the sample shows takes, the remainder of the flock can be revaccinated. If only a small percentage is susceptible, revaccination of the rest of the flock should be postponed. If birds are revaccinated, it is good practice to use the opposite leg site for the second vaccination in order to avoid possible local skin immunity which would prevent a good reaction.

The wing web is not recommended as a site for applying the vaccine because of disastrous results that have followed the use of this site. One flock of 8-week-old poults under the observation of the writer, which was vaccinated in the web of the wing by the puncture method, suffered nearly a 50 per cent loss from fowl pox. Lesions developed on the head parts, in the mouth, and even in the mucous membrane of the upper esophagus, crop, and lower esophagus. Figure 41.23A and B shows the results of wing-web vaccination in an adult bird. At least 10 per cent of
FIG. 41.23 — (A) Wing-web vaccination. Taken about 6 weeks after vaccinating in the wing web by a single stab of the inoculating knife. Shows how the disease spread from this single inoculation to other areas on the wing and head. The bird died within a few days after the picture was taken. (B) Close-up of A at a somewhat earlier stage. (Hinshaw, Univ. of Calif.)

the flock from which the bird came was affected in a similar manner. Such spread of the infection is worse during damp or foggy weather and apparently associated with the birds picking at the vaccinated area before immunity develops.

The skin of the upper thigh has certain advantages over other sites for routine vaccination (Fig. 41.24). These are easy accessibility to the operator, absence of feathers, and inaccessibility to the vaccinated birds or their penmates. The last point is important from the standpoint of the spread of fowl pox by fighting before immunity has been established.

The same methods of applying the vaccine are used for chickens and turkeys, and the reader is referred to the general section on fowl pox for these procedures. Figure 41.28 illustrates a method for handling turkeys while vaccinating them.

Control of an outbreak. If fowl pox appears in a flock, the following procedure is recommended:

1. Isolate all birds showing lesions.
2. Vaccinate as soon as possible all birds not showing lesions.
3. Place infected birds in warm, dry quarters if available.
4. Separate the males or keep careful watch over them to prevent fighting.
5. Treat infected birds individually by removing the scabs and touching the wounds with iodine, iodine ointment, or an antibiotic ointment.
6. Individual feeding of valuable birds with the aid of a funnel and rubber tubing inserted into the crop may be advisable.

Drugs for internal treatment are not

FIG. 41.24 — (A) Restraint of turkey for vaccinating on upper thigh. Note that the table is covered with newspapers. This aids in preventing undue spread of vaccine. (B) A close-up, taken to show the suggested location. The long tuft of feathers that normally covers this naked area is being held back by the vaccinator's left hand. The heavy glass inkwell is a convenient holder for the vaccine. To prevent excessive dust contamination, it is covered with a piece of rubber with a small opening. (Hinshaw, Univ. of Calif.)

recommended. Since loss of flesh and retarded development are the chief causes of economic loss in most outbreaks, careful management and attention to the feeding program during and after an outbreak are essential for a speedy return to normal. The course of the disease can be shortened by the use of shelter for roosting and by general protection from damp weather.

INFECTIOUS SINUSITIS (Swellhead, Air-Sac Infection, Chronic Respiratory Disease—CRD, Airsacculitis, Mycoplasmosis)

This disease is of great economic importance wherever turkeys are reared. It is characterized by inflammation of the lining membranes of the infraorbital sinuses, following which the sinuses become distended with a semigelatinous exudate (Fig. 41.25 A and B). Lower respiratory tract involvement is also seen, with the air sacs the most usual site of infection. The period of incubation is erratic and may vary from 1 week to several weeks. The first accurate description of the disease was probably made by Dodd (1905) in England under the name of "epizootic pneumoenteritis." M'Fadyean (1893) had already reported a similar disease in England which he called "pneumo-endocarditis" and which may have been the same as

that described by Dodd. In the United States, Tyzzer (1926) was the first to describe it. The name "infectious sinusitis" was suggested by Dickinson and Hinshaw (1938) to differentiate it from the inflammation of the sinuses noted in vitamin A deficient turkeys.

Excellent reviews on the disease comparing it to the similar disease CRD in chickens are given by Van Roekel et al. (1957) and Osborn and Pomeroy (1958a). In September, 1962, the U.S. Department of Agriculture sponsored a workshop on Mycoplasmosis as it affects both chickens and turkeys. The report of this group (Anon., 1962) summarizes the current status of the disease and makes specific recommendations on diagnosis, handling, and preventing outbreaks. Since it is generally accepted that chronic respiratory disease (CRD) of chickens and infectious sinusitis of turkeys are etiologically similar, the

reader is referred to Chapter 13 for a detailed review.

Etiology. It is generally accepted that a pleuropneumonialike organism, *Mycoplasma gallisepticum*, is an important etiological factor, if not the specific causative agent, of infectious sinusitis. A number of investigators (Jerstad and Hamilton, 1948; Groupé and Winn, 1949; Delaplane, 1919; Jerstad et al., 1950; Van Roekel et al., 1952; Grumbles et al., 1952) showed the relationship of the two diseases before Markham and Wong (1952) succeeded in propagating the agents on a cell-free medium and identifying them.

Evidence is accumulating that there are multiple antigenic types of Mycoplasma prevalent in both turkeys and chickens, and that strains vary in their ability to produce disease (Adler et al., 1957; Grumbles et al., 1958; Jerstad et al., 1959c; Adler, 1960; Kleckner, 1960; and Yoder and Hofstad, 1962). Evidence that *M. gallisepticum* in pure culture can produce the respiratory phase of the disease in "germ-free" turkeys has been reported by Smibert et al. (1959a). Winterfield (1953) describes a case in pigeons which was transmitted to turkeys and in which typical sinusitis developed.

Van Roekel et al. (1957), in a technical report on research on the etiology and pathology of CRD in chickens, include a good historical review on the etiology of infectious sinusitis in turkeys.

Signs. Two forms of the disease are recognized. The sinus form is the one from which the disease derives its name. The other is the respiratory form which involves the lower respiratory tract and especially the air sacs and produces a syndrome resembling CRD in chickens. Prodromes of the disease are given when birds shake their heads and when discharges are found on the feathers over the wing where the bird has attempted to clean its nostrils. These manifestations are followed by foaming of the eye secretions and by a clear nasal discharge. Swelling of the sinuses and, in advanced cases, a partial to complete closing of the eyes follow these early signs (Fig. 41.25). The appetite remains good as long as the bird can see to eat. As the disease progresses, the affected birds become thin. Labored breathing, in some cases, results from air-sac involvement or from complete closing of the palatine opening because of pressure from the exudate in the sinuses.
FIG. 41.25 — (A) An advanced case of infectious sinusitis involving both sides of the face. (B) A similar case after the exudate in one sinus has been removed. (Hinshaw, Univ. of Calif.)

Bacteria may cause similar clinical signs. Beach and Schalm (1936) produced typical sinusitis in turkeys with *Hemophilus gallinarum*, the causative organism of fowl coryza. Delaplane (1944) isolated a Pasteurellalike bacterium from exudate in field cases of sinusitis in turkeys. This organism produced typical signs in chickens, and exudate from the infected sinuses of the chickens produced sinusitis in turkeys. The role which other microorganisms, including other *Mycoplasma* species, play in production of similar signs and lesions is reported by Smibert et al. (1959b) and Kumar et al. (1963).

Fahey (1956) described a chronic respiratory disease in turkeys from which he isolated both a virus and a PPLO. In the outbreaks described by him, 2 weeks after onset of respiratory symptoms, 40 to 60 per cent of the birds were manifesting sinusitis. A review of the current status of the role of this virus as a cause of respiratory disease in turkeys is reported by Subramanyam and Pomeroy (1960).

The disease must also be differentiated from sinusitis associated with vitamin A deficiency. Mechanical injury caused by a piece of grain or mash or other foreign body becoming lodged in the sinus may result in a swollen sinus. As a rule these mechanical cases are unilateral.

Transmission. Jerstad et al. (1950) were able to transmit the disease experimentally by instillation of infective material by several routes. These included drop instillation into the palatine cleft of 2- and 3-day-old poults, instillation into the crop, intramuscular injection, swabbing the trachea, and by contact with birds manifesting the respiratory form of the disease, as well as by the usual procedure of injecting the infective material into the infraorbital sinuses. They were able to confirm Jungherr's (1949) contention that the two common manifestations of the disease—swollen sinuses and air-sac infection—are one and the same entity. The incubation period varied from 2 weeks to 17 weeks. Field observations indicate the disease is airborne and that dust storms play an impor-

tant part in transmission. Air-borne transmission of the disease is more likely to occur, according to the writer's experience, if the lower respiratory form is prevalent.

There is ample evidence to indicate that in certain stages, the disease may be transmitted in a small percentage of the eggs laid by infected birds. Jerstad et al (1949 and 1959a, b) demonstrated that transmission of the disease is possible, but somewhat inconsistent. They concluded by experimental as well as by field observations that infected breeders may transmit the disease to some of their progeny. They found no evidence that so-called silent carriers in a healthy flock are at important factor in egg transmissions. Hofstad (1957a), Richey et al. (1958). Osborn and Pomeroy (1958b), Abbott et al. (1960), and Kumar et al. (1963) have reported additional evidence of egg transmission.

Course and Mortality. Sinusitis of the contagious type runs a chronic course and may exist in a flock for weeks. Although the number of deaths may be less than in some more acute diseases, the financial loss may be greater. Failure to gain weight accounts for as much damage as does mortality.

Necropsy findings. The filling of the sinuses with exudate, the presence of pneumonia, and pleuritis are manifestations of sinusitis. This disease may occur without involvement of the other respiratory passages, but inflammatory changes in all the respiratory organs may be noted. In some instances, the lesions will be confined to the lower respiratory passages without involvement of the sinuses. Caseated exudate in the air sacs is common in acute outbreaks. When the lungs are affected, the bronchi are chiefly concerned.

The exudate in the sinuses in the first stages is watery in consistency, later becoming semigelatinous and finally caseated and whitish-yellow in color. In typical outbreaks, caseation of the exudate is the exception. In sinusitis associated with vitamin A deficiency, the lesions described under avitaminosis A will also be seen.

References on the microscopic pathology

of the disease include Jungherr (1949), Hitchner (1949a), and Barber (1962). Jungherr reported that histopathologically experimental sinus infection was characterized in the early stages by severe catarrhal inflammation of the mucosa and in the later stages by infiltration, fibrosis, and hyperplastic lymphofollicular nodules in the submucosa. Pneumonia and air-sac infections were accompanied by development of massive lymphofollicular nodules which assumed a pathognomonic significance. Cordy and Adler (1957) describe an encephalitis produced artificially in turkeys by a neurotropic strain of PPLO isolated from a naturally occurring case of infectious sinusitis which had exhibited symptoms of encephalitis.

Final diagnosis depends on isolation and identification of the causative agent.

Prevention, control, and treatment. Turkeys which recover from sinusitis may remain carriers the following year, so all contact between them and growing poults should be avoided.

Since egg transmission is possible, every effort should be made to eliminate from breeding programs those flocks that have a history of previous infections.

The recent findings that the causative agent of chronic respiratory disease of chickens will cause the disease presents another reason for keeping turkeys segregated from chickens.

It has not been possible to artificially immunize turkeys against the disease (Adler *et al.*, 1960). Recovery from the disease according to Adler and his associates does confer a measurable degree of immunity but does not eliminate the carrier state of all recovered birds.

Detection of carriers is possible by means of the hemagglutination inhibition (HI), tube agglutination, and slide agglutination tests using *M. gallisepticum* (S-6) antigen (Hofstad, 1957b; Adler, 1958; and Adler *et al.*, 1962). Although the slide agglutination test is less sensitive than the tube agglutination test, Adler *et al.* (1962) stated that with an improved antigen they have found it suitable for routine testing. They cautioned that an antigen satisfactory for testing chicken sera might be unsatisfactory for testing turkey sera. These serologic tests, according to Adler *et al.*, are valuable to detect flock infections and the stage of disease in a flock but not in individuals. They are not recommended for use in repeated tests for removal of reactors to eliminate the disease from a breeding flock. They might be used in selecting the market time for birds that have gone through an acute stage of the disease. Both Hofstad (1957b) and Adler (1958) showed a reduction in the serologic titer following medication. This suggests another possible application of the tests.

A number of the states now have a Mycoplasma infection eradication program which is operated in conjunction with the pullorum disease-fowl typhoid program in cooperation with the National Poultry and Turkey Improvement Plans. (For details the reader is referred to his state official agency for these plans.) Elimination of infected flocks and the establishment of Mycoplasma-free breeding flocks as sources of replacement flocks are the primary objectives of these cooperative plans. The general practices and recommendations used by them are outlined in the U.S.D.A. Committee Report on *Mycoplasma gallisepticum* Inspection in Poultry (Anon., 1962). A recent publication by Rosenwald and Adler (1962) is also recommended.

Madsen (1938) reported good results in the control of sinusitis, uncomplicated by lower respiratory involvement, by the use of 1.0 cc. of a 4 per cent solution of silver nitrate injected into the affected sinus after the removal of the sinus exudate with the aid of a hypodermic syringe. Tyzzer (1926), Dickinson and Hinshaw (1938), and Hart (1940) have used a 15 per cent argyrol solution in a similar manner. McNeil and Hinshaw (1946) compared the efficiency of silver nitrate with three colloidal silver preparations and two ephedrine remedies containing sulfonamides. The latter were of no value, while the colloidal silver drugs were from 50 to 70 per cent effective as compared with

about 85 per cent effectiveness of the silver nitrate. *These silver preparations have little if any value in flocks where the majority of the birds are suffering from air-sac infection as well as swollen sinuses.*

The method, which can also be used for injection of antibiotics or other drugs, consists in withdrawing the gelatinous exudate from the sinus with the aid of a 5 or 10 cc. syringe fitted with a 15- or 16-gauge needle, 1½ inches long. The needle is inserted through the skin and sinus membranes into the filled sinus. Withdrawal of the syringe plunger will remove the semifluid exudate. The needle is left inserted in the sinus, and with a second syringe the remedy is injected and worked through the tissues by gentle massage. Care should be taken to avoid excessive dosage.

These treatments cause considerable swelling of the affected areas, but this subsides within 2 or 3 days, and complete recovery usually takes place within 10 days. In severe cases a second treatment may be necessary.

It is essential to administer this treatment in the early stages of the disease when the exudate is in a semigelatinous state. Figure 41.26 shows the method of inserting the needle for removal of the exudate, and for injection of the remedy. If silver nitrate solution is used, it should be freshly prepared, and it is advisable for

the operator to use leather or rubber gloves because this remedy is caustic to the skin.

Of the antibiotics tried, streptomycin, erythromycin, Tylosin, and chloramphenicol appear to be the ones of choice for injection into infected sinuses. Reports on the effectiveness of streptomycin have been published by Groupé and Winn (1949), Hitchner (1949b), McArthur (1950), Glover (1950), and Grumbles and Boney (1951). Hitchner found that 0.6 ml. of a sterile aqueous solution containing 150 mg. of the drug, injected directly into the sinuses without removal of exudate, resulted in a high percentage of recoveries in 7 to 14 days. The effective dose of Aureomycin given by Hitchner is from 25 to 50 mg. Hamdy *et al.* (1958), Holper *et al.* (1958), and Barnes *et al.* (1960) all found erythromycin to be effective against the sinusitis form if given intrasinally at the rate of 50 mg. per sinus after the removal of the exudate. Intramuscular injections or the use as a feed additive were both ineffective. A review on the use of Tylosin is given by Yoder *et al.* (1961).

In England, Cook *et al.* (1963) have reported on the effective use of Spiramycin in the treatment of mycoplasmosis of turkeys. Cure rates up to 90 per cent were reported following the subcutaneous injection of single doses of 100 mg. per kilogram of body weight. The recommended site of
FIG. 41.26 — (A) Treatment of infectious sinusitis. Method of insertion of the hypodermic needle into the sinus for withdrawal of exudate and inoculation of remedy. (B) After withdrawal of the exudate, the needle is left in the sinus until the therapeutic agent is introduced. (Hinshaw, Univ. of Calif.)

inoculation was the area at the base of the neck.

The information available on the effectiveness of these drugs for the lower respiratory type of the disease indicates that the broad-spectrum antibiotics are of value. Hitchner injected 150 to 250 mg of streptomycin into the dewlaps of five turkeys showing symptoms of only the lower respiratory tract type. Four of these became free of clinical signs within 8 days and the fifth in 15 days following treatment. Injection of the drug into the dewlap had no effect on infected sinuses. Grumbles and Boney (1950) reported little or no effect on the lower respiratory disease following treatment with streptomycin.

Grumbles and Boney (1951) used chloramphenicol and Terramycin in the feed for turkeys suffering from both the sinusitis and lower respiratory types of the disease. Chloramphenicol in an all-mash ration was effective in treatment of both types when given at levels of 0.25 to 0.5 per cent in the feed for 8 to 12 days. Terramycin was not as effective in the few birds tried.

Benton and Cover (1958) compared the effectiveness of injections of several of the nitrofurans, two antibiotics, and silver nitrate in treatment of experimentally

produced sinusitis. The nitrofurans were also used in drinking water and applied as an aerosol (dusting). Results obtained were not encouraging. Drugs injected directly into the sinuses were more effective than those used in drinking water or as an aerosol.

Osborn and Pomeroy (1958b) found that prolonged high-level treatment of turkey hens with broad-spectrum antibiotics did not completely eliminate egg transmission. Drug-resistant strains may complicate any control program (Fahey, 1957).

The use of antibiotics for elimination of *Mycoplasma* sp. from hatching eggs as an aid in preventing spread by this means has been reported by a number of investigators including Chalquist and Fabricant (1959), Levine and Fabricant (1962), and Olson *et al.* (1962). The method consists in dipping warmed (37° C.) eggs into a chilled solution of the antibiotic in an attempt to produce sufficient absorption of the antibiotic from the dip solutions into the eggs to prevent infection of the developing embryo. Oxytetracycline, erythromycin, and Tylosin have yielded encouraging results in the limited experimental trials reported. The practicability of this method of destroying microorganisms in hatching eggs is yet to be determined.

FOWL TYPHOID[*]

Fowl typhoid is a septicemic infection caused by *Salmonella gallinarum*. Contact with chickens or yards used by chickens is an important factor in the spread of fowl typhoid to turkeys. Pfeiler and Roepke (1917), Kaupp and Dearstyne (1924), Martinaglia (1929), and Hinshaw (1930) reported the disease in turkeys reared on farms where it was also prevalent in chickens. Evidence that the disease may be transmitted through the egg in the same manner as is pullorum disease is presented by Boney (1947), Hinshaw and Taylor (1933), and Johnson and Pollard (1940). Johnson and Pollard reported outbreaks in poults with clinical signs, mortal-

ity, and pathology comparable to those of pullorum disease. Usually, however, the disease is reported in mature or nearly mature turkeys. Vidovic (1931) claimed that strains of the causative organism isolated from turkeys were more pathogenic than strains isolated from chickens. The strains isolated from turkeys by Hinshaw have appeared identical to those isolated from other fowl. A more complete list of references is included in the general section on fowl typhoid.

Signs, course, and mortality. Increased thirst, loss of appetite, listlessness, tendency to separate themselves from the well birds, and greenish to greenish-yellow diarrhea characterize the disease in the field. The sick turkeys sit with drooping tails, sagging wings, and heads hung low or carried back

* See also Chapter 10.

over the body and resting on or under the wing. As indicated by the increased thirst, the body temperature rises several degrees, to as high as 112° F., until just before death, when it may drop as low as 103° F.

Often birds die without having shown any previous clinical signs, but usually they linger for a day or two after the signs appear. Several outbreaks may occur in a flock in a single season, or the original one may be acute and last for only a few days. Intermittent outbreaks are more liable to occur if the birds are left on the originally infected premises or have constant contact with carrier chickens or turkeys. The initial outbreak usually causes the heaviest mortality, which is followed by intermittent recurrence in a few birds, with a low mortality at each subsequent flare-up of the disease. Although the average mortality in four outbreaks studied was 26.5 per cent, heavier losses have often been reported. One flock owner lost 169 out of 175 turkeys during the fall and winter in intermittent outbreaks. In very young poults the signs, course, and mortality are similar to pullorum disease.

Necropsy findings. The lesions resemble those observed in chickens. Because of the short duration of the disease, the birds nearly always die while in good flesh. The muscles of the breast have a tendency to be congested and often appear as if partially cooked. The heart is usually swollen and contains small, grayish necrotic areas or petechiae; in a few cases both have been observed. The liver is friable and is consistently enlarged to two or three times its normal size; it is bronze- to mahogany-colored or covered with a mixture of bronze- and mahogany-colored streaks. Pinpoint areas of necrosis have been noted. On cutting the organ, the blood flows readily. The spleen is always enlarged to two or three times its normal size, is friable, and appears mottled. In most birds the lungs present a parboiled appearance and often are more firm than normal because of minute caseated abscesses. The kidneys are usually enlarged and may show some petechiae.

The crop usually contains food, which suggests paralysis of the digestive tract, since birds seldom eat after clinical signs appear. The mucous membrane of the proventriculus sloughs readily. The gizzard contains food, and the lining is easily removed. With a few exceptions the intestine appears anemic when viewed from the exterior, and ulcerations of the mucous membrane may be visible through the serosa. Ulceration is most severe in the duodenum; a few ulcers from 1.0 to 4.0 mm. in diameter have been observed throughout the intestine, extending to the ceca.

The enlarged mahogany- or bronze-streaked liver, the enlarged spleen, the area of necrosis in the heart, and the grayish lungs are pathognomonic. Hemorrhagic enteritis, especially of the duodenum, and marked ulceration of the intestine, although uncommon in chickens, are more or less consistent lesions in turkeys. *Salmonella gallinarum*, the causative organism, can readily be isolated from all organs. In birds that have been dead for some time, pure cultures are more easily isolated from the bone marrow than from the liver, spleen, and heart blood.

In young poults Johnson and Pollard (1940) described the following necropsy findings: an increased percentage of large retained yolks, slightly enlarged somewhat friable liver of a white creamy color, with the surface mottled with slight hemorrhagic areas, and slight congestion in the anterior duodenum. The crops, gizzards, and intestines were always devoid of food, indicating lack of appetite for several hours before death. In adult carriers, there is, as in the case of pullorum disease, a predilection for the reproductive organs (Fig. 41.27).

Prevention, control, and treatment. Since chickens are apparently the most common carriers of the disease to turkeys, the two species should never be allowed to mingle. It is equally important to keep turkeys from yards or ranges that have recently been used for chickens.

Survivors of an outbreak should not be

FIG. 41.27 — Ovary from turkey hen, showing affected ova caused by fowl typhoid. No normal ova were present. (Hinshaw, Univ. of Calif.)
kept for breeders because of the danger of transmission of the disease through the egg.

It has been the general experience of research workers that drugs which are effective in reducing mortality are not effective in eliminating carriers.

Poults for replacements should be purchased only from hatcheries which can guarantee the poults to be free of the disease, i.e., U.S Pullorum-Typhoid Clean or Passed or of an equivalent grade (Nat. Poultry and Turkey Improvement Plans, 1963).

Control depends upon eliminating the infection in the flock. The removal of all sick birds and the transfer of the well birds to a new range that has not been used for either chickens or turkeys is recommended. One method for separating sick birds from well ones in an acute outbreak is to take the temperatures of all birds in the flock and eliminate those showing temperatures above 108° F.

The successful control of fowl typhoid in turkeys by the use of furazolidone, if given early in an outbreak, has been reported by Grumbles *et al.* (1954) and Cosgrove (1954). Grumbles *et al.* found that 100 gm. of the drug per ton of feed given as late as 3 days following exposure

prevented mortality. When given at the rate of 50 gm. per ton continuously beginning 3 days before exposure, at the time of exposure, and 3 days after exposure, mortality was prevented, but this amount did not provide a desirable degree of protection if started 5 days after exposure. Cosgrove stopped mortality in field outbreaks by giving feed containing 100 gm. per ton for 3 days and then feeding 50 gm. per ton until the disease was under control. This drug is relatively insoluble in water so must be given in the feed or administered individually. Grumbles reported that in a limited number of trials sick turkeys were successfully treated with 100-mg. capsules of furazolidone per bird *per os*. Attention is called to the observations of Hall and Cartrite (1961) and Stuart *et al.* (1963) that continuous feeding of furazolidone may encourage the development of resistant strains of *Salmonella gallinarum*.

In vitro and *in vivo* (with chickens) studies on the sensitivity of *S. gallinarum* to antibiotics (Glantz and Gordeuk, 1955) showed that chloramphenicol and aureomycin are of value against this disease in chickens. Chloramphenicol given at the rate of 200 mg. per bird per day *per os* or 1 to 2 gm. per pound of feed gave ex-

cellent protection if started on the day of infection. A relapse occurred when treatment was discontinued. Aureomycin at a level of 1 gm. per gallon of water was not effective. When it was given at the rate of 1 gm. per pound of feed, losses were only reduced to 25 per cent, but there was no relapse when the treatment was discontinued. Richey and Morgan (1959) successfully controlled artificially produced fowl typhoid in poults by administration of chloromycetin at the rate of 1.0 gm. per pound of feed providing treatment was started 5 days before inoculation and continued for 10 days. Treatment did not prevent development of carriers in survivors.

As the greatest source of the spread of the disease is the droppings, the roosts

should be screened to prevent the birds from having access to them. Sick birds should be taken out of the flock as soon as noted; frequent changes of the watering and feeding areas should be made; and whenever many new cases appear, the flock should be moved again to new quarters.

Next to the droppings, the greatest sources of infection are the food and water containers. They should be cleaned and disinfected daily or even oftener. In the absence of running water, fresh, clean water should be given several times daily.

Experimental work has not demonstrated that vaccination with fowl-typhoid bacterins is effective for preventing or controlling the disease in turkeys.

NEWCASTLE DISEASE

The reader is referred to the more complete discussion of this disease in Chapter 22. Turkeys are susceptible to Newcastle disease; the signs and pathology are similar to those seen in chickens.

Turkeys should not be reared in close proximity to chicken-rearing communities

where the disease is prevalent. If it is necessary to so rear them, vaccination of the turkeys should be considered.

SALMONELLOSIS (Paratyphoid)

This group of diseases is one of the major causes of losses, especially in young turkeys. This section deals with the types

other than *S. pullorum* and *S. gallinarum* infections (pullorum disease and fowl typhoid). For further reading, Chapter 9 and a review on salmonellosis by Edwards (1958b) are recommended. A revised, simplified scheme for serological typing has been compiled by Kauffmann and Edwards (1957), Kauffmann (1959), and Edwards (1962). Buxton (1957) gives a review of salmonellosis in animals. Especially valuable are the groupings of serotypes by isolations according to animal species contained in this reference.

Over 800 serotypes of Salmonellae have been described (Edwards and Ewing, 1962). The following list records 102 types which have been reported from turkeys. When the list was first compiled for the third edition in 1952, 62 types were recorded. From 1952 to 1959 an additional 19 types were added. Since the publication of the fourth edition in 1959, six more have been reported; these are *S. denver*, *S. java*, *S. johannesburg*, *S. livingston*, *S. manila*, and *S. uno*, all from United States (Moran, 1961).

No additional serotypes from other countries were found in the literature reviewed. Gordon and Tucker (1957) reported the isolation of *S. infantis* from a turkey poult in England and stated that this appeared to be the first isolation of this type from turkeys. It probably is the first published case, although *S. infantis* was listed from turkeys in the third edition. The report for that listing was obtained from Dr. P. R. Edwards in a personal communication. *S. infantis* is now frequently isolated from both turkeys and chickens in the United States. Moran (1961) lists 78 isolations from turkeys and 94 isolations from chickens for the period of January, 1957, to July, 1961. Dixon (1962) reported the isolation of *S. menston* from two turkeys in a survey made of two turkey processing plants in England. It was first reported by Colbeck *et al.* (1951) from England.

This list, probably incomplete, was compiled through the cooperation of research workers and diagnostic laboratory direc-

tors, and by a survey of the available worldwide literature. Earlier references include Edwards (1939), Saxer (1932), Nakamura *et al* (1939), Bruner and Moran (1949), Edwards and Hermann (1949), Bruner (1951, 1956), Edwards and McWhorter (1953), Edwards *et al.* (1954), Lukas and Bradford (1954), McWhorter and Edwards (1956), and Burr *et al.* 1957). Personal communications contributing to the list are acknowledged from Browne (1958), Bruner (1958), Dickinson (1958), Edwards (1958), Pomeroy (1958), Van Ryzin (1958), and Worcester (1958). Summaries of isolations of Salmonella serotypes from turkeys in England are given by Colbeck *et al.* (1951), Smith and Buxton (1951), and Buxton (1948, 1957). The long list of Salmonella types now known to be capable of producing disease in turkeys becomes more significant when one considers that the first report of losses in turkeys in the United States was made as recently as 1933 (Rettger *et al.*, 1933). In a summary by Edwards *et al.* (1948) over 2,200 additional outbreaks and 40 new types were added to the original list given by Edwards (1939). Of 19 types found in California outbreaks (Hinshaw *et al.*, 1944), *S. typhi-murium* accounted for 60 per cent. This type is still one of the most important causes of turkey losses. It is also one of the most common types isolated from other animals, including man. Saxer (1932) reported an outbreak caused by *S. enteritidis* (Gaertner type) after feeding turkeys meat from a calf suffering from navel infection. Nakamura *et al.* (1939) also reported an outbreak in Japan caused by *S. enteritidis*.

The ten most frequently reported types in turkeys in the United States from 1957 to 1961 according to Moran (1961) were *S. typhi-murium*, *S. san diego*, *S. anatum*, *S. newport*, *S. heidelberg*, *S. saint-paul*, *S. chester*, *S. munenchen*, *S. bredeney*, and *S. enteritidis*, in the order given.

Transmission. Evidence that this group of diseases may be transmitted through the egg in a manner similar to pullorum disease has been presented by Cherrington *et al.* (1937), who succeeded in iso-

lating *S. typhi-murium* from 2 of 6 ovaries removed from reacting turkeys, and from 3 of 30 "dead-in-shell" embryos. Lee *et al.* (1936) in an earlier paper reported the isolation of this organism from 4 of 10 ovaries removed from artificially infected turkey hens. *S. typhi-murium* has been isolated from both the ovary and oviduct of turkey hens by Hinshaw and McNeil (1943).

The incidence of *S. typhi-murium* in eggs laid by carriers is not high according to the literature available and our own experience. Pomeroy and Fenstermacher (1939) reported the isolation of paratyphoid organisms from 7 out of 200 incubated eggs that failed to hatch. *S. typhi-murium* was isolated from the ovaries of 2 of the 9 reactors that laid the above-mentioned eggs. Pomeroy and Fenstermacher (1941) showed that *S. typhi-murium* will pass through the unbroken eggshell and infect developing embryos, some of which hatch and become a source

of infection to normal poults. Bigland and Paps (1953), Frank and Wright (1956), and Wright and Frank (1956) have confirmed these results. Frank and Wright found that dipping eggs, artificially infected with *S. typhi-murium*, in sodium hydroxide at concentrations up to 2 per cent for 5 minutes failed to prevent penetration of the eggshells. They also showed that lower specific gravities (<1.070) favored penetration.

Hinshaw and McNeil (1943) reported that 81 per cent of adult *S. typhi-murium* carriers yielded the organism from the intestines, in contrast to 17 per cent which yielded it from the reproductive organs. Gauger and Greaves (1946) made similar observations in attempts to isolate *S. typhi-murium* from eggs laid by naturally and artificially infected hens. In their studies a much higher percentage of positive isolations was made from the outside of the shells than from egg contents. Likewise, necropsy of the birds showed a

higher incidence of *S. typhi-murium* isolations from the digestive tract than from the reproductive tract.

From the information available it would seem that the important means of egg contamination and subsequent infection of the poult is from infected intestinal contents coming in contact with the shell during expulsion from the body or in the nest. Ovarian transmission, however, must not be ignored.

Boyer *et al.* (1962) discuss the role of Salmonella-contaminated feed in the transmission of the disease. They conclude that this is an important source of the disease in turkeys and stress the need for eliminating this source of infection.

Yamamoto *et al.* (1961) made an experimental study of *S. typhi-murium* infection in market-age turkeys. The turkeys used in the experiment were infected by inoculations into the crop, and were kept under observation for 33 to 44 days. At the end of 14 days 83.4 per cent were shedding the organism in feces, and 27.8 per cent were still shedders at the termination of the experiment. At necropsy, one of 18 birds yielded a positive culture from the reproductive tract in contrast to 11 positive cultures isolated from the intestinal tract. Shells of eggs laid yielded positive cultures but contents of incubated eggs were negative. There was a 38.8 per cent correlation of serologic response and positive culture isolations at the termination of the trial.

Signs. The signs in young poults are indistinguishable from pullorum disease. The age at which poults may be affected ranges from a few days after hatching to maturity. In general, however, the age incidence is that of pullorum disease—from 5 or 4 days of age to 1 month. The age at which the disease is first observed in poults will depend on whether the poults are infected while in the incubator or after being placed in the brooder. In one outbreak studied, symptoms were seen 2 days after the poults were taken from the incubator, indicating transmission in the incubator soon after the eggs had started to hatch.

Diarrhea in young poults is not constant and often poults normal in the evening may be found dead in the morning. Where death is delayed for several days, weakness, unthriftiness, sagging wings, and diarrhea are characteristic symptoms. Many poults that survive for several days will become emaciated, and the feathers around the vent will be matted with fecal material. Higgins *et al.* (1944) reported inflammation and swelling of the leg joints of poults suffering from *S. enteritidis* infection.

In older turkeys, loss of appetite, unthriftiness, loss of flesh, and a general unkempt appearance have been most commonly observed. Diarrhea may or may not be in evidence. Death usually follows after several days of sickness.

Necropsy findings. Inflammation of the duodenum, congestion of the liver, kidney, gallbladder, and heart muscle are the most constant postmortem findings. The pericardial sac is often filled with a serous straw-colored fluid. Another common finding is a ceeal plug similar to that sometimes seen in pullorum disease. Lung and heart lesions are rare, but air-sac involvement is common.

In adult turkeys, marked inflammation of the intestine with occasional necrotic ulcers is seen. The liver and spleen in these cases are usually swollen and congested. Diagnosis depends on isolating and identifying the causal organism.

Prevention. Prevention consists in obtaining stock which is free of the disease and in preventing the birds from being exposed to other animal reservoirs of infection. Salmonella-contaminated feed must also be avoided. Most of the types of Salmonella responsible for losses in turkeys are also prevalent in other animals including man. Thus the program of prevention must be extended to all animals on the ranch. Eradication of rats, mice, flies, and reptiles is essential. If the disease is diagnosed in any group of poults, these poults should be reared separately from other groups. Such infected groups should never

be used for breeders.

The use of the agglutination test as an aid in determining the presence or absence of the disease on the premises will depend on the facilities available for having such tests made. Each ranch must be handled as an individual unit when making plans for testing. A separate test must be made for each species isolated, and complete knowledge of the disease history of the flock is essential to a successful program. The agglutination test for the paratyphoids is more complicated and, as now conducted, more subject to variation than is the one for pullorum disease. To conduct it properly, the laboratorian must be thoroughly familiar with the antigenic structure of Salmonellae and be able accurately to interpret results. It is absolutely necessary to know the type causing the disease, and, as may often be the case, there may be two or more species responsible (Edwards and Bruner, 1940). If the complete history is known and a competent laboratory is available, testing may be advised (Hinshaw and McNeil, 1943; McNeil and Hinshaw, 1951; Yamamoto et al., 1962).

A Salmonella and Arizona typing center for strains isolated from nonprimate animal sources has been established by the United States Department of Agriculture at Ames, Iowa. The mailing address for the Center is Salmonella Typing Center, U.S.D.A.-A.R.S., National Animal Disease Laboratory, Box 70, Ames, Iowa 50011.

According to Williams (Chapter 9), at least three states, Minnesota, California, and Texas, have official rules and regulations including a blood-testing program for control of S. typhi-murium infection. The California system is described by Delay et al. (1955) and Goetz (1962). In any program, the agglutination test should be only used to locate diseased flocks and these should be eliminated from the breeding program.

Preincubation fumigation of hatching eggs is being used by many breeder flock owners as a preventive measure to reduce the chances of egg contamination. The method described by Stover (1960) is in general use for this procedure. For details see Chapters 5 and 9.

Hatcheries and egg-selling groups can help prevent the group of diseases from spreading by keeping thoroughly familiar with all the ranches furnishing hatching eggs. Frequent use of the diagnostic laboratory is urged during the brooding season in order to insure a high percentage of diagnoses of the outbreaks which occur. Whenever a diagnosis is made, the owner should be made familiar with the problem and responsibility he has in preventing the spread of the disease. Often, when only one brood is affected, it will be good insurance to destroy all the survivors. In any case, survivors of an outbreak normally should not be used for breeding purposes.

Other animal and bird reservoirs on the ranch must also be eliminated if the disease is to be eradicated. Cats, flies, and even snakes and lizards are important carriers of this group of diseases, and should not be overlooked in outlining the control program (McNeil and Hinshaw 1944; Hinshaw and McNeil, 1945, 1947).

Treatment and control. Pomeroy et al. (1948) reported that sulfathiazole, sulfaguanidine, and sulfadiazine are about one-half as effective in reducing losses from S. typhi-murium infection among poults as compared with chicks similarly infected and treated. In general the sulfonamides are more toxic for poults than for chicks and must, therefore, be used with caution.

Furazolidone was used successfully by Smith (1955), Wilson (1955), and Bierer and Vickers (1960) for treatment of experimentally produced S. typhi-murium infection in turkey poults and chicks. The usual practice in the United States, according to Sieburth (1957a), is to use a 0.005 per cent level continuously for prevention and a 0.01 per cent level for treatment of Salmonella infections. Sieburth also reported that furazolidone at these levels suppressed the formation of

agglutinins but not the formation of indirect hemagglutinins (Sieburth, 1957b) to *S. typhi-murium* in orally infected chickens. Because of his findings, the use of this drug should be avoided until completion of pullorum and paratyphoid testing programs.

These drugs have not proven of value in eliminating carriers from an infected flock, and should only be used for the purpose of salvaging as many as possible survivors. Salvaged birds should not be sold for meat purposes until thoroughly recovered from the disease.

West *et al.* (1945) studied the effect of streptomycin *in vitro* on 412 cultures of all the recognized types of Salmonella. The majority of the strains required from two to four times as much streptomycin to inhibit growth as did a standard test strain of *E. coli*. Bacterins for prevention and control cannot be recommended. The multiplicity of types makes the general use of bacterins as impossible as a generalized testing program.

See Chapter 9 for a detailed discussion on control and treatment.

Arizona Infections (Paracolon Infections)

For a more complete discussion on paracolon infection of birds, the reader is referred to Chapter 9. The diseases included in this group are caused by Gram-negative bacteria which are serologically and biochemically related. They occupy a position between the coliforms and Salmonellae and possess characteristics common to both.

Paracolon types belonging to the Arizona group (Edwards et al., 1947, and Edwards et al., 1956) are most often the cause of disease in turkeys They cause

clinical signs indistinguishable from those seen in salmonellosis. Eye involvement is common in this disease. Reports on paracolon infections have been made by a number of research workers including Hinshaw and McNeil (1944, 1946), Bruner and Peckham (1952), Goetz and Quortrup (1953), and Goetz et al. (1954, 1955).

Prevention, control, and treatment are the same as for salmonellosis. Transmission through the egg has been proven, so it is essential that infected flocks are not kept for breeders.

PULLORUM DISEASE*

This disease, caused by Salmonella pullorum, has been increasing in economic importance to the turkey industry since the advent of the commercial hatching of turkey eggs. It was first described in turkeys by Hewitt (1928) in Minnesota and has since become widespread among turkeys in America as well as in some of the other countries of the world. Comprehensive reviews of the literature have been given by Tittsler (1932), Johnson and Anderson (1936), Hinshaw (1939), and Carpenter et al. (1949). Investigators in other countries who have reported on the disease in turkeys include Dalling et al. (1929), Jansen (1932), and Barboni (1937).

Previous to 1938 when Johnson and Anderson reported an outbreak which ap-

parently originated from eggs laid by turkey carriers, all the evidence pointed to chickens as the main source of the infection in turkeys. The disease, however, soon became established in many turkey flocks, and the cycle of infection has been shown to be identical to that for chickens (Hinshaw et al., 1942; Carpenter et al., 1949; and Gwatkin and Dzenis, 1953).

Signs. The clinical signs in poults are similar to those described for chicks. The disease is usually acute, and many poults die without showing noticeable signs. Sick poults seem cold and sit around the hot part of the hover space. Their wings sag, their heads hang, and their feathers appear unkempt. The skin over the feet and legs usually appears dry and somewhat wrinkled. Diarrhea may or may not be present; but in most of the cases that are prolonged for 2 or 3 days, diarrhea is in-

* See also Chapter 8.

dicated by the pasting of the down around the vent. Labored breathing, due to pneumonia, is commonly observed.

Course and mortality. Most of the losses occur during the first 3 weeks after hatching and may start as early as the second day. It is not uncommon for relapses to occur at any time up to maturity, with varying degrees of mortality. Frequently, when survivors of an early age outbreak reach 9 to 10 weeks of age and are transferred to a growing ration or moved to new quarters, a second outbreak occurs with a subsequent mortality of 5 to 15 per cent. Outbreaks may occur in turkeys 3 to 6 months of age. Losses of this age group have, as a rule, been small. Subacute outbreaks have been experienced in breeding flocks after they are in production. Such outbreaks are attributed to transmission by eating infected eggs and subsequent spread by the intestinal shedders of the organisms.

The mortality in poults under 1 month of age varies from less than 10 to as high as 100 per cent of a brood, depending on the virulence of the organism and the management of the brood.

Necropsy findings. Minute caseous abscesses in the lungs and heart muscles similar to those seen in chicks are the most characteristic lesions. Similar abscesses may be found in the gizzard muscles. The intestines usually lack tone and contain an excessive mucous discharge. Cecal cores are seen, but they are not pathognomonic. The liver is often congested and swollen and may be of an ocher to a bronze color streaked with areas of congestion. Pin-point areas of necrosis are common.

The postmortem findings in partially grown poults are similar to those seen in younger ones, but these are usually less pronounced. Lung lesions are only occasionally seen, but necrotic foci in the liver are frequent findings, as are nodules in the gizzard and catarrhal enteritis.

The lesions seen in adult carriers are similar to those seen in carrier chickens and are principally confined to the re-

productive tract. S. pullorum has also been isolated occasionally from the lungs, intestines, bursa of Fabricius, and liver, and in one instance from the testes of reactors. A frequent finding in adults that have been killed in subacute outbreaks is marked ascites. In these cases as much as 1,000 cc. of fluid containing yellowish caseated flaky masses may be removed from a single bird. As a rule, such specimens yield S. pullorum from all tissues including the intestines.

Prevention. The first prerequisite in a program of prevention is to establish a source of pullorum-disease-free eggs. The second is to have such eggs hatched in a hatchery that accepts eggs only from pullorum-disease-free flocks of turkeys, chickens, and other fowl. The third is to brood and rear the poults in brooders with equipment that has had no contact with birds of any species that have had pullorum disease. If these three prerequisites are followed together with a good management program, there is little danger that pullorum disease will become established in a flock of turkeys.

When an outbreak occurs, it is recommended that the survivors be marked and reared separately from broods that have not had the disease. Such groups of survivors should be sold for market and never kept for breeders. They should be marketed before they start to lay eggs. The remainder of the birds on the premises, if they are to be kept for breeders, should be tested by means of the tube agglutination test. According to Hinshaw *et al.* (1942), this test, using a 1:25 dilution, made according to the procedure recommended in the National Poultry and Turkey Improvement Plans and Auxiliary Provisions (1963) is a reliable aid in locating pullorum-disease-free flocks. Hinshaw *et al.* (1910) reported that the whole-blood stained antigen test was 50 per cent as efficient as the standard tube test for detecting carriers of S. pullorum. Several investigators such as Bushnell (1915), Corpron *et al.* (1917), Gauger (1917), Garland *et al.* (1919), and Wright *et al.* (1957)

FIG. 41.28 — (A) Type of catching chute for handling large numbers of turkeys for vaccination, blood collection, or other purposes. (B) The same arrangement showing how a bird can be removed from the side, by reaching through the burlap "fence," without disturbing the other turkeys. (Hinshaw, Univ. of Calif.)
FIG. 41.29 — Pullorum disease. Method of withdrawing a blood sample from the median vein of the wing. (Hinshaw, Univ. of Calif.)

These rinse waters should be boiled before use and should be changed frequently.

An efficient crew consists of the operator and at least two assistants: one for banding the birds and one for recording the band numbers, emptying the syringes, and cleaning them. If speed is to be maintained, the operator should only have to withdraw the blood. It is, therefore, necessary that the flockowner furnish ample help in order always to have a bird on the table ready to be bled. Figures 41.30, 41.31, and 41.32 illustrate a few of the steps in this technique.

Control and treatment. There is no practical method of control or treatment once the disease has become established in a brood. Daily cleaning and the removal of all sick and dead poults several hours daily will aid in preventing its spread

FIG 41.30 — Pullorum disease Equipment used by a bleeding crew for collecting blood samples by the syringe technique. (Hinshaw, Univ. of Calif.)

Increasing the heat in the brooder may be helpful in preventing excessive loss. Cleaning and disinfecting the water fountains and feed hoppers several times daily and the use of fresh, unadulterated water are also recommended.

Bottorff and Kiser (1947), Mullen (1946), Anderson (1946), and Pomeroy et al (1948) have shown that mortality can be reduced by the use of sulfonamides

FIG. 41.31 — Type of rack used by the California Poultry Improvement Advisory Board for holding blood samples during the bleeding procedure. (Hinshaw, Univ. of Calif.)

given at the rate of 0.25 to 2.0 per cent in the mash for periods up to a week. Drugs tried by these investigators include sullamerazine, sulfadiazine, sulfamethazine, sulfapyrazine, and sulfaguanidine. Complete prevention of losses has not been reported. Pomeroy et al. concluded that the sulfonamides tried by them were of little or no value in reducing mortality among poults experimentally infected with S. pullorum.

For reviews on the value of antibiotics and other recently introduced drugs for treatment of Salmonella infection the reader is referred to the sections on salmonellosis, fowl typhoid, and Chapter 8.

Treatment with drugs should be made only after a positive diagnosis has been made, and then only upon the advice of a competent veterinarian. *Carriers are not eliminated by drugs, so their use is not a substitute for a testing program.*

Every precaution should be taken to prevent contact of an infected brood with other broods that are to be brought into the house after the outbreak is in progress. The brood suffering from the disease should be kept in isolated quarters. Under no circumstances should equipment used for the infected brood be used

FIG. 41.32 — Pullorum disease. A crew at work bleeding a flock of turkeys. (Hinshaw, Univ. of Calif.)

for later hatches until it has been thoroughly cleaned and disinfected.

When the disease has run its course, the survivors should be toe-marked and raised separately from the other lots. *None of the survivors should be saved for breeding purposes.* The survivors should be marketed as soon as they are in condition and the breeders selected from groups that have not suffered from the disease. These breeders should be tested as described under prevention.

SPIROCHAETOSIS

Until Hoffman *et al.* (1916) and Hoffman and Jackson (1946) reported an outbreak of spirochaetosis in turkeys in California, the disease was not known to exist in North America. No vector could be incriminated in the California outbreak although a careful search was made. Burroughs (1947) reported a case of spirochaetosis in a fowl which was produced by feeding fowl ticks (*Argas persicus*) obtained from a poultry flock in Texas. Burroughs' findings would indicate that the disease may be prevalent in chickens in Texas even though it was not previously reported. Hinshaw and McNeil (1946) studied the spirochaete obtained from Hoffman's outbreak and found it to have all the characteristics of *Borrelia anserina* (Sakharoff) (= *Spirochaeta gallinarum,* Blanchard).

Approximately a year after the outbreak referred to by Hoffman *et al.* occurred, another outbreak was diagnosed by McNeil *et al.* (1949) in a flock of adult turkeys located about 150 miles from the original outbreak. As was the case in the original outbreak, fowl ticks could not be found on the infected ranch. The spirochaetes obtained from the second outbreak were compared with those from the first outbreak and proved to be identical. Loomis (1953) reviewed the cases reported in California and attempted, without success, to transmit the disease to turkeys by means of ticks collected on ranches where the disease had been diagnosed. Other outbreaks reported in the United States include one in pheasants in California by Mathey and Siddle (1955); and in chickens in Arizona, New Mexico, and Texas by Francis (1956) and Rokey and Snell (1961). Dickie and Barrera (1964) have recently demonstrated fowl ticks in California to be carriers of *B. anserina* and capable of transmitting the disease to fowl.

Fowl spirochaetosis is widely distributed over the world. For a more complete world-wide review the student is referred to van Heelsbergen (1929), Reis and Nobrega (1957), and Lesbouyries (1941). Reviews of the literature are also given by Sreenivasan and Sankaranarayan (1945), El-Dardiry (1945), and Moreos *et al.* (1946). The only other published reference to a natural outbreak in turkeys is one by Stylianopoulos (1925) which is referred to by Lesbouyries (1941). This outbreak occurred in Greece in turkey poults. For a complete description of this disease in turkeys and its causative agent the reader is referred to McNeil *et al.* (1949). For a good general review of pathogenic spirochaetes, the reader is referred to Stavitsky (1948). For other fowl see Chapters 14 and 37.

Description of the organism. *Bergey's Manual of Determinative Bacteriology*, seventh edition (Breed *et al.*, 1957), lists *Borrelia anserina* as the accepted name of the spirochaete originally isolated from geese by Sakharoff (1891) and called by him *Spirochaeta anserina*. Other synonyms are *Sp. gallinarum, Sp. anatis,* and *Treponema anserinum*. Bergey's sixth edition (Breed, *et al.*, 1948) and Davis (1948) give a more exhaustive historical résumé of the organism than does the condensed seventh edition of *Bergey's Manual*. Sakharoff (1891) first described the organism from the

blood of geese suffering from a severe febrile disease in the Caucasus. His original description includes a photomicrograph which shows about six spirals, but does not give measurements of length. Reports in the literature of the length have varied from 6 to 30μ, and there is wide variation in the same bird, due to division stages. Hinshaw and McNeil (1946) reported an average of 14μ (7 to 21μ) with six spirals (Fig. 41.33). The organism is motile, stains readily with aniline dyes (in contrast to Leptospira and Treponema), and is soluble in 10 per cent ox bile and 10 per cent saponin. At crisis the spirochaetes are in large clumps and are often granular (Fig. 41.34). *Borrelia anserina* also differs from Treponema in having loose, rather than tight, coils and in the ease with which it can be stained. DeLamater and Saurino (1952) compared *Treponema pallidum* after various methods of antigenic extraction and found little if any antigenic relationship. It differs from Leptospira in having looser coils and in the absence of a terminal hook as well as in ease of staining.

It should be emphasized that the spirochaete referred to by Steinhaus and Hughes (1947) is not *Borrelia anserina*. The form they described is smaller and more tightly coiled and was found in eggs infected with chicken liver tissue. It was nonpathogenic for chickens, guinea pigs, and mice. Likewise the spirochaetes described by Mathey and Zander (1955) as being associated with cecal nodules in chickens are in all probability the same as described by Steinhaus and Hughes.

Vectors. Although the fowl tick *Argas persicus* is generally referred to as the vector for *Borrelia anserina*, it is by no means the only one. Others that have been reported include the common red mite *Dermanyssus gallinae* by Hungerford and Hart (1937), and Culex mosquitoes by Zuelzer (1936). Direct transmission is also possible by several routes including oral, intranasal, intraorbital, intravenous, and subcutaneous. Kapur (1940) was able to transmit the disease in chickens by smearing the infected material on the unbroken skin of the comb or the breast. The incubation period in such cases was 2 to 6 days.

Signs. Listlessness, cyanosis of the head, increased thirst, fever, and yellowish-green diarrhea with increased urates are characteristic. The area around the vent
FIG. 41.33 — Borrelia anserina in turkey blood. This smear was made in the early stages of the disease. ×1,200. (McNeil et al., 1949.)

FIG. 41.34 – *Borrelia anserina*, showing clumping in the late stage of the disease. ×1,200. (McNeil et al., 1949.)

is nearly always stained with urates. In turkeys artificially infected by the intravenous route, the body temperature usually increases within 24 hours following infection and reaches a peak of 109.0° to 111.0° F. on the fourth or fifth day. By the end of the seventh or eighth day, if the bird lives, the temperature usually returns to normal. In naturally developed cases, temperatures as high as 109.4° F. have been observed. Infected birds tend to sit with their eyes closed unless disturbed. Chronically affected individuals develop leg weakness and sit characteristically on their hocks (Fig. 41.35). When disturbed they move about by hopping, often in a semisquatting position rather than on their feet. Others walk with a stilted gait. Complete paralysis has occasionally been noted.

Necropsy findings. The most characteristic gross change noted at necropsy is a marked enlargement and mottling of the spleen, due to ecchymotic hemorrhages such as are seen in Figure 41.36. The heart may be enlarged and have a parboiled appearance. The liver is usually enlarged, congested, and more or less studded with minute areas of necrosis. In advanced cases the areas of necrosis may be as much as a centimeter in diameter. Peripheral infarcts reported in chickens have not been a common finding in turkeys. The kidneys are enlarged and, as a rule, slightly pale. The intestines appear anemic when superficially examined. There is always a marked catarrhal enteritis, and the contents are bile stained. The increase in urates is noted by the abnormal amount in the rectum; these are yellowish-green in color.

Histopathology. McNeil et al. (1949) give a detailed description of the microscopic tissue changes observed by them. The spleen presented the most characteristic changes macroscopically (Fig. 41.36) as well as microscopically (Fig. 41.37). The characteristic structure of the spleen is not
FIG. 41.35 — Spirochaetosis. Typical altitudes seen in acute outbreaks in turkey flocks. (Hinshaw.)

lost. The reticular cells are increased in number and size and present a foamy appearance due to the ingestion of lipoid material. The centers of the groups of reticular cells undergo hyalinization, and massive areas of hemorrhage are present (Fig. 41.37) due to the rupture of the walls of veins and sinusoids. The endothelial cells lining these structures appear swollen and present the foamy appearance seen in the primitive reticular cells. The diffuse lymphatic tissue undergoes rapid growth. The cells consist of young, large- and medium-sized lymphocytes and hemocytoblasts with numerous mitotic figures. In poults spirochaetes occur in foci throughout the spleen but do not appear to have been phagocytized by the reticular cells.

The liver shows congestion and an increase in the periportal lymphoid deposits. Silver stains show the majority of the spirochaetes to be in the intercellular spaces and in the bile capillaries. Those within the hepatic cells underwent fragmentation or coiled upon themselves to form small rings.

The kidneys show marked congestion and some hemorrhage. The glomeruli and convoluted tubules appear normal. There is marked degeneration and desquamation, with hyaline casts in the collecting tubules. The interstitial tissue shows lymphocytic infiltration. No spirochaetes have been found in the kidneys of the adults outside of the larger blood vessels. In poults spirochaetes were found in the intercellular

FIG 41 37 — Section of spleen showing massive areas of hemorrhage. ×150. (McNeil et al., 1949.)

spaces and in the lumens of the tubules.

The intestines show a marked degree of catarrhal enteritis The lymphoid follicles in the submucosa are hypertrophied, and there is a generalized lymphocytic infiltration of the submucosa. The tips of some of the villi appear necrotic. The most severe injury occurs in the jejunum. The pancreas appears normal except for slight vacuolization of the secreting cells.

Diagnosis. An accurate diagnosis depends on finding spirochaetes in stained blood smears and tissues from typically sick individuals (Figs. 41.33 and 41.34). The organisms are readily stained by the Giemsa technique. Tunnicliff's technique for using her modified Gram's stain for spirochaetes is a simple and rapid method for staining blood smears for routine examinations. In tissues it is best demonstrated by some method of silver impregnation such as that of Levaditi or by the slow method of Giemsa.

A method of diagnosing the disease in dead birds, where it is impossible to demonstrate the parasites, is described by Nobrega and Reis (1947). The method is based on demonstration of antibodies in the spleen and is briefly as follows:

The spleen is weighed and a 30 per cent suspension of it is made in physiological saline to which is added 10 per cent fresh rabbit serum. To each 1 cc. of this mixture is added 0.25 cc. of a 1:10 dilution of known infected blood. The samples are incubated for 1.5 hours at 37° C. and then inoculated intramuscularly into 1- to 2-month-old cockerels. A parallel series is inoculated with spleen suspensions only and others with infected blood only. The blood of all birds is examined on the fourth day after inoculation. Failure of the cockerels in the first group to develop spirochaetosis indicates that the dead bird donor had the disease and had developed enough antibodies to prevent infection. The authors claim an 85 per cent increase in efficiency in diagnosis in dead birds by this technique.

B. anserina is not easily cultivated in vitro. For a discussion of the methods of culture see McNeil et al. (1949). Many workers prefer to maintain the spirochaetes in the tick Argas persicus, but one hesi-

tates to use this method in an area where the disease is not enzootic. Knowles *et al.* (1932) were able to grow them in embryonated but not in infertile eggs. In embryos the infection usually kills the embryo. McNeil *et al.* (1949) were able to cultivate them in both chicken- and turkey-embryonated eggs, but, under conditions available at the time, found it more feasible to maintain cultures by passage in chicks at 5-day intervals. McKercher (1950) successfully propagated the organisms in chicken embryos by a modification of the Knowles *et al.* method.

McNeil *et al.* (1949) found that the organisms remained alive in tissues of infected chicks and poults when stored at 32° F. Tissues (spleen, heart, and liver) stored at this temperature for as long as 31 days were infective when injected intraperitoneally into young chicks and poults. Infected blood stored at 20° F. for 8 days was still infective. McKercher (1950) found that infected chorio-allantoic fluid stored at 39° F. (4° C.) remained infective for 2 to 3 weeks.

Prevention and control. Since this disease is normally transmitted by such vectors as fowl ticks, mosquitoes, and fowl lice, a program for eradication of these will do much to prevent the spread of the disease. DDT has been found to be effective against fowl ticks. Drugs that have proven to be effective for the disease in chickens include the arsenicals (Moreos *et al.*, 1946) and penicillin (Nobrega and Bueno, 1945). McNeil *et al.* (1949) confirmed the findings of Nobrega and Bueno and indicate that a single dose of 10,000 to 15,000 units of penicillin given intramuscularly to mature turkeys is highly effective as treatment if given when clinical signs are first noted. A single dose of penicillin injected into the breast muscles at this time has proved an effective method of controlling an outbreak. Sick birds should be removed as soon as observed and treat-

ed immediately, after which they should be kept separately from the remainder of the flock for observation for a few days. A few birds may have to be retreated but the majority recover with one treatment. Recovered birds treated after the spirochaetes had invaded the tissues (showing symptoms) were found to be immune. Sulfonamides and streptomycin were not effective in controlling the disease. Neoarsphenamine (10 mg per kilogram) and mapharsen (5 mg per kilogram) were no more effective than penicillin.

Packchanian (1950) and Hsiang and Packchanian (1951) used 2- to 4-day-old chicks for studying the effectiveness of a number of antibiotics and drugs. Terramycin in single doses of 0.1 mg. per 50 gm. was the most effective of the antibiotics tried in young chicks. Others that were effective, but less so, included Aureomycin, bacitracin, penicillin-G, and streptomycin. Of the other drugs tried, neoarsphenamine in a single dose of 1.0 mg. was the most effective. Turkeys were not used in these trials.

Nobrega and Reis (1941) reported the successful use of a formalized vaccine prepared from infected chicken embryos for prevention of the disease. Their vaccine is prepared by inoculation of 12-day-old embryos with 0.05 to 1.0 cc. of chicken blood containing live spirochaetes. On the fifth day of incubation after infection, the organs of the embryo with the amniotic fluid are ground together and suspended in saline to make 30 cc. for each egg. Formalin is added to make 0.5 per cent. and the suspension is then left in the refrigerator for 24 hours before being filtered through sterile gauze. This "stock suspension" is diluted with 3 parts of saline for use, and 1.0 cc. is injected intramuscularly in each bird. A modification of the method of Nobrega and Reis has been described and used successfully by Rao *et al.* (1954).

STAPHYLOCOCCOSIS (Staphylococcal Synovitis, Staphylococcal Arthritis)

Jungherr (1933) and Jungherr and Plastridge (1941) reported this disease and similar ones in poultry under the name "staphylococcosis," and reviewed the literature to those dates. Madsen (1942) described a similar disease characterized by

synovitis without involvement of the articular joints. Hinshaw and McNeil (1952) reported field observations on the disease in turkeys and also reported results on experimental production of the disease in turkeys and chickens. The causative organism studied by them is a strain of *Staphylococcus aureus* which has a characteristic biochemical reaction. It ferments dextrose, lactose, maltose, mannitol, xylose, cellobiose, dulcitol, and salicin. It is indol negative, liquefies gelatin, reduces nitrates to nitrites and is Voges-Proskauer and methyl-red positive. The individual strains varied in their ability to coagulate turkey plasma. The pigment produced varied from cream to yellow in color. Of the media tested, beef heart infusion agar or beef heart infusion broth gave best results. Primary isolation was more successful in broth than on solid medium.

The Utah Agricultural Experiment Station has probably done the most intensive research on this disease in recent years (Miner, 1957; Smith *et al.*, 1961a). Smith *et al.* (1961a) obtained 9 new staphylophages and a previously described one (44A) from 27 staphylococcal cultures isolated from 23 turkeys, 2 mice caught in a turkey yard, and one sample of turkey yard soil. Based on their studies it would appear that several phage types may be involved in outbreaks of the disease in turkeys. All turkey strains studied produced alpha-type hemolysin, fermented mannitol, utilized gelatin, and were positive for coagulase.

Fahey (1954) described an outbreak in poults in Canada, and Smith (1954a, b) reported experimental production of the disease in chickens. Other references to staphylococcus infections in birds will be found in Chapter 16.

According to Smart and Miner (1961) staphylococcosis can be seen in turkeys from 3 weeks of age to maturity. Poults have yielded the organism before they leave the hatchery at 2 days of age (Smith *et al.*, 1961b) even though clinical illness and death may not come for many weeks. This could suggest egg transmission or even transmission by human carriers handling poults during the hatching operations. Phage typing of strains of *Staph. aureus* isolated from hatchery operators and poults in the same hatchery would aid in locating sources of infection. The possibility of man to poult or poult to man transmission is suggested by the report of Williams and Daines (1942) on the relationship of staphylococcal omphalitis in poults to impetigo staphylogenes among turkey hatchery workers.

Signs. It should be emphasized that in turkeys the disease is first of all a septicemia with later localization in the tibiometatarsal and femorotibial joints, in the feet, and in sternal abscesses.

The acute symptoms are similar to those of such diseases as fowl cholera. In artificially produced cases the birds become listless within 24 to 72 hours. This is accompanied by loss of appetite, loss in weight, and an increase in temperature to 109.0° F. Within 2 to 5 days the feces become fetid and sulfur-colored and the disease could be mistaken for histomoniasis. The birds seem to suffer great pain and cry out when handled or forced to walk. Paralysis occurs but not as often as in chickens artificially infected. Swelling of the feet and hock joints appears 48 to 96 hours after intravenous inoculation (Figs. 41.38 and 41.39). Sternal abscesses, which in the field outbreaks are often considered the primary lesion, developed in these cases as early as the swollen joints.

Necropsy findings and diagnosis. Necropsy of acute cases reveals an enlarged

FIG. 41.38 — Staphylococcal arthritis in young poult. (Hinshaw, Univ. of Calif.)

FIG. 41.39 — (A) Staphylococcal arthritis in an adult turkey. Note swollen joints of the feet. (B) Close-up of the feet of the turkey shown in A. (Hinshaw, Univ. of Calif.)

A   B
and dark liver and congestion of the mucous membranes of the intestines. The intestinal contents are watery and yellowish in color Inflammation of the synovial membranes of the hock joints, with increased fluid, is characteristic. Chronic cases show, principally, involvement of the joints and muscles of the legs and feet The exudate may vary from a semigelatinous to a cheeselike flaky consistency. One of the common lesions is a sternal abscess. Often this is a sac pustule 2–3 inches long and 1 inch wide, filled with a yellow purulent to a caseous exudate. Occasionally abscesses between the pectoral muscles are seen. Fibrinous pericarditis has been observed in acute cases.

Diagnosis depends on isolation of the causative organism. The disease must be differentiated from other types of joint inflammations. Scott (1950, 1951) described a deformity in poults characterized by swelling of the tibiometatarsal joint which is associated with a failure in retention of creatinine. This disease is a different entity but could predispose turkeys to staphylococcosis. Other dietary disturbances affecting the joints could likewise influence the effect of the disease in

a flock. The disease must also be differentiated from infectious synovitis which is caused by a viruslike agent affecting both chickens and turkeys (Cover and Benton, 1957).

Control and prevention. Hinshaw and McNeil (1952) tried penicillin, sulfanilamide, sulfathiazole, sulfamerazine, and suffamethazine in field outbreaks without success. They also observed that inoculated turkeys surviving the infection were not immune when reinoculated at a later date. The strains isolated from outbreaks by them were resistant to penicillin when tested in vitro. Of interest in this connection was that a penicillin-resistant strain isolated from a mastitis outbreak in cattle produced the typical disease in turkeys. Fahey (1954) and Miner et al. (1958) also found that most of the strains isolated by them from outbreaks were penicillin-resistant. Fahey (1955) stated that in uncomplicated outbreaks, 300 gm. of a mixture (100 gm. each) of streptomycin, Terramycin, and Aureomycin given in feed for 1 week yielded good results.

Miner et al. (1958) and Smart and Miner (1961) found that the antibiotic novobiocin has promise of being a successful drug for

treatment of the disease. The drug was given at the rate of 200 to 600 grams of feed grade of novobiocin per ton of feed starting soon after the disease appeared in a flock. These investigators found that furazolidone was of little if any value in controlling the disease. It appears, on the basis of present knowledge, that broad-spectrum antibiotics have the most merit

in controlling field outbreaks of this disease. *The drug of choice for a specific outbreak should be ascertained by an early determination of the antibiotic sensitivity of the strain of Staphylococcus responsible for the outbreak.*

The general recommendations for handling other infectious diseases are suggested.

STREPTOCOCCOSIS

Volkmar (1932) reported several outbreaks of apoplectiform septicemia in turkeys caused by a streptococcus, and described the disease as resembling fowl cholera. The losses were sporadic in nature, the disease was acute, and clinical signs were seldom seen before death. The principal lesions noted on necropsy were congestion or diffuse hemorrhages in the skin and breast muscles, together with generalized congestion of the internal organs. Hemorrhagic enteritis and peritonitis were common, and the heart sac was often filled with a blood-tinged fluid. The disease must be differentiated by bacteriologic studies.

Acute outbreaks of a disease in young

poults with signs and necropsy findings resembling pullorum disease were found by McNeil and Hinshaw in California (unpublished data). Losses in these cases have equalled those of pullorum disease or paratyphoid infections. Examples of mortality experienced in these outbreaks are: 430 out of 1,080 poults; 500 out of 1,200 poults; and 450 out of 1,500 poults. Losses started within the first week and continued for two weeks. The signs resembled those of pullorum disease. Necropsy findings included congestion and necrosis of the liver, lungs, congestion and necrosis of the liver, and enteritis. Pin-point areas of necrosis in the livers were especially common. A short-chain streptococcus which has the

characteristics of *Streptococcus zymogenes* was consistently isolated from these cases. No detailed studies have been made of this disease, but mention is made of it

since it may be confused with pullorum disease. Other references to avian streptococcosis will be found in Chapter 16.

TUBERCULOSIS*

Tuberculosis, a chronic disease affecting turkeys and other fowls, is caused by *Mycobacterium avium*. It is not common in commercial turkey flocks and is most often associated with tuberculous chickens.

Signs. There are no typical clinical signs. Lameness and emaciation have occasionally been observed Many turkeys that show lesions on necropsy maintained their weight for several months before death Tuberculous turkeys placed in individual cages and observed for periods of 1 to 10 weeks held their initial weight, and a few even gained Such birds often went through intermittent periods of normality and depression lasting for 2 or 3 weeks before death.

Clinical diagnosis. Tuberculosis in turkeys flocks has been more often detected by accidental discovery of lesions during postmortem examination by the owner, or by the housewife while preparing a bird for roasting, than by signs seen in the flock or by the use of the tuberculin test. Hinshaw *et al.* (1932) found that about 75 per cent efficiency can be expected from the use of the tuberculin test as a means of diagnosis. The edge of the wing web proved to be the best site for inoculation of the tuberculin, but the results, even in this area, were more difficult to interpret than in other animals

Necropsy findings. The gross pathology of tuberculosis in turkeys is not markedly different from that of the disease in chickens. The distribution of lesions indicates a tendency for a greater number of organs to become infected than in chickens, and, as in chickens, the disease is principally abdominal in nature. Seven cases of tuberculosis in turkeys from five California

outbreaks were typed and found to be of avian origin.

A study of the distribution of lesions in turkeys from seven California outbreaks showed that the liver, bone marrow, spleen, intestines, ovaries, mesentery, skin, thymus gland, and lungs were, in the order given, the most common sites of lesions. Cutaneous lesions in turkeys have also been reported by Scrivner and Elder (1931) and according to Feldman (Chapter 12) by Chrétien *et al.* (1925) and Dietrich (1927). The ovary and the thymus glands were more often found to be infected than in chickens. Attention is also called to the large percentage of cases of bonemarrow lesions. The number of birds examined for bone-marrow lesions was small as compared to the total, but they were in all stages of the disease. When lesions were found in the bone marrow, they were always found in at least one other organ.

Differential diagnosis. Some of the conditions which might be confused with tuberculosis in turkeys are mycosis, blackhead, and tumors. Mycotic lesions in the liver and kidney, which on first glance are suggestive of tubercles, have been observed. These are not definitely encapsulated and circumscribed, however. On microscopic examination, mycelia are found, while acid-fast rods cannot be demonstrated.

Infectious enterohepatitis should not be confused with tuberculosis, because the lesions in the liver do not resemble tubercles. Furthermore, the well-known characteristic lesions in the ceca should help to differentiate it from tuberculosis. On the other hand, tumors of the liver and ovary have been noted that were suggestive of tuberculosis until a microscopic examination was made.

Prevention and control. Complete isolation of turkeys from chickens will do much

* See also Chapter 12.

to prevent tuberculosis. Once the disease is found, it is a good plan to dispose of the entire flock as well as all chickens on the premises.

Day-old poults, rather than adult stock, should be purchased as replacements. They should be brooded away from the infected area and should not be allowed to range there for at least one year after the disposal of diseased birds. The entire flock should be sold and replaced with day-old stock each spring for several years in order to insure freedom from tuberculosis.

TRANSMISSIBLE ENTERITIS (Avian Monocytosis, Bluecomb Disease)

This disease is described under various names, including avian monocytosis and bluecomb disease, because of characteristics in common with the disease of chickens known under these names. Transmissible enteritis has been suggested by Sieburth and Johnson (1957) as the most appropriate name for the disease of turkeys. It has also been confused with hexamitiasis because of many characteristics common to the two diseases. It is now generally accepted that the cause is a filterable agent (Sieburth and Johnson, 1957; Tumlin et al., 1957; Tumlin and Pomeroy, 1958; Truscott et al., 1960; and Truscott and Morin, 1963). Truscott and Morin have isolated a Vibrio sp. which they believe to be an etiological factor in production of the disease. Pomeroy (personal interview, 1964) reported that he and his colleagues (unpublished data) have also isolated a Vibrio sp. as well as a viral agent from field outbreaks. The true etiological significance of these microorganisms remains to be determined.

The disease affects susceptible turkeys of all ages, without regard to season, especially on farms that practice a continuous rearing program. In young poults the first signs of the disease may appear as early as the fourth or fifth day after exposure. They are very similar to those seen in hexamitiasis and include listlessness, tendency to seek heat, subnormal temperature, watery droppings, and rapid loss of weight. Since these are also characteristic symptoms of hexamitiasis, the two diseases must be differentiated by demonstration of their respective etiological agents. Because of the similar age range of susceptibility, it is highly probable that combined infections may occur.

Because of the similarity to avian monocytosis of chickens, the reader is referred to Chapter 31, Avian Monocytosis, for complete information on the etiology, pathology, prevention, and control of that disease.

VIRAL HEPATITIS

Viral hepatitis of turkeys was first described simultaneously by Snoeyenbos et al. (1959) from Massachusetts, and by Mongeau et al. (1959) from Ontario, Canada. Both outbreaks occurred in poults under three weeks of age. In neither instance was the mortality excessive. The poults in the Massachusetts outbreak were 17 days of age, and the mortality was less than 5 per cent of the group of 800 birds which returned to normal appearance in 3 or 4 days. The principal clinical sign was a slight depression of activity. In another report Snoeyenbos and Basch (1960) reported the disease in 11 outbreaks in poults under 5 weeks of age with mortality rates of 1 to 25 per cent.

They also reported two cases in 6- and 8-week-old poults, and 4 diagnoses in mature stock from specimens taken at the time of slaughter. In these cases, liver condemnations of 30 to 90 per cent were recorded by the processors. Adult turkey breeder hens were infected by Snoeyenbos and Basch by intravenous injections of the virus. These birds remained clinically normal. However, at necropsy, representative birds sacrificed 2 to 16 days postinoculation yielded virus from all the livers and less frequently from other organs. In one instance, the virus was isolated from retrogressing ovarian follicular contents.

Some immunity developed in the artificially infected birds as determined by reexposure of recovered poults. Egg transmission has been suggested as one means of dissemination. No specific methods of prevention or control have been reported and no treatment is available.

Virus hepatitis as described herein must not be confused with avian vibrionic hepatitis described by Hofstad et al. (1958) and Peckham (1958). The disease described by them and others is caused by a vibrio. Peckham was able to infect turkey poults with his strain of vibrio but as far as is known there have been no reports of naturally occurring outbreaks in turkeys. A report on vibrionic hepatitis is given by Snoeyenbos in Chapter 14.

LEUKOSIS

Although the leukosis complex is recognized as a definite economic problem by the turkey industry, there are few specific references to it in the published literature. Evidence of the susceptibility of turkeys to leukosis and of its prevalence in them is given by McKee (1963, 1964). He reported that according to the 1960–64 official records of the USDA Agricultural Marketing Service, Poultry Inspection Branch, from 0.4 to 1.2 per cent of all turkeys condemned yearly in official processing plants were culled because of leukosis. The two types of leukosis most often seen in turkey processing plants are lymphomatosis and osteopetrosis, although all types are seen.

The importance of the need for recognizing this group of diseases and for differentiation from other diseases of turkeys is emphasized by McKee et al. (1963). Problems concerned with making differential diagnoses are also discussed by them. Diseases which may confuse a diagnostician include other neoplasms, certain chronic mycotic infections (Olney, 1950), tuberculosis, and histomoniasis. Turkeys suffering from histomoniasis may show granulomatouslike liver lesions which can only be dif-

ferentiated by micro-histological examination or by demonstration of histomonads. The fact that in such instances a number of typical histomoniasis cases usually appear in the same lot of turkeys being inspected is an aid in making a diagnosis unless both diseases are present in the same flock.

No attempt has been made to give an exhaustive review of the subject in this section. The reader is referred to Chapter 19 for a detailed discussion. Pertinent references to the leukosis complex in turkeys in addition to those given above include Andrewes and Glover (1939), Simpson et al. (1957), Belding and Sanger (1961), and Helmboldt and Frazier (1962).

MISCELLANEOUS INFECTIOUS DISEASES

Numerous reports of sporadic outbreaks due to miscellaneous bacteria and viruses have been made by investigators.

Pseudomonas Infections

Pseudomonas sp. are among the common contaminants of eggshells and contents and produce the so-called "green-rot" (Lorenz et al., 1952; Orel; 1959; and Hartung and Stadelman, 1963). They must be considered as potential causes of disease in hatching poults. Personal experience of the author indicates that severe brooder losses may occur especially under unfavorable environment.

In outbreaks caused by a hemolytic Pseudomonas, Stafseth (1939) and Stafseth et al. (1940) stated that there was a morbidity of 50 per cent and a low mortality. The outstanding necropsy findings are dark and often uncoagulated blood, pin-point areas of necrosis or yellowish-gray streaks in the liver, mottled spleen, and hemorrhagic enteritis. According to these investigators, the species of Pseudomonas responsible for the outbreak in turkeys differs in several respects from P. aeruginosa, a common inhabitant in fowls.

Escherichia Infections

Frequently, diagnostic laboratories report the isolation of organisms belonging to the colon-acrogenes group of bacteria from outbreaks of septicemic diseases in young poults. In similar outbreaks organisms belonging to the paracolon groups are also reported. Paracolon infections are discussed as a separate subject in Chapter 9.

Listeriosis

Listeriosis of fowl, caused by Listeria monocytogenes, is fully described in Chapter 15. Belding and Meyer (1957), Maletwitz et al. (1957), Gray (1958), and Bolin and Eveleth (1961) have summarized the literature concerning this disease in turkeys. It is not a frequently reported disease in turkeys even in an environment where it might be expected to occur. In areas where listeriosis exists in other animals, the possibility of it occurring in turkeys must, however, be considered.

Clinical signs described include depression, nervousness, diarrhea, and at times torticollis and complete paralysis. At necropsy, necrosis of the liver which is often cropsy, necrosis of the liver which is often mottled and hemorrhages of the epicardium were described. Brain lesions were not

common. Microscopically the lesions resembled those of an acute disease.

Clostridium Infections

Fenstermacher and Pomeroy (1939) described losses in breeding turkey hens associated with several species of *Clostridium*. The outbreak involved a flock of 1,000 turkey hens in which there was a low mortality. The losses occurred during the early part of the breeding season, and the investigators stated that the atria of infection were probably wounds inflicted at the time of mating. Subcutaneous edema and emphysema around the head and *thighs were the principal symptoms* reported. Injuries due to mating can be prevented by proper management. (See section on injuries and material on botulism.)

Omphalitis

Bolin et al. (1949) described a virus isolated from chicks and poults suffering from omphalitis. The disease was characterized by a high mortality during the first three weeks after hatching. Necrosis of the tissues around the navel was an outstanding lesion. The virus proved more pathogenic for poults than chicks but could be cultivated in 10- to 12 day-old embryonated chicken eggs These workers believe the virus is transmitted through the egg. Williams and Daines (1942) also isolated a strain of *Staphylococcus aureus* from omphalitis of turkey poults which they believed to be the causative agent of an outbreak studied by them. Human cases of impetigo staphylogenes were associated with the outbreak described by them.

Actinomycosis

Olney (1950) has described an actinomyceslike chronic disease of turkeys which is characterized by liver and intestinal lesions that may be mistaken for tuberculosis. The livers in these cases are usually studded with raised nodules that may reach an inch in diameter. On cutting, these are found to be caseated, capsulated, and have fimbriated processes extending into the liver tissue from the main body of the nodule. In the outbreak described by Olney, the disease was confined to three lots of 500 poults each, all 6 weeks of age, in a total flock of 9,000 poults. When the flock was put on range at 8 weeks of age, the infected lots mingled with the normal birds, and the infection spread to them. The grower estimated a total loss of 45 per cent by the end of the season. When the birds were marketed in December, 10 per cent of them showed lesions. This disease must be differentiated from tuberculosis, histomoniasis, and lymphomatosis. More study is needed to confirm its etiology.

Pseudotuberculosis

Pseudotuberculosis is a contagious disease of many animals including turkeys and is caused by *Pasteurella pseudotuberculosis*. For a detailed description and review of the literature the reader is referred to Chapter 14. Reports of the disease in turkeys include Rosenwald and Dickinson (1944), Mathey and Siddle (1954), and Kilian et al. (1962). The disease is characterized by an acute septicemia of short duration, followed by a chronic focalized infection resulting in tubercular lesions in various organs—thus the name. The cultural characteristics of the etiological agent resembles *Salmonella pullorum*. In fact, the strain isolated by Kilian et al. agglutinated Salmonella Group D, 9, 12 antiserum when tested with the live culture, but not with alcohol-treated antigen. Serum from *P. pseudotuberculosis* infected turkeys did not however agglutinate either *S. pullorum* or *S. typhimurium* antigens. The findings of these investigators emphasize the need for positively identifying such organisms isolated from turkeys in pullorum testing programs.

Others

Numerous other infectious diseases of birds may occur in turkeys. Examples that are described in other chapters include fowl plague, psittacosis, equine and avian encephalomyelitis, coli-granuloma

(Hjärre's disease), avian hepatitis, omphalitis, and infectious synovitis. Western type equine encephalomyelitis has been reported in turkeys by Woodring (1957). Spalatin et al. (1961) have reported eastern equine encephalitis in Wisconsin turkeys, and Porterfield (1961) has described a meningoencephalitis virus from turkeys in Israel.

A recent outbreak of fowl plague in turkeys is described by Wells (1963). This outbreak occurred in a flock of turkeys on the North Norfolk coast of England in the spring of 1963. The main features of the outbreak were typical of the disease and included rapid spread, sudden deaths, high mortality, and marked drop in egg production in the layers. The source was not discovered but it was thought to be introduced by migrating birds. The outbreak was eradicated by radical quarantine and slaughter methods. Within a month, 29,000 turkeys were dead from the disease or by slaughter.

Protozoan Diseases*

HISTOMONIASIS (Infectious Enterohepatitis, Blackhead)

This disease, first described by Cushman (1893), is caused by a protozoan parasite, Histomonas meleagridis. It is credited with being the cause of the temporary abandonment of the turkey industry in some sections of eastern and mid-western United States. The early researches of Smith (1895), Moore (1896), Curtice (1907), Higgins (1915), Smith and Graybill (1920), and Tyzzer (1920) paved the

* See also Chapter 37.

way for later studies which proved that the disease is preventable.

Etiology. *Histomonas meleagridis*, the causative agent, is classified as a flagellate but is one of the few that likewise has an amoeboid stage. It is harbored by the common poultry cecal worm, *Heterakis gallinarum*, found in the ceca, or blind pouches, of a large percentage of chickens. This, together with the fact that chickens are not, as a rule, highly susceptible to histomoniatis, explains the frequent transmission of the disease from apparently healthy chickens to turkeys.

The parasites are capable of living for long periods in the cecal worm and its eggs. Van Es and Olney (1934) found that the infection remained on vacant yards from the middle of November until the middle of June during each of 5 years when turkeys were reared in the yards from June to November. For a more detailed discussion of the parasite and a description of the organism, reference is made to the works of Tyzzer (1920), Delaplane (1932), DeVolt and Davis (1936), Wehrich (1943), Connell (1950), and the chapter on protozoa. Recent reports which have aided in a better understanding of the etiology and pathogenesis of this disease include McGuire and Cavette (1952), DeLappe (1953,a,b,c,d), Harrison *et al.* (1954), Lund (1955, 1956, 1958a), Lund and Burtner (1957), Malewitz *et al.* (1958), and Goedbloed and Bool (1962). Lund (1963) described a new species of a histomonad, *H. wenrichi*, which inhabits the lumen of the cecum but does not apparently invade the tissues or produce the typical disease. For a more complete discussion of this species see Chapter 37. Figure 41 40 from Lund (1958b) illustrates how the cecal worm plays an important role in the transmission of this disease.

New evidence has been presented by Lund *et al.* (1963) that earthworms are true hosts of Heterakis and are thus of importance in transmitting blackhead. Because of this new discovery, the life cycle depicted in Figure 41.40 will need to be revised to include the earthworm.

Signs. "Blackhead," the common name, is a misnomer. Drowsiness, weakness, drooping wings and tail, a lowered head, ruffled feathers, and constant sulfur-colored diarrhea are characteristic symptoms. As a rule, adult birds are sick for several days and become emaciated before dying. Young poults may have an acute type of the disease and die soon after symptoms are noted. Although turkeys of all ages are susceptible, the heaviest losses occur during the first 12 weeks of life.

The mortality is high, often approaching 100 per cent, and averages about 50 per cent unless kept under control. Once the disease attacks a flock, occasional birds are likely to die between the intermittent periods of heavier losses, especially if the flock is not moved frequently to clean grounds. The period of incubation after contact with infection is 15 to 21 days.

Necropsy findings. The liver and the ceca are the principal organs showing marked changes. The severity of these changes varies with individuals. The cecal lesions are apparently the primary ones, and one or both ceca may be affected (Fig. 41.41). The lesions consist of marked inflammatory changes and ulcerations, sometimes involving most of the organ. A single ulcer may involve the serosa and pierce the wall. The mucous membrane often becomes necrotic, much thickened, and covered with a characteristic foul-smelling, yellowish-green, semi-caseous exudate; or a dry, hard, cheesy core may fill the cecum.

The affected liver (Fig. 41.42) presents a characteristic appearance, with areas of necrotic and degenerated tissues on the surface. These are more or less circular, have a yellowish to yellowish-green appearance, and in contrast to tumors and tubercles (tuberculosis), are somewhat depressed below the liver surface. They extend deeply into the tissue and are more or less confluent with the healthy tissue. In older birds the individual lesions are often merged. Evidence of healing is seen in the large amount of scar tissue in older birds.

FIG. 41.40 — Histomoniasis. Chart showing cycle of infection and role played by the cecal worm in the transmission of the disease. (Lund, 1958b.)

FIG. 41 41 — Ceca of a turkey affected with blackhead. Note the swollen condition of one cecum and the discolored diseased areas near the middle and at the tip. The other shows a single lesion near its middle portion. (Oroybill, Univ. of Calif.)

Occasionally, peritonitis and involvement of the other organs may be observed

Differential diagnosis. Histomoniasis must be differentiated from other diseases involving the liver and cecum. Chief among these are tuberculosis, tumors, and mycotic diseases. Demonstration of the causative agent by microscopic examination and culturing is necessary for final diagnosis.

Treatment. No drug or combination of drugs has been found entirely satisfactory for stopping losses once the disease has obtained a foothold in a flock. Nicotine products and phenothiazine have gained their reputation because of claimed successes in removal of cecal worms, thus aiding prevention of the disease. Neither agent has been proven effective against Histomonas meleagridis.

A large number of drugs have been screened for their possible effectiveness against this disease but only a few have shown promise. A review of the literature on the current status of the effectiveness of drugs for control of the disease is given by Horton-Smith and Long (1956), Jerstad (1957), Wehr et al. (1958), and McGuire et al. (1964). Among the drugs listed by Wehr et al. as having some therapeutic value are 4-nitro-benzenearsonic acid, 1-ethyl-3-(5-nitro-2-thiazolyl) urea, furazolidone, and 2-acetylamino-5-nitrothiazole. Welter and Clark (1961) reported successful treatment with p-ureido-benzenearsonic acid and Lindquist (1962) with an antibiotic paromomycin sulfate. McGuire et al. (1964) and McGregor et al. (1964) review the literature on the use of dimetridazole (1,2-dimethyl-5-nitroimidazole) and report additional trials on its use against the disease.

Inasmuch as rapid strides are being made on research in therapeutics, the reader is urged to review recent literature to determine if more effective drugs have been developed. Recommendations of manufacturers should be carefully observed when administering these drugs.

It should be emphasized that none of the drugs so far developed is highly effective once the disease has obtained a foothold in a flock. Furthermore, once treatment is discontinued, the disease is likely to reappear since little or no immunity is developed in infected birds and there is no cumulative action of the drugs tested. These facts indicate the need to realize treatment of any kind is only an adjunct to the prevention program outlined below.

Prevention. This is a "filth-borne" disease dependent on carriers, including not only chickens and turkeys but other birds

FIG. 41.42 — liver of turkey affected with blackhead. (Graybill, Univ. of Calif.)

as well. For a discussion of carriers other than chickens and turkeys the reader is referred to the chapter on protozoa. These carriers eliminate the causal organism in the feces, alone or within the cecal worm and its eggs. When the organism is ingested by susceptible stock, infection results. Both Horton-Smith and Long (1955) and Lund (1956) have shown that *Histomonas meleagridis* usually cannot live to establish an infection unless it is protected by some resistant body such as the egg of the cecal worm. The resistance of *H. meleagridis* when protected by cecal worms or their eggs was demonstrated by Farr (1956, 1961). She was able to recover both *H. meleagridis* and Heterakis larvae from turkeys fed droppings which had remained on soil for over 4 years. This also demonstrates the marked resistance of Heterakis eggs. This fact emphasizes the importance of the cecal worm in perpetuation and transmission of the disease. In turn, it emphasizes the importance of elimination of the cecal worm as a preventive measure in controlling the disease. The discovery by Lund *et al.* (1963) that both Heterakis and Histomonas may

be carried by earthworms and that blackhead may be transmitted by them complicates the prevention and control program.

Because there is no practicable method of identifying carriers, all chickens and turkeys must be under suspicion. Examples of methods of mechanical transmission of the disease are feed sacks and grains (corn, oats, wheat, etc.) that become contaminated with feces from chickens or turkeys harboring both the cecal worm and the *H. meleagridis*. Frank (1953) succeeded in transmitting the disease to turkeys by feeding grasshoppers that had been previously infected with cecal worm eggs.

Billings (1928) suggests a four-yard rearing system consisting of dividing 1 acre into four yards. These are divided as suggested in Figure 41.43. Three hundred poults can be raised in such a unit. The poults are reared for a month in each of the other yards in succession. They are moved each month until marketed. The acre of ground can be fenced into the ¼-acre sections, or the fence may be a temporary one, set up around a different section each month. Regardless of the system used in rearing
FIG. 41.43 — Two systems for rotation of runs suggested by Billings for prevention of blackhead. (Hinshaw, Univ. of Calif.)

turkeys, the following precautions must also be observed:

1. Keep the turkeys entirely separated from the chickens or chicken yards. Drain age from chicken yards to turkey yards is a common source of the disease.

2. Do not rear turkeys on ground that has been fertilized with chicken or turkey manure.

3. Do not rear turkeys in yards where losses have occurred until at least 2 years after the removal of the last diseased bird. (See Farr, 1961.)

4. Do not introduce new stock without quarantining it for 3 weeks before adding it to the flock.

5. Feed an adequate ration, with plenty of fresh, clean water.

According to Lund (1958b) no drug is yet known which will attack the cecal worm before it can transmit histomoniasis. Phenothiazine will, however, eliminate over 90 per cent of the cecal worms and thus reduce the danger of transmission. It will not affect the cecal worm eggs already in the soil, so it is only after continuous treatment over a period of 2 to 3 years that complete elimination can be expected. Phenothiazine has no effect on *H. meleagridis*. (See Wehr *et al.*, 1958.)

Such remedial measures as just described are not recommended for general use where blackhead can be readily controlled by methods not involving drugs. Nor are these remedies recommended as general procedures if blackhead has not been proven a problem.

COCCIDIOSIS

Losses in young turkeys are often mistakenly ascribed to coccidiosis when some other disease is responsible. Most of the cases of bloody diarrhea in turkeys which are attributed to coccidia are not caused by these parasites.

Nine species of turkey coccidia have been described: Eimeria meleagridis, E. meleagrimitis, E. dispersa, E. gallopavonis, E. adenoeides, E. innocua, E. subrotunda, Isospora haisini, and Cryptosporidium meleagridis. These last two species described respectively by Svanbaev (1955) from USSR, and by Slavin (1955) from Scotland have not been reported from the United States.

Signs. The only two species which are highly pathogenic for poults are E. meleagrimitis and E. adenoeides (Hawkins, 1952; Moore and Brown, 1951, 1952). Hawkins, who first described E. gallopavonis, presented limited information to indicate that this species is also pathogenic.

This observation has been confirmed by Farr et al. (1961) and Wehr et al. who found this species highly pathogenic for 3- to 6-week-old poults and less so for 11-week-old poults. The other species can be considered nonpathogenic under normal environments. *E. meleagridis* may produce mild symptoms and slight losses under poor management (Hawkins, 1952; Moore et al., 1954).

The common clinical signs seen in outbreaks include listlessness, huddling into groups, constant cheeping, and lack of appetite beginning about the fourth day following infection and lasting for 4 to 5 days. Feed consumption falls on the fourth or fifth day but is resumed within a week unless the outbreak is especially acute. Rapid loss in weight occurs during this period. The peak of mortality is reached from the fifth to seventh day.

Hemorrhagic diarrhea as observed in *E. tenella* infections in chickens is not seen. Hawkins (1952) found that in poults artificially infected with *E. meleagrimitis* the droppings were scanty and slightly fluid with occasional blood flecks. At the peak of the infection (5 to 6 days), some of the fecal matter appeared in cylindrical forms 1 to 2 cm. in length and 3 to 6 mm. in diameter with sharply cut ends. Moore and Brown (1951) found the feces in severe *E. adenoeides* infections to be more fluid than normal, occasionally blood tinged, and containing mucous casts 1 to 2 inches long. These abnormal droppings appeared several hours previous to elimination of oocysts and persisted for about 4 days.

Age resistance has been noted for both the pathogenic species, but immunity following infection is only relative. Both species produce more acute symptoms in poults under 5 weeks of age with smaller dosages of oocysts than in older poults. In older poults, loss in weight over the short period of infection is the only noticeable symptom.

Necropsy findings. Hawkins (1952) summarizes the gross pathology of *E. meleagrimitis* infection as follows: Four days after infection, the duodenum and jejunum con-

tain an excessive amount of fluid. The jejunum is slightly thickened, dilated, and small areas of congestion are noted. The posterior part of the jejunum and the ileum may contain a greenish mucus. By the end of 5 to 6 days, the lumen of the small intestine is devoid of food, and the walls become covered with a white mucous deposit containing myriads of coccidia. If blood is present in the fluid, it is only in amounts sufficient to slightly tinge the liquid. Small flecks of clots may be noted. Mucous strands in the upper intestine are numerous. By the end of a week, irregular areas of congestion may be noted in the duodenum and jejunum. Greenish mucoid casts may be found in the posterior jejunum and in the ileum.

These are also essentially the findings of Moore and Brown (1951) for *E. adenoeides* infection. Thus, catarrhal enteritis, marked accumulation of fluid, which may be slightly blood tinged, and the presence of mucoid casts, which may be greenish, are the significant lesions. The site of the lesions may vary because of different locations of the sites of infection. The site of *E. meleagrimitis* infection is primarily in the jejunum, while the primary site for *E. adenoeides* is the lower ileum, rectum, and ceca. In severe infections with *E. gallopavonis* the mucosa of the lower small intestine and the proximal portions of the ceca show marked inflammatory changes (Farr et al., 1961; Wehr et al., 1962).

For greater details, histopathology, and differential characteristics between these and the other species the reader is referred to Chapter 37. Final diagnosis will depend on demonstration and identification of the coccidial species involved. The finding of coccidial oocysts alone is not evidence enough to warrant a diagnosis of coccidiosis as the cause of losses in a flock.

Prevention. In artificial brooding, preventive measures are more practicable than when turkeys are brooded naturally; but two important avenues of infection exist — namely, the feed and the attendant. Indirectly, the attendant is a carrier of coccidia by way of feed, especially if he shovels it from one pile to another on

floor, since he cannot avoid walking on feed mixed in this manner. Visitors are also potential mechanical carriers.

A rigorous sanitation program will aid in keeping coccidial infection reduced to a minimum and in turn aid in building up an immunity to the disease. Coccidial oocysts must have moisture in order to form spores, without which they cannot produce disease. Keeping thoroughly dry all areas to which poults have access will do much, therefore, to prevent acute outbreaks. Frequent changing of litter, the use of wire-screened platforms for water and feed containers, and ample floor space are aids in keeping the floors of the brooder houses dry.

Control and treatment. There are two objects for use of drugs. One is to give the drug at a low daily level in the feed during the susceptible age in order to prevent acute outbreaks and to aid in establishing immunity by keeping the number of oocysts reduced to a level below that needed to produce the acute disease. The second is to administer the drug early in an acute outbreak to prevent undue losses. In either case good management procedures are a necessary adjunct to successful control.

A number of drugs have been proven of value for control of coccidiosis in chickens. The same ones are effective in control of the disease in turkeys, so the reader is referred to the section on coccidiosis in Chapter 37 for details. There are only a few references to specific treatment of the disease in turkeys. Moore (1949) found that sulfaquinoxaline, sulfaguanidine, sulfamethazine, and sulfamerazine were of equal value for the control of the disease in turkeys. The percentage amount used in the feed for each drug was as follows: sulfaquinoxaline, 0.03 per cent; sulfaguanidine, 1.0 per cent, sulfamethazine, 0.5 per cent; and sulfamerazine, 0.5 per cent Morehouse (1949) tested six sulfonamides, including the ones referred to by Moore, and found five of them effective against coccidiosis of turkeys. Boyer and Brown (1953) review the literature on treatment of turkeys. Additional references to specific treatment of turkeys include Cuckler et al (1956) on the use of nicarbazin; Cuckler et al (1961) on the efficacy of amprolium; Ball and Warren (1963) on the use of the sulfaquinoxaline and amprolium; and Hymas and Stevenson (1962) on Zoalene (3,5-dinitro-0-toluamide) for both chickens and turkeys

HEXAMITIASIS

Hexamitiasis is a disease of young poults, causing its greatest mortality in those under 10 weeks of age. It was thought for many years that the disease was caused by trichomonads, but Hinshaw *et al.* (1938a, b) reported that a species of Hexamita and not a Trichomonas was responsible for the disease. They found that neither *T. eberthi* nor *T. gallinarum* (commonly found in the ceca of turkeys and chickens) was capable of producing a similar disease. The causal agent has been named *Hexamita meleagridis* by McNeil *et al* (1941). They describe the parasite as follows:

"This organism (minus flagella) varies in length from 6 to 12μ (average 9μ) and in width from 2 to 5μ (average 3μ). The nuclear membrane is distinct, and the karyosomes are round and fairly large (two-thirds diameter of the nucleus). Anterior to the nuclei are 2 large blepharoplasts (or groups of blepharoplasts) from which arise the 4 anterior and 2 anterolateral flagella. The flagella are all of about the same length, measured from the point of emergence from the body. The 4 anterior flagella are usually curved back along the body. Just posterior to these 2 large blepharoplasts are 2 others

from which arise the 2 caudal flagella. These flagella pass posteriorly in a granular line of cytoplasm to their pockets of emergence near the posterior end of the body" (Fig. 41.44A and B).

Slavin and Wilson (1953, 1960) have done an exhaustive morphological study of Hexamita from turkeys in Scotland. Their studies indicate that *H. meleagridis* does not divide by simple binary fission, and that a reproductive cycle can be demonstrated in the reticuloendothelial cells and tissue interspaces of the bowel wall.

The disease is prevalent in most sections of the United States. Published reports in addition to those from California include one from Connecticut by Jungherr and Gifford (1944) and one from Indiana by Doyle *et al.* (1947). Campbell (1945) reported the presence of Hexamita in turkeys, infected also with Cochlosoma, in an outbreak in Scotland. He considered that Cochlosoma was the primary cause of losses in this outbreak. The reports of Slavin and Wilson (1953) and Wilson and Slavin (1955) further establish the existence of the disease in Scotland. Vance and Bigland (1956) have reported it from Canada.

Signs. In the early stages of acute outbreaks the poults are nervous and require
FIG. 41.44 — (A, B) *Hexamita meleagridis* from the intestine of the turkey, showing individual variation in size and shape. X1,875. (McNeil, Hinshaw, and Kofoid, Am. Jour. Hyg.)

more heat than normally; the body temperature is normal or subnormal; the gait is stilted; and the feathers are ruffled and unkempt. There is foamy watery diarrhea, but the cecal droppings do not appear changed.

In most cases the poults continue to eat and may even appear to consume more feed due to a nervousness that is always evident. This nervousness is also manifested by the continual chirping of the birds, especially in the early stages. Due to improper digestion and assimilation of feed, the poults lose weight rapidly. Many of the survivors continue to be underweight for weeks. In the later stages of the disease the poults become listless, sit under the hover, and go into a coma. Finally, they struggle, flap their wings, and die.

Subacute attacks of the disease may occur in young poults early in the season before the infection reaches the epidemic stage. Milder outbreaks may occur in poults that reach a resistant age. In such outbreaks, listlessness and loss of weight are the most prominent symptoms. Loss of appetite will depend on the severity of the disease. Large numbers of stunted individuals result from this form.

Course and mortality. In experimentally produced outbreaks symptoms appear 4 to 7 days after ingestion of the parasites. The period of incubation varies with the amount of inoculum and the age of the individual. If temperatures are taken daily following infection, a drop will often be noted a day before visible symptoms are seen. Likewise, daily weight records will usually show a decline in the daily gain before symptoms appear.

Mortality may start within a day after symptoms appear. In acute outbreaks the course of the disease is typical of an acute infectious disease, with the peak of mortality occurring in 7 to 10 days following the appearance of symptoms. In most instances straggling losses occur for as long as 3 weeks, and in a few flocks, a second peak of mortality has been observed.

In outbreaks complicated with other infections, such as salmonellosis, or by faulty management, the course may be varied and the mortality increased. Heavy losses seldom occur in poults over 10 weeks of age unless there has been some lowering of resistance due to another infection or due to environmental factors. It is always desirable to eliminate the possibility of such complications whenever losses associated with the presence of *Hexamita meleagridis* are encountered in older turkeys.

Environmental and husbandry factors, as well as age, greatly influence the mortality. It may vary from a few poults to the entire flock. Under experimental conditions, using normal poults, we have not been able to produce heavy mortality in poults over 8 weeks of age.

Necropsy findings. At necropsy the birds are in poor condition; the feathers lack luster; the skin is dry; the flesh of the breast is dehydrated and reddened. In young poults suffering from an acute outbreak, the crop usually contains some food; in poults that linger longer before death, it is usually empty.

The principal pathological change occurs in the duodenum, jejunum, and ileum, where there is catarrhal inflammation with marked lack of tone. The intestinal contents may vary from a thick mucous type to a thin watery, foamy type. The latter is most characteristic. Localized bulbous areas filled with watery contents are also characteristic. The mucous membrane of these areas is often congested.

The contents of the ceca may be more fluid than normal, but seldom changed otherwise. The only change noted in the ceca is a congestion of the cecal tonsils.

Diagnosis. Diagnosis must be based on finding Hexamita in the upper intestines. The examination of cecal or rectal contents is not recommended as a diagnostic procedure because of the necessity of having to differentiate other flagellates from *Hexamita meleagridis* (Fig. 41.11). If smears are made from the duodenum or jejunum, and diluted with physiological saline, Hexamita, if present, will usually be found free from other flagellates.

Cochlosoma, a flagellate first reported in ducks by Kimura (1934), has been found by McNeil and Hinshaw (1942) associated with *Hexamita meleagridis* in a few outbreaks. Cochlosoma can be readily distinguished from Hexamita by its characteristic rolling movement and its cochleal shape. It is necessary, for best results, to examine poults that have recently died, but the parasites have been found in refrigerated specimens 48 hours after death. It may be necessary to warm the slide at 35° to 40° C. for a few minutes if the smears are taken from such specimens

The parasites may also be found in the bursa of Fabricius; in the carrier stage they localize in this organ as well as in the cecal tonsils. When the acute disease subsides, Hexamita can seldom be found in the upper intestines.

Transmissible enteritis (avian monocytosis, bluecomb) of turkeys, which is now recognized as being caused by a filterable agent (Sieburth and Johnson, 1957; and Tumlin *et al.*, 1957), must be differentiated from hexamitiasis because of many characteristics in common. McNeil (1958) suggests that in many field cases transmissible enteritis may occur simultaneously with hexamitiasis with a resultant increased severity in the total outbreak. She also postulates that virus particles of the disease may become attached to Hexamita and become transmitted in this manner. If this is true, then other viruses like that causing viral hepatitis could possibly be transmitted in the same manner. The reader is referred to the chapter on Avian Monocytosis and to the section on transmissible enteritis in this chapter for a more complete discussion.

Transmission. McNeil *et al.* (1939) found *Hexamita meleagridis* in California valley quail, Gambel's quail, and in chukar partridges. Hinshaw and McNeil (1941), in a survey of possible carriers, found Hexamita in 16.5 per cent of 79 live adult turkeys by rectal examination and in 32.4 per cent of 74 turkeys by examination of scrapings from the cecal tonsil at necropsy. All these birds were survivors

of acute outbreaks. They also examined 11 species of game and wild birds other than quail and chukars killed on or near infected ranches. None harbored Hexamita. Chickens, ducks, pigeons, and guinea fowl were negative for *Hexamita meleagridis*, but pigeons harbored *Hexamita columbae* (McNeil and Hinshaw, 1941a) Ducks and chickens were artificially infected with *Hexamita meleagridis*, but symptoms of the disease were not produced Kimura (1934), in a paper on Cochlosoma in ducks, mentions the occurrence of Hexamita in the ceca and large intestine of domesticated ducks in California. McNeil and Hinshaw (1941b) found the parasite in chickens artificially infected 22 weeks after inoculation. Hexamita has also been reported in peafowl. (California State Department of Agriculture, 1941) and in pheasants by Hinshaw and McNeil (1942) and Stover (1943). Thus, surviving turkeys, quail, chukars, pheasants, peafowl, chickens, and ducks must be considered potential carriers of *Hexamita meleagridis*.

No insect transmitter has been found. It has consistently been possible to keep noninfected poults free from the disease when reared in proximity to infected brooders even though flies were abundant.

Epizootiology. Management and environment play important roles in the transmission of this disease. The adult turkey that has survived an outbreak is the most important factor in perpetuation of the disease on a ranch. Chukar partridges, quail, pheasants, peafowl, and ducks may also play a part in starting an outbreak. Even though chickens have not been found infected under natural conditions, the fact that they may be artificially infected means that the parasite may sometimes be adapted to them, and they must be considered potential carriers. Outbreaks of hexamitiasis have been definitely traced to infected quail and pheasants ranging with turkeys.

In the field the acute disease is usually seen in the later hatches and often after the breeders have been marketed. Thus

adult transmission is often difficult for the owner to understand, because his earlier groups did not show symptoms. The explanation, based on experimental and field studies, is that the early hatched poults act as a reservoir for increasing the dosage and probably the virulence of the parasites and serve as the intermediary transmitter from the breeders to the later hatched poults. Experimentally, it takes from three to five passages of parasites removed from turkeys in the carrier stage through young poults before the infection is increased to insure acute outbreaks.

Environmental and husbandry factors also play an important part in establishing the infection in epidemic proportions. In most instances, as the brooding season advances, the volume of work on the ranch increases, and the space available per bird is less, thus increasing the chances for spread of disease. The difficulties arising with the hot weather, and in some areas the late spring fogs, also contribute to the development of the disease in later broods.

Prevention, control, and treatment. The primary source of infection is the intestinal contents of carriers. The entire program of prevention must be built around the recognition of this fact. Finding a satisfactory method of preventing the transfer of droppings from carriers to young birds is the most efficient method of preventing disease. *No general recommendations as to the best procedure to follow can be given because every ranch requires a separate solution of the problem of eliminating the danger of having carriers on the ranch.*

Factors which will aid in solving the individual problems are:

1. Separate units and caretakers for the breeding flock and the young poults.
2. Separate equipment for each age group.
3. Intelligent use of wire platforms for feed and water.
4. Intelligent use of cement yards and wire pens.
5. Arrangement of feeding and watering equipment for easy access to the attendant

without entering the pen, to avoid contamination.

6. If the poults have undergone an outbreak of pullorum disease or paratyphoid infection, avoid changes in brooding until they are 12 to 16 weeks of age.
7. Sell all breeding birds 2 weeks before any poults are hatched.
8. Avoid ranges frequented by pheasants, quail, and chukars.

An accurate laboratory diagnosis is the first essential in the advent of a suspected outbreak. Live sick birds are necessary for the accurate diagnosis of hexamitiasis, although Hexamita may be found as long as 48 hours after death of the poult if decomposition has not advanced too far.

Complete isolation and quarantine of infected pens to prevent spread of the disease to normal poults is the most important factor in the control program. *Keeping the poults warm by increasing the heat in the brooder house and increased effort to keep them comfortable are essential.* Removal and destruction by burial or burning of all dead poults several times daily, and daily dry cleaning of the houses and yards are essential to prevent spread of the infection.

Drugs and combinations of drugs that have been tried experimentally and proved to have no therapeutic value include mercuric chloride (1:8,000 and 1:4,000 as a substitute for drinking water) (McNeil and Hinshaw, 1945); sodium bicarbonate (baking soda), copper sulfate, nicotine sulfate, iodine, sulfonamides, penicillin, and several arsenical preparations.

McNeil (1948) obtained promising results by the use of a mixture of 3 per cent by weight of dried whey in a 1:2,000 aqueous solution of copper sulfate. This mixture, given in place of all drinking water for several days beginning early in an outbreak, should only be used as an adjunct to the recommended sanitary and management program. The cause of action of this combination on the disease is not known, but it is believed to be associated with the effect of the lactose-copper combination on lower intestine metabo-

lism (McNeil et al., 1948). Dried whey containing from 50 to 70 per cent lactose is essential, and it must not be caramelized. The mixture must be kept fresh, stirred frequently, replaced often, and kept in clean containers. If poults fail to drink it readily after 3 to 4 days, it should be replaced with fresh water for a few days. The usual experience following its use is an increased appetite with marked increase in feed consumption.

Almquist and Johnson (1951) did a preliminary screening test on four antibiotics using 9-week-old poults in which the disease was artificially produced. Streptomycin was of no value, but encouraging results were obtained with Aureomycin (200 mg. per pound of mash), and Terramycin (25 mg. per poult), and penicillin-G (25 mg. per poult). The treatments were continued for 3 to 14 days. They also fed 2-amino-5-nitrothiazole (ANT) at the rate of 0.1 per cent in the mash for 14 days with good results.

Mangum et al. (1955) obtained favorable results with furazolidone when it was added to the ration at the rate of 50 mg. per pound of feed. Wilson and Slavin (1955) tried a number of drugs and found most of them of no value. Enheptin (Entamin in England), 2-amino-5-nitrothiazole, was never more than 50 per cent effective. Di-n-butyltin dilaurate (Tinostat) appeared to control mild outbreaks and lower death rates in severe field outbreaks, but had no effect when given to birds experimentally infected with a lethal dose of the parasite. They state that any drug to be effective would have to be one which could be given in the drinking water because infected birds cease to eat early in the course of the disease. Fogg (1957) found Nithiazide an effective treatment in field outbreaks when given in drinking water at the rate of 0.02 per cent. Again it is emphasized that drugs are not substitutes for preventive management.

LEUCOCYTOZOON INFECTIONS*

Smith (1895) discovered a protozoan parasite in the blood of turkeys, which later was named by Volkmar (1930) *Leucocytozoon smithi.* According to Wenyon (1926), Laveran and Lucet in 1905 found a similar blood parasite in turkeys in France. Volkmar in 1930 reported the parasite in turkeys from Minnesota and North Dakota, and Skidmore (1932) reported an outbreak of disease in turkeys from Nebraska caused by *Leucocytozoon smithi.* Skidmore presented evidence that black flies identified as *Simulium occidentale* (Townsend) were the transmitters of the parasite from turkey to turkey.

Johnson et al. (1938), Travis et al. (1939), and West and Starr (1910) have published the results of extensive studies on Leucocytozoon infections and possible carriers. Other published reports on the disease in North America include the following: California, by Hinshaw and McNeil (1943); Texas, by Banks (1943); and Manitoba, Canada, by Savage and Isa (1915).

For a complete description of the parasite and the disease, the reader is referred to Johnson et al. (1938), Johnson (1942), Bierer (1954), and Wehr (1962).

Signs. Poults under 12 weeks are most affected. Loss of appetite, droopiness, and a tendency to sit are common signs. Visible signs seldom last over 2 or 3 days, after which the birds either die or start to recover. When disturbed they move with difficulty, and in the later stages may fall over, gasp, go into coma, and die.

Recovered birds may suffer no serious after effects, but they may carry the parasite in the blood for months. Some individuals develop a chronic type of the disease. Male birds carrying large numbers of the organism in the blood rarely strut or pay any attention to the female.

Moist tracheal rales are common in chronic cases, and the affected individuals make repeated attempts to clear their throats when excited. Death may result from undue excitement or handling of such birds.

Necropsy findings. Slight inflammation of the duodenum is the only consistent gross lesion noted in young birds. Anemia and various degrees of emaciation may be noted, the flesh is flabby, and the musculature is of a brownish color.

In adult carriers no gross lesions are seen as a rule, but occasionally the liver is icteric, enlarged, and cirrhotic. Johnson and his associates believe that the respiratory symptoms are due to circulatory obstruction by large numbers of parasites, resulting in anemia of some of the vital organs. The pathology of the disease is described in detail by Newberne (1955).

Diagnosis. Microscopic examination of the tissues of diseased birds reveals large numbers of the parasites (Fig. 41.15).

* See also Chapter 37.

Dried blood smears stained according to Wright's or Giemsa's method make satisfactory specimens for examination. Finding one of the species of Simulium feeding on turkeys is further evidence that a Leucocytozoon is involved.

Transmission. Skidmore (1932), Johnson et al. (1938), Underhill (1939), and Bierer (1954) have shown that at least three species of Simulium, *Simulium occidentale*, *S. nigroparvum*, and *S. slossonae*, may transmit leucocytozoa by biting turkeys. These are very small stout-bodied, black flies which live along streams. (See also chapter on External Parasites.)

Prevention and control. No satisfactory treatment has been reported. Confinement-rearing in houses screened against simuliids until the poults are several weeks old is considered practical by Johnson (1939). It is necessary to make the houses for such method of rearing fly proof by the use of cheesecloth. Screen of 16 mesh to the inch failed to keep the flies from entering houses. According to Bierer (1954), the use of DDT or other insecticides for large area control of the fly transmitters has not been successful, although a few individual turkey growers have reported success by this preventive measure.

Complete segregation of breeding and brooding operations will do much to prevent transmission from adult carriers to poults. Selling of adult breeders, before the poults that are to be kept for replacements are hatched, is recommended.

Johnson et al (1938) failed to find the parasites in pheasants, ruffed grouse, crows, hawks, and buzzards, but did find them in wild turkeys. Travis et al. (1939) examined chickens, peafowls, guinea hens, and ducks on infected ranches and found them to be negative for leucocytozoa. They found wild turkeys infected in Missouri, Georgia, and Florida. Therefore, wild turkeys may be a source of infection, and their control must be considered in a prevention program. The same precautions recommended for hexamitiasis will also help in preventing this disease.

TRICHOMONIASIS OF THE UPPER DIGESTIVE TRACT

History. Jungherr (1927) was the first to describe this clinical entity. At the time he suggested that a fungus was the probable cause. Three years later Volkmar (1930) reported that *Trichomonas diversa*, now designated as *Trichomonas gallinae*, is present in the crops of turkeys suffering from this disease. Hawn (1937) later showed this parasite to be the etiological agent. Stabler (1938a, b, 1954) has shown the similarity of this trichomonad to the one in pigeons, which he points out should be known as *T. gallinae* instead of *T. columbae*. He suggested that the species in turkeys be called by this name instead of *T. diversa.*

Levine *et al* (1941) reported evidence that the species found in turkeys is the same as that found in chickens and pigeons They were able to produce the typical disease in turkeys, chickens, bobwhite quail, canaries, and English sparrows with a species isolated from chickens.

Epizootiology. Most of the cases studied by Hinshaw have been in turkeys from 16 to 30 weeks of age reared on range land. The following description of one outbreak in California is typical of the environment in which most of the cases are found:

The turkeys involved in this outbreak had been reared on the home ranch under semiconfinement methods until the middle of September, when they were driven daily to a cut-over rice field about ½ mile from the ranch. Each day the birds were allowed to feed for 2 or 3 hours on the shattered rice left by the harvester. After this procedure had been continued for about a month, the flock was permanently moved to the rice field and allowed to range at will. They were fed a mash supplement that was left near the roosts located on a dry area in a cut-over barley field adjacent to the rice. Water was hauled from the home ranch, but the birds had access to the sluggish, algae-contaminated water in an irrigation ditch, which they had to cross in order to reach the rice from the roosting and mash-feeding areas. Seepage from the ditch had caused a large, muddy, stagnant pool to form near the edge of the rice field. The turkeys drank a great deal of this water and picked up the rice in the mud at the edge of the pool. Several similar pools were found in other parts of the field. The disease started within 10 days after the birds were permanently located on the rice field. Pigeons, abundant in the area, may have been the transmitting agent.

Signs. The signs are similar to those seen in many other diseases. Darkened heads with sunken sinuses and a generally haggard appearance are characteristic. The chest always has a depressed appearance, with the crop empty and drawn in towards the body. This typical attitude is seen in Figure 41.46. Lack of appetite, drooling from the mouth, roughened unkempt feathers, and a normal or slightly subnormal temperature are also observed. Diarrhea does not, as a rule, accompany the disease. A foul odor is always present. The course of the disease varies, but as a rule, it

FIG. 41.46 — Posture typical in trichomoniasis of the crop. Note especially the sunken appearance of the crop area. (Hinshaw, Univ. of Calif.)

is prolonged, and the birds become emaciated before death.

Necropsy findings. Chronic ulceration of the crop is the most common necropsy finding. The lower esophagus and, less often, the proventriculus and upper esophagus may be involved. The lower digestive tract and the other organs are, as a rule, normal. Aspergillosis of the lungs may be secondary to the necrotic ulceration of the upper digestive tract.

The lesions involve the glandular tissue and vary in size from a few to 15 mm. in diameter at the base (Figs. 41.47A and B, and 41.48). They taper to a point in concentric rings of piled-up necrotic tissue to as much as 5 mm. above the surface. They may extend into the tissue 3 or 4 mm. The surface protruding into the lumen of the organ is rough, irregular,

and surrounded at the base by a circular hemorrhagic ring. The lesions in the esophagus are usually smaller than those in the crop but are similar in shape and structure. When the proventriculus is involved, the esophageal portion is most affected. The lesions in the proventriculus are, as a rule, coalesced and may appear as a solid ring of necrotic material causing a marked thickening of the tissues and resulting in partial to complete occlusion of the lumen. Impactions of the lower esophagus have been noted in such cases.

Prevention and control. Since the disease is directly associated with insanitary surroundings, sanitation is of primary importance. Contact with pigeons should also be avoided.

The first requisite for control is sanitation. As soon as the disease is observed,
FIG. 41.47 — (A) Necrotic ulceration of the esophagus and crop seen in trichomoniasis. (B) Close-up of typical pyramidlike necrotic ulcers characteristic of trichomoniasis of the upper digestive tract. (Hinshaw, Univ. of Calif.)

FIG. 41.48 — Necrotic ulceration of the proventriculus often seen in trichomoniasis of this organ. (Hinshaw, Univ. of Calif.)

the flock should be moved to a dry, clean area and given plenty of pure, fresh water to drink. Sick birds should be kept separate and cared for by a person who has no contact with the healthy birds. Removing the causal agent and giving the birds good care is more essential than treatment with drugs.

Jacquette (1948) found copper sulfate of value in treating the comparable disease in pigeons. Other reports on use of drugs for the disease in pigeons are Stabler and Mellentin (1953), Samberg and Bornstein (1955), Stabler et al. (1958), and Bussiéras et al (1961). Stabler et al reported on the successful use of soluble Enheptin (2-amino-5-nitrothiazole) at the rate of 6.3 grams per gallon of water for pigeons. Bussiéras et al. reported on a drug which shows considerable promise for treatment of trichomoniasis in many hosts. It is metronidazole (1-beta-hydroxyethyl-2-methyl-5-nitroimidazole). It prevented mortality in pigeons when given orally at the rate of 60 mg/kg body weight over a 5-day period. One advantage over Enheptin is that it reportedly does not affect fertility of breeders. As far as is known the drugs mentioned have not been used against the disease in turkeys.

For a detailed discussion on T. gallinae as well as on other species the reader is referred to Chapter 37.

MISCELLANEOUS PROTOZOAN DISEASES

Protozoan infections that have been reported one or more times, and which may in the future prove to be significant causes of mortality, are briefly described below.

A *Cochlosoma*, first described by Kotlán (1923) from ducks in Europe, was named by him *C. anatis*. Kimura (1934) described a species from American ducks which he called *C. rostratum*. Travis (1938), in a synopsis of the genus, considers these species synonymous. McNeil and Hinshaw (1942) described a species in turkeys which was apparently the same species as described by Kotlán and Kimura. Campbell (1945) found *Cochlosoma* in turkey poults in Scotland. The true pathogenic significance of this flagellate is not known, although both Kotlán and Campbell suggest that it may be the cause of enteritis. Hinshaw has always found it associated with *Hexamita* or *Salmonella*.

Haemoproteus has been found by Morehouse (1915) in turkeys in Texas. Banks (1943) also suggested its presence in turkeys in Texas. This genus is usually carried by flies of the genus *Pseudolynchia*. Morehouse does not mention the insect vector for the species found in turkeys. Rivero (1947) has reported that the cone nosed bug, *Triatoma*, is able to transmit *Haemoproteus columbae*.

Herman (1941) described *Plasmodium durae* as the cause of bird malaria in a turkey in Kenya Colony, British East Africa.

McNeil and Hinshaw (1944) found an intraerythrocytic parasite in turkey poults. The organism probably belongs in the Babesiidae.

For a more detailed discussion of these diseases, the reader is referred to Chapter 37.

Miscellaneous Diseases

This section includes diseases and conditions which cause considerable financial loss in certain flocks but which are more or less sporadic in nature.

ABSCESS OF THE FOOT PADS

Turkeys sometimes suffer from abscesses of the foot pads (Fig. 41.49). These may resemble corns and are similar to a condition, commonly called bumblefoot, in chickens. The cause is not known, but the abscess probably starts from an infection following an injury to the foot pad. Some of the cases observed have resembled foot rot as seen in other animals. In these instances the affected turkeys had been in

FIG. 41.49 — Abscesses of the foot pads (bumblefoot). (Hinshaw, Univ. of Calif.)

yards that were in constant use and which were covered with several months' collection of feces; cases usually appeared after the fall rains when the yards became very muddy. No doubt many cases of abscesses of the foot pads are also identical with staphylococcal arthritis.

Putting the birds in clean dry quarters and treating the diseased pad will cure many cases. If pus is present, it should be removed, and the area cleaned and treated with an antiseptic healing ointment or tincture of iodine.

Rotating the runs and removing the birds to a clean well-drained yard just before the breeding season are recommended as preventive measures.

ASCITES

Although not a hatchery problem, ascites caused by excess of sodium compounds including common salt (Scrivner, 1916;

Doll et al, 1916) and by exposure to certain disinfectant fumes (Bullis and Van Rockel, 1911) is sometimes confused with omphalitis due to infection described by Brandly (1932). Ascites (dropsy, watery belly, etc.) due to chemical poisoning is seen in young poults or chicks from 2 or 3 days to 2 weeks of age. Excess of salt in the ration and fumes from certain types of disinfectants used for spraying brooder floors are common causes. Excessive salt is usually accidental and may be due to improper mixes or poor screening which allows lumps to get into the mash. The addition of salt to mashes which already contain it because of salted protein concentrates has also been responsible for a few outbreaks. Hatcherymen should warn customers regarding excessive salt in mashes and of the dangers of putting chicks into brooders too soon after spraying the floors with volatile disinfectants.

BLUEBACK AND CANNIBALISM

Blueback, as the name indicates, is a condition in which the backs of the affected turkeys are discolored blue or black. According to Billings (1940), it is caused

by an injury to the quills of the feathers at the point of entrance into the skin which allows the pigment to escape and tattoo the surrounding skin (Fig. 41.50). Feather picking is the immediate cause, according to him. Exposure to sunlight
FIG. 41.50 — "Blueback" of turkeys. (Ralston Purina Co.)

after picking is necessary to produce the pigmented condition. Some of the other causes are overcrowding in the brooder, keeping the poults too long on the sun porch, and lack of sufficient fiber in the ration. After picking becomes a habit, the vice is difficult to control, and the financial loss due to lowering of the market grade of the carcass may be considerable.

Another form of cannibalism which often results in evisceration may also be started by feather picking.

Prevention and control consist in correcting the vice. Overcrowding in the brooder should be avoided. Moving poults to the range as soon as picking starts or reducing the numbers in a house are suggested means of control. The feeding of whole oats is recommended by some as another means of prevention.

Mechanical devices are commonly used for the prevention of these vices. Two types are used. The first, inserted in the beak, is patterned after the hog nose ring, in use by swine raisers for prevention of "rooting" These are inserted in one side of the lower mandible (lower beak). A similar type sold by one manufacturer is pinned in the upper beak. The promoters of these nose-guard types claim that turkeys so fitted cannot pick feathers.

Trimming the edges of the beaks will temporarily prevent picking. An electrically heated cauterizing knife has been developed for removing a portion of the upper beak of birds to prevent feather picking and cannibalism. This instrument can be recommended for the prevention of these vices in turkeys. Figure 41.51 from Payne (1956) shows an electrical cauterizing knife used for debeaking and a turkey that has been properly debeaked.

Several ointments are on the market for
FIG. 41.51 — An electric debeaker in use. The upper beak is removed half way between tip and nostril. (Payne, 1956.)

use on injured birds, principally for prevention of feather picking. These usually consist of a vaseline base, some bitter drug such as aloes, and a red coloring like

carmine. Ewing (1940) suggests an ointment made by mixing 4 ounces of vaseline, ¼ ounce of carmine, and ½ ounce of aloes. Roofing tar is also used.

ENTERITIS (NONSPECIFIC) (Inflammation of the Intestines)

Every year numerous immature turkeys die of enteritis from unknown causes. Further research may prove some of these outbreaks to be infectious in nature. At present, however, they must be handled as nonspecific and can probably be attributed to a number of causes.

Stampeding, failure of brooder heaters, sudden changes in the weather, piling in the brooder houses, heat prostrations, sudden changes of feeding methods, and probably, in many cases, faulty feeding methods over a period of several weeks are examples of obscure causes of mortality, with enteritis as the principal pathological manifestation. These various factors may also pave the way for secondary invasion by microorganisms normally of low virulence, which, under such conditions, may cause heavy mortality.

An example of losses starting from an obscure cause that may easily be overlooked follows: Three lots of turkeys about 12 weeks of age were in similar yards where it had been necessary to use an undesirable watering system until a modern drip system was installed. This new system was installed in all three yards at the same time, and the old system removed. Within 48 hours two of the three lots of turkeys became ill, while the third remained normal. On the third day it was discovered that the two groups of sick birds were not drinking the water because of an apparent fear of the new equipment. When the old equipment was replaced in these pens, the birds fought to get at the water and drank three or four times as

much as normal for the day. Only 1 per cent of the birds died before and within 24 hours after the discovery of the cause, but there was a distinct difference between the two affected lots and the third lot for nearly a month. A difficulty usually experienced in making a diagnosis for such outbreaks is the lack of sufficient history.

Losses are commonly experienced by turkey growers following the transfer of poults from the starting brooders to the "cooling" brooders. A common practice is to rear poults in small units in battery types for 3 to 4 weeks, and transfer from these to regular brooder houses with yards or wire porches. Losses following such transfers are usually due to failure to use the same type of feeders and waterers as in the starting brooders. Use of similar equipment and careful watching of the poults to see that they start eating and drinking properly after such moves will avoid losses.

Signs. The principal signs are loss of appetite, a tendency to separate from the well birds, diarrhea, and a general haggard appearance. Temperatures are usually normal or subnormal. The birds may sit in a listless manner with their heads hung or turned up over their backs. On open ranges, where the majority of the flock is affected, difficulty is often experienced in keeping the birds under control; the turkeys appear nervous and may wander for hours, often straying ½ mile or more from the main camp. During the course of the disease, often a period of several weeks, a marked loss of flesh may occur. The mortality is not, as a rule, high for a single

day; but over a period of 3 or 4 weeks, 25 per cent or more of the birds may die.

Necropsy findings. Emaciation and enteritis, varying from a catarrhal to a more advanced inflammatory type, are the principal necropsy findings. The heart is usually flabby. The blood, in many instances, fails to clot for several hours after death; it is usually very dark in appearance. The liver often appears congested, and dark venous blood oozes from cuts made on its surface. In many respects the symptoms and necropsy findings resemble those of acute poisoning.

Prevention, control, and treatment. It is extremely difficult to give methods of prevention, control, and treatment for enteritis of an unknown cause. Every effort should be made to determine the cause before treatment with drugs is planned. Exploratory trials with the new drugs, rather than total flock treatment, is recommended until the efficacy of a particular drug is determined.

Sound, rational turkey husbandry is probably the best preventive. An adequate diet and an ample supply of pure, fresh water are important. Avoiding the possible causes of enteritis is essential. A few have already been mentioned, and others will suggest themselves. Any abnormality that will cause the bird to lose its appetite or develop an intestinal disturbance, even for a few days, may cause heavy losses for several weeks.

Sudden changes of feed should be avoided, but if the flock is definitely not doing well on a particular diet, the reason should be sought. If the feed is responsible, a gradual change to another method should be made. If the original method is resumed after the birds have recovered, the shift should also be gradual.

Turkeys that are to be taken off a full-feed ration and transferred to a grain field should be fed some of the same type of grain as that grown in the field for a week or two before being moved to the range. This procedure accustoms them to the new grain and will prevent a setback and

possible heavy losses In addition, for a few days after they are moved to the range, the birds should have some of the mash previously used.

ENTERITIS (HEMORRHAGIC)

Pomeroy and Fenstermacher (1937) describe a hemorrhagic enteritis in turkeys ranging from 7 to 12 weeks of age. The disease appeared in Minnesota during the summer months and caused a mortality of about 10 per cent. The flocks involved in this outbreak had been reared on wire porches for 6 to 8 weeks and were then transferred to field ranges. The losses occurred from 10 to 14 days after the poults were put on range. The ranges were very poor that year, greens were not available in sufficient quantities, and there was a distinct lack of sunshade and shelter. *Escherichia coli* and an unidentified Gram-positive rod were the only bacteriological findings. Neither of these was proved to be the causal factor.

A condition similar to that reported by Pomeroy and Fenstermacher has been observed in a few instances by Hinshaw. In these outbreaks the losses have always occurred a few days after transferring the poults to ranges or to yards adjoining the range brooder. In two such outbreaks the range contained a young succulent growth of alfalfa, and in a third the yard was overgrown with weeds and grasses including some sweet clover. Losses stopped in all three instances when the poults were returned to the brooders and were put back on a dry mash ration. Later they were put back on the range for short intervals at first and finally for the full period and without further losses. The causal factors were not determined. These findings constitute additional reasons for use of great precaution when moving poults from one environment to another.

Gale and Wyne (1957) describe two outbreaks of hemorrhagic enteritis in 7. to 11-week-old turkeys. Both occurred in turkeys being reared in confinement. Bacteriological examination revealed *Escher-*

ichia coli infection in the livers of about 20 per cent of the poults. No evidence of a viral infection could be established. No mention is made by them of attempts to isolate toxic fungi such as described by Forgacs and Carll (1955) and Forgacs *et al.* (1958) as a cause of a similar condition in chickens. Toxic fungi should not be overlooked as a possible cause of hemorrhagic enteritis in turkeys. Poisoning due to overdose of drugs (Sanger *et al.,* 1956) should not be overlooked. Toxic substances such as beat-aminopropionitrile

(BAPN) (Barnett *et al.,* 1957; Pritchard *et al.,* 1958) and vitamin K deficiency should also be considered in making a diagnosis.

The condition described as aortic rupture (dissecting aneurism) in turkeys by McSherry *et al.* (1954), Carnaghan (1955), Gibson and DeGruchy (1955), and Pritchard *et al.* (1958) should not be confused with hemorrhagic enteritis.

See prevention, control, and treatment under enteritis (nonspecific), above.

AORTIC RUPTURE (Dissecting Aneurism)

Internal hemorrhage caused by aortic rupture or dissecting aneurism has become an important cause of mortality in turkeys. The first report of the disease was made by Dorrell *et al.* (1952). They reported its presence in many of the United States. McSherry (1954) described losses in Canada that occurred also in 1952. Further evidence of the widespread occurrence are the reports from Great Britain by Carnaghan (1955) and Gibson and DeGruchy (1955). McSherry *et al.* (1954) and Pritchard *et al.* (1958) describe the disease in detail.

The etiology has not been clearly established. A number of investigators including Barnett *et al.* (1957), Pritchard *et al.*

(1958), and Waibel and Pomeroy (1958) have been able to artificially produce aortic rupture by feeding small quantities of beta-aminopropionitrile (BAPN) a toxic factor found in sweet-pea seeds. Since sweet-pea seeds are not used in turkey rations this source is unlikely, and no other source has yet been reported.

High blood pressure, induced by any one of a number of stress factors is considered as a contributing cause (Ringer, 1961). Ringer (1962) also considers genetic inheritance of a defective blood vessel as a possible factor. Atherosclerosis, predisposed by inheritance, has also been proposed by Ringer.

Aortic ruptures occur under field condi-

tions in rapidly growing birds and mortality is highest in males. Losses occur most often in birds from 10 to 16 weeks of age.

Clinical signs are seldom seen, and the owner first realizes his problem when he discovers a dead bird showing a typical blanched head. Occasionally death is preceded by gasping and by blood running from the mouth.

On necropsy the abdominal cavity is seen to be filled with blood due to the massive hemorrhage. No evidence of trauma is seen. Rupture of the posterior aorta due to a typical dissecting aneurism is most often

seen at a location in the region between the kidneys. Blood may be found in the air sacs, lungs, and even in the mouth and crop.

A number of remedies have been suggested, but the tranquilizer, reserpine, is most commonly used. Its real value remains to be determined. It is given in the feed and recommendation of the manufacturer should be observed.

Reviews on the use of reserpine in turkeys will be found in papers by Craig et al. (1962), Speckman and Ringer (1962), and Krista et al. (1963).

HEAT PROSTRATION (Heat Stroke)

Heat prostration is usually associated with high humidity accompanying high temperatures or with very low humidity on excessively hot days. Stiles (1943) reported a case of heat exhaustion in a flock of 3 week-old turkey poults which were abruptly transferred from cool turkey brooders to quarters where the heat inside the building and on the sun porches was extremely hot. Wilson and Woodard (1955) found that air temperatures above 90° F. cause hyperthermy in turkeys and that the body temperature is definitely

influenced by the amount of shade at such temperatures.

The symptoms are labored breathing, weakness, excessive thirst, and high temperature, followed by complete prostration. Losses can be prevented by furnishing ample shade facilities, especially for the poults just transferred from the brooder house to an open yard or range. If a house is available on the range, the young poults may well be sheltered in it during the hottest part of the day, but with all the wintest part of the day, but with all the windows open for ample circulation of air. As soon as the poults become accustomed

to the new quarters, they will stay inside during the excessive heat; water and feed should be left both inside and outside the house for the first few weeks. Out of doors, trees make the best shade; but an abundance of cheap artificial shade can be made from old lumber and posts. Thatched roofs may be used advantageously if material for covering the shelter can be secured. Pure, fresh water must be available at all times. It should be kept in a shady place and in enough containers so that the birds will have no difficulty

in getting to it. If, in spite of all precautions, turkeys are overcome by the heat, they should be put in a shady, well-protected place and sprayed with cold water. Used in time, this procedure will save a large number. Filling the crop with cold water by means of a rubber tubing and a funnel is also advisable. Dipping the birds in cold water may be effective, but care must be taken to prevent drowning. As they may remain weak for several days, they should be kept in the shade with food and water easily accessible.

INJURIES

Injury to the female by the male. Severe losses occur in many breeding flocks because of the females' backs being badly torn by the male during the mating process (Fig. 41.52). Badly torn females seldom recover sufficiently to produce fertile eggs during the remainder of the season; and if the wound does heal, the area is tender and easily torn when the bird is trodden again.

Some males are much more vigorous and rough in the mating than others, and many of the losses can be traced to one or two individuals in a flock. These males should immediately be *replaced* by reserves. One method of prevention is the removal of the toenails from the males (Fig. 41.53A and B) This should be

done about a week before the males are put into the breeding pens. A convenient instrument for removing the toenails is a pair of pruning shears of the roll-cut type shown in Figure 41.53A. An electric soldering iron or some other form of a searing iron can be used for searing the cut surface to stop hemorrhage.

Another method of preventing breeding females from being torn is to fit a canvass jacket over the back (Figs. 41.54 and 41.55). These jackets, which can be purchased at a reasonable price, are recommended for general use. Care should be taken to purchase saddles which fit correctly in order to prevent strangulation or injury to the body or wings.

If an injured hen is discovered im-

FIG. 41.52 — Turkey hen with a severe laceration caused by a male during the mating process. (Hinshaw, Univ. of Calif.)
FIG. 41.53 — (A) A method of trimming the toenails of a male turkey to prevent injuries during the mating season. (B) Feet of a male turkey after trimming the toenails as illustrated in A. (Hinshaw, Univ. of Calif.)

mediately, the torn edges of skin should be sutured. The bird should then be placed in a pen where there are no males and left for about 2 weeks. An antiseptic dusting powder will induce healing and prevent attacks by flies. As soon as the wound begins to heal normally, the hen can be fitted with the canvas jacket described above and can be returned to the breeding pen. She should be carefully watched, however, and if again injured

FIG. 41.54 — A type of "apron" or "saddle" in common use for prevention of injuries to females during the mating season. See Figure 41.55. (Hinshaw, Univ. of Calif.)

by the males, should be returned to the isolation pen.

Where several males are in one pen, the transfer of a male to a pen of injured females may be a better procedure than putting the injured hens back in the regular pen. The time required for complete recovery depends on the extent of the injury and the efficiency of the treatment. Whether or not treatment is worth-while depends on the value of the individual and the time available.

Injuries from fighting. As males are more likely to be injured from fighting than are females, often a valuable male should be separated from its penmates if it is not able to defend itself successfully. A male which has been away from the flock for any length of time or which has just been purchased must be protected when placed with other males, because they will invariably fight it.

Minor injuries seldom require treatment and will heal readily if the bird is unmolested. Severe lacerations about the head usually respond to an antiseptic dusting powder.

Miscellaneous injuries. Injuries from being caught in fences, from flying into objects during stampedes, from rough handling, and from many other causes are cared for in much the same manner as injury by a male.

Wickware (1945) reported that grasshoppers may caused death of turkeys by mechanically injuring the walls of the

FIG. 41.55 — Turkey hen with the "saddle" shown in Figure 41.54 in place. (Hinshaw, Univ. of Calif.)

crop and intestine In some of these cases the walls of these organs were punctured by grasshopper legs He suggests that such losses can be prevented by feeding plenty of mash to turkeys that have access to ranges where grasshoppers are abundant.

Dickinson and Clark (1946) and Bullis and Van Roekel (1944) have reported brooder stove residue burns on the heads of turkey poults that were brooded under stoves heated with gas briquets or kerosene. The injuries in these cases are similar and range from mild burns to dry gangrene Dickinson and Clark state that the use of tight-fitting stove pipe joints will prevent seepage of the oily residue

responsible for gas briquet type burns. Attention paid to kerosene or similar burners to prevent leakage of oil will stop losses from such causes.

A type of injury seen now and then is shown in Figure 41.56. The bird is usually found with its head hanging downward and forward and is unable to change this position. The neck muscles are much swollen and are hot to the touch. Often one will find a tuft of feathers pulled from the side of the neck and evidence of a bruise. Dislocation of a vertebra or fracture of a vertebral process has been found to be the cause in most cases. In at least two, the injury resulted from entanglement in a wire fence during attempts to reach feed. Correction of the dislocation by massage and tension gave relief and complete recovery in about 2 weeks. Other cases have taken from 3 to 6 weeks to recover but have shown no detrimental aftereffects. If such an injury is found in a flock, the cause should be determined. Any dislocation found should be corrected. Until recovered the bird should be isolated but placed near water and feed containers.

FIG. 41.56 — Posture of turkey suffering from a slight dislocation of one vertebra of the neck. The bird could not raise its head, and the muscles of the area were severely swollen. (Hinshaw, Univ. of Calif.)

KERATOCONJUNCTIVITIS
(Blepharoconjunctivitis)

Bierer (1956, 1958) describes a disease characterized by inflammation of the eyelids and, in more advanced stages, an ulceration of the anterior portion of the eyeball. According to him, the disease generally is found in adult turkeys in the early breeder flocks — November to January. Hens appear to be more often affected than toms. Economic losses may be severe from high mortality, loss in egg production, and reduced fertility. The market value of the affected birds is lowered.

Signs. Bierer describes the following signs of disease. The first evidence is a whitish foam at the inner corner of the eye near the nictitating membrane. One or both eyes may be affected. A whitish crust may be seen on the outer surface of the eyelid. Excessive lacrimation occurs when the bird begins to rub the affected eye on its feathers. The conjunctiva becomes progressively more inflamed, caseous exudate appears, and finally the lids become encrusted, preventing vision. Ulceration of the cornea, destruction of it, loss of aqueous humor from the anterior chamber, and
FIG. 41.57 — Keratoconjunctivitis. Left: (upper) severe conjunctivitis; (middle) thickened eyelids and conjunctival sac filled with cheesy matter; (lower) eyelids removed to show the presence of the cheesy matter. Right: (upper) ulceration of the cornea, eyelids removed; (middle and lower) severe keratitis with extensive destruction of corneal tissue, eyelids removed. (Bierer, 1956.)

permanent blindness are the terminal phases of the disease. Death may result from inability to obtain adequate feed and water. Actual mortality in the flock usually is low, but the morbidity may reach 35 to 40 per cent of the flock. The greatest economic loss is from loss in egg production, poor fertility, and lowered market value of the affected birds. Figure 41.57 shows various stages in the development of the lesions.

Etiology. The etiology is obscure. Bierer (1958) presents convincing evidence that deficiency of vitamin A plays an important role probably as a stress factor. Secondary infections probably account for many of the pathological changes although Bierer was unable to incriminate any single microorganism.

Differential diagnosis. There are a number of reports on eye involvements in turkeys that must be differentiated from this disease. Included are Manson's eyeworm disease (Schwabe, 1950); Plasmo-

dium lophurae infection (Becker et al., 1949); aspergillosis (Moore, 1953); salmonellosis (Evans et al., 1955); paracolon infections (Hinshaw and McNeil, 1946); and granulomatous chorioretinitis (Saunders and Moore, 1957). Similar signs and lesions are sometimes seen in turkeys that have been vaccinated against fowl pox at an early age and exposed several months later after the initial immunity has been reduced or lost. These cases usually develop in old breeders following fighting. In such cases the causative virus can be easily isolated and demonstrated as the cause.

Prevention and control. Bierer suggests prompt isolation of the affected birds to avoid cannibalism by mates. Individual treatment following surgical cleaning of the area with antibiotic ointment has given good results. Administration of vitamin A to each bird is indicated. Supplementing the ration with feed containing a high vitamin A level is suggested by Bierer as a preventive measure.

OMPHALITIS

Omphalitis, or navel infection, is characterized by failure of the navel opening (umbilicus) to close properly, with resultant infection of the internal organs. The disease can often be traced to faulty incubation or to hatchery insanitation. In most instances the poults are weak when removed from the incubator, and losses may start before time for shipment from the hatchery.

Published reports of the disease include those of Volkmar (1929), Brandly (1932). and Williams and Daines (1942). Williams and Daines associated a severe outbreak of impetigo staphylogenes among hatchery workers with a concurrent outbreak of omphalitis in poults in the same hatchery.

The signs are general weakness, lack of body tone, and a tendency to huddle. In the brooder the poults appear cold and stay under the hover. When handled they

feel flabby, the abdomen is enlarged, and they do not have the firmness of a normal poult. The navel opening, which usually is completely healed within 72 hours, is inflamed, moist, and fails to close for several days. Often a definite scab forms over the opening. The course is rapid, death often occurring within a day after signs are noted; the mortality is high, often reaching 50 per cent of the brood. The course of the disease and the mortality depend on the type of microbial flora that exists in the hatchery and on the promptness of initiating preventive measures.

On necropsy, edema of the muscles of the abdomen and breast, an unabsorbed yolk, and peritonitis are the principal observations. The contents of the retained yolk are usually more liquid than normal, and rupture of the yolk sac is common.

The disease is probably a result of a

mixed infection of hatchery origin. In the outbreaks reported to the writer, thorough cleaning and disinfection of the hatchery rooms and incubators have prevented further losses. The formaldehyde fumigation method, outlined under the section on disinfectants (page 131) will eliminate the disease from the hatchery. Insko et al. (1941) and Insko (1949) suggest that two to three times the amounts of formalin and potassium permanganate be used to fumigate incubators known to be spreading omphalitis. This strength should be used between hatches. Incubator rooms and all hatchery equipment as well as the incubators should be fumigated. (See section on formaldehyde fumigation, page 132.)

No remedy or adequate method of controlling the disease in the brooder has been found. Keeping the poults comfortable and applying hygienic measures will help reduce the mortality to a minimum.

PENDULOUS CROP

Serious losses from pendulous crop (Fig. 41.58A) in some flocks are, according to Hinshaw and Asmundson (1936) and Asmundson and Hinshaw (1938), the result of a hereditary predisposition toward the condition. Turkeys with the inherent weakness develop pendulous crops after the increased liquid intake that follows the first wave of excessively hot weather. The crop, once expanded, seldom returns to normal size, especially if the hot, dry weather continues. It may contract for a few days, if the weather becomes cool, and then expand again during the next hot spell. Although a few birds recover, the majority continue to have pendulous crops. In this condition the crop does not empty normally; stagnant, sour liquid contents are

retained in the bulbous portion. As time goes on, the mucous membrane thickens and may become ulcerated (Fig. 41.58B) due to secondary microbial infections.

The appetite is not greatly affected, but digestion is hindered. The feed and water remaining in the crop may increase until the crop and its contents equal one-fourth of the total live weight of the bird. The bird may continue to grow, but will remain unthrifty and may become emaciated.

Pendulous crops caused by an inherent weakness must be distinguished from similar conditions that sporadically result from impactions, mycosis, trichomoniasis, and other crop infections. These conditions, however, may be exaggerated in flocks having a hereditary tendency towards pendulous crops.

Studies by Rigdon et al. 1958) and Man-
FIG. 41.58.—(A) An 8-month-old female turkey with a pendulous crop of about 5 months' duration. (B) Section of a pendulous crop showing thickening and ulceration of the mucous membrane. (Hinshaw, Univ. of Calif.)

ire et al. (1958) indicate that the normal diets fed turkeys do not greatly influence the incidence of pendulous crops in a flock. They, however, experimentally produced pendulous crops in turkeys by feeding a ration containing cerelose as a substitute for starch. When such birds were returned to a starch ration, the pendulous crops regressed. No mention is made as to whether the turkeys used were from parent stock having a hereditary tendency to this condition. They also found that *Saccharomyces tellustris* grows and multiplies rapidly in crops of turkeys fed cerelose. This yeast produces large amounts of gas which is thought to be the cause of the expansion of the crops of cerelose-fed birds. *Candida albicans* was also found to be a common inhabitant of the crops of the turkeys used in the cerelose experiments, but it did not multiply when cerelose was fed, and no frank cases of candidiasis developed.

Course, mortality, and causes of death. The course of the disease is chronic; as mentioned above, very few birds recover even with treatment. Some live for as long as 2 years, but the mortality of the affected birds in a flock may exceed 50 per cent.

The causes of death are (1) rupture of the crop by the bird's toes in its attempt to walk or run, (2) mechanical pneumonia from the seepage of crop contents into the bronchi during mechanical efforts to drain the crop or as a result of a backflow when the bird lowers its head, and (3) starvation due to insufficient intake of food or to improper digestion.

Necropsy findings. Necrotic ulcers, varying in nature according to the type of the contents and severity of the case, frequently occur. Scraping the necrotic membrane from the surface leaves a denuded, bleeding area. This type of necrosis is distinguished from that seen in trichomoniasis by the tendency of the latter to form individual pyramidal ulcers (Fig. 41.47) as compared with the diffuse, spreading nature of the former. Demonstration of trichomonads furnishes a further means of differentiation. In a few cases, lesions typical of moniliasis (thrush) (Fig. 41.12) have also been observed. In these cases fungi are readily demonstrated. The contents of the crops have varied from a watery, sour-smelling mass to a solid bolus of mud, feces, and grain. Semiliquid contents have been most common. The contents usually suggest a depraved appetite.

Few or no changes in any organ except the crop and possibly the lower esophagus are seen on necropsy. The mucous mem-

brane of the bulbous portion of the crop is thickened and in folds. Areas of diseased lung tissue varying in size are easily seen in those cases where the cause of death has been mechanical pneumonia caused by the entrance of crop contents into the lung. In such cases, food particles are found in the bronchi when the latter are carefully dissected. The air sacs are sometimes involved, and foreign matter can be seen when scrapings from them are examined microscopically.

Prevention, control, and treatment. Since pendulous crops are usually associated with a hereditary weakness, the best preventive measure is to avoid mating any birds that have a family history of this weakness. Although this is a difficult procedure in the flock that is not trapnested, much can be done to prevent the condition from becoming established. Poults with affected crops should be caught and toe-marked or banded so that they can be eliminated at the time turkeys are selected for breeding.

Sufficient shade during the hot months will reduce the numbers of pendulous crops in a flock. It is doubtful, however, whether any procedure other than eliminating the inherent tendency will remove the possibility of having a few cases.

Many methods for "curing" pendulous crops have been described by turkey growers. These have included various operations, the use of cloth vests or supporters, and methods of portioning out the water supply to the affected birds. Most of the methods have produced few actual recoveries.

Removing a portion of the crop surgically results in a high percentage of recoveries, but the time consumed probably does not warrant the procedure as a routine practice. Washing out the crop with warm water containing a weak antiseptic and then tying off a portion of the skin over the enlarged crop will yield temporary relief until market time. If only a few cases appear, it is more economical to kill the affected birds

POISONING*

Although losses from poisoning in turkey flocks are not great, a few cases are briefly described below. The tolerance of turkeys to rodent poisons is also discussed in answer to inquiries on this subject. In most outbreaks traced to poisoning, the signs and necropsy findings resemble those already described under the heading of enteritis. The diagnosis depends on discovering poison by chemical analysis of the crop or gizzard contents or on finding poison in the food supply.

Arsenic. DeLay (1910) reported losses in

10-week-old poults from eating grasshopper bait containing sodium arsenite and bran moistened with water. The bait was spread unevenly on a turkey range so that the birds had access to clumps of the mixture as well as to the grasshoppers. The owner reported a mortality of 5 per cent from the poisoning. DeLay fed some of the same mixture to 8-week-old poults in such a manner that the poults consumed from 0.25 to 0.5 gram of arsenic trioxide. Both dosages killed the experimental poults; the larger dose in 2 to 12 hours, and the smaller dose in 20 to 72 hours after being fed. The smaller dosage approximated that consumed on the ranch. The postmortem findings in the field cases

---

* See also Chapter 40.

described by him were grasshoppers in the crop, hemorrhagic inflammation of the duodenum and jejunum, and a "sweetish" odor of the gizzard and intestinal contents Arsenic was detected in the intestinal contents and in the grasshoppers found in the crop by the Gutzeit method.

According to Whitehead (1931) arsenic in bran used for grasshopper poisoning is not present in sufficient amounts to produce mortality in birds if the mixture is spread evenly and thinly over the ground Growers are cautioned, however, to be sure that these recommendations are followed if such a procedure is necessary on a turkey range

Copper sulfate (bluestone). According to experimental work by Hinshaw and Lloyd (1931), turkeys may be poisoned by copper sulfate added to the drinking water in concentrations greater than 0.2 per cent (1 500 dilution). As turkeys do not like copper sulfate solutions in any dilution and will avoid them if untreated water is present, poisoning is unlikely unless no other source of drinking water is available. In cool weather turkeys may go without drinking for several days rather than drink water containing even nontoxic doses of this chemical. For these reasons, copper sulfate is not recommended except for specific uses and in concentrations not exceeding 0.05 per cent (1:2,000 dilution). The poisoning is usually evidenced by a greenish-blue stain on the crop. Marked erosion of the mucous membranes follows excessive doses

Mercuric chloride (corrosive sublimate). Mercuric chloride is well known for its toxic nature, but in spite of this is often carelessly used on turkey ranches as a disinfectant and remedy. It is too commonly recommended for treatment of drinking water without experimental basis for the recommendation.

A series of trials made on the toxicity of this chemical for turkeys by McNeil and Hinshaw (1945) showed that a 1:4,000 dilution as a sole source of drinking water was toxic. The principal necropsy finding in mercuric chloride poisoning was a marked thickening and necrosis of the gizzard lining. There was some escharotic thickening in the crop, and the mucous membrane of the proventriculus was often sloughed.

Poisonous weeds. The fact that turkeys are often ranged among poisonous weeds suggests the reason for losses that are sometimes experienced on pasture lands. There are no experimental data available, however, on weed poisoning in turkeys. Where heavy losses occur in young turkeys reared on pasture, poisonous weeds should be sought as a possible cause. Suspected plants should be sent to a diagnostic laboratory together with tissue specimens for diagnosis and identification.

As a rule, animals or birds will not eat poisonous plants, unless other forms are not available. Most cases of poisoning result from the eating of young, growing shoots that come up in the spring before more palatable and nonpoisonous plants appear. Under certain conditions the seeds of poisonous plants may cause losses if accidentally mixed with grains.

The only method of control is to remove the cause. If the birds are ranging in suspected areas, confining them in enclosures for a few days and supplying them with sufficient freshly cut greens is recommended. When they are again turned out on the range, the supply of fresh greens should be continued until the suspected poisonous plants have been replaced by nonpoisonous varieties.

Examples of poisonous weeds which have been known to cause losses in turkeys are the seeds of certain of the lupine, young shoots of oleander, and the second, succulent growth of Sudan.

Oleander (Nerium oleander) poisoning in turkeys is occasionally seen, but under normal feeding conditions poults will not eat even the young succulent shoots. In one experimental trial by McNeil and Denny (1939), five out of six 4-week-old poults were killed by inserting leaves of oleander sprouts into their crops. The same poults had refused to eat the leaves when offered as greens. The poults died

within 24 hours after the forced feeding, and at necropsy showed hemorrhagic enteritis. Three adult turkeys were fed young succulent oleander shoots for 2 weeks in lieu of greens. The birds continually refused them, even when they were cut up and mixed with the grain. The presence of oleander leaves in the crop and gizzard, together with a history of the poults eating the plant, is evidence of poisoning.

Sodium bicarbonate (baking soda). Sodium bicarbonate has been shown by several investigators (Delaplane, 1934; Hoffman, 1942; and Witter, 1936) to cause losses in chickens. These losses are manifested by lesions in the kidneys and other organs similar to those seen in gout. Hoffman found that the continuous use of amounts of sodium bicarbonate in excess of 15 grams per gallon of drinking water is toxic for baby chicks if used as a substitute for all other drinking water.

The toxicity of sodium bicarbonate for turkey poults from 4 to 8 weeks of age has been determined at the California station (unpublished data). The results obtained were similar to those reported by the above investigators. When more than 0.6 per cent of sodium bicarbonate was given in the drinking water to 4- and 6-week-old poults, some mortality resulted, while 8-week-old poults were able to tolerate 1.2 per cent. Marked uremia and arthritis developed in all ages when over 0.6 per cent was given. As noted by Witter, sodium bicarbonate given in subtoxic doses also caused increased water consumption and diarrhea in turkey poults. Therefore, sodium bicarbonate is not a safe drug to use on the turkey ranch.

Sodium chloride (common salt). One outbreak of enteritis in turkeys about two-thirds grown finally proved to be associated with the use of well water containing a high percentage of common salt. This was the only source of water, and the losses probably resulted from heat prostration combined with salt dehydration; the turkeys did not like the water and drank only small quantities. A supply of fresh

water stopped the losses within a few days. Another instance of losses from enteritis probably due to salt consumption was traced to boxes of salt placed on the range for sheep that were being pastured with the turkeys (See material on ascites, page 1344).

Strychnine. Inquiries on possible poisoning by the strychnine coated grain used for rodent control on cut-over grain fields stimulated a series of experiments to determine the tolerance of turkeys for strychnine. Based on the results, turkeys will tolerate the usual amounts of strychnine in poisoned grain. Despite considerable variation in individual tolerance, there is probably little danger, provided other grain is available. Turkeys dislike grain coated with even minute amounts of strychnine and, after the first taste, will usually leave the planted poison bait alone and seek more palatable food.

Miscellaneous. Many other poisons could be mentioned, but they are not common causes of losses, and little is known about the exact tolerance of turkeys to them. Circumstantial evidence often points to poisoning when it is difficult to prove that a particular poison is responsible. Such chemicals as mercuric chloride, lead arsenate, and thallium, used occasionally on the farm, should be stored out of reach of turkeys. While chemical dusts are being applied in sprays or dusts are being applied in orchards where turkeys are ranging, the birds should be removed. After the orchard has been sprayed or dusted, there is still some danger from the residue on the cover crop; if other range is available, the birds should be kept out of the orchard for several additional days or until a rain has reduced the residue remaining on the forage.

A source of poisoning for turkeys, as well as for other fowls, is seed corn or other grains treated for control of fungi. One of these fungicides used in treating seed is Arasan, the active ingredient of which is tetramethylthiuram disulfide (TMTD). Seed corn treated with Arasan contains about 630 p.p.m. of TMTD. It

is hazardous to feed such percentage of the ration even as a small percentage of the ration according to Waibel et al. (1957). Poultry fed Arasan-treated corn developed enlarged hocks, slipped tendons, and an unsteady gait. When rations containing Arasan-treated corn were fed to laying hens, the results were disastrous, simulating acute infectious bronchitis.

Apparently the common weed killers have little or no effect on turkeys if used on vegetation in the usual recommended amounts (Roberts and Rogers, 1957).

NEMATODE, CESTODE, AND TREMATODE INFESTATIONS

Since most of the parasitic worms affecting turkeys are also common to chickens, the reader is referred to Chapters 34, 35, and 36 for detailed descriptions of these parasites. Control and treatment are also discussed in these chapters on pages, 995, 1029, and 1052.

Capillaria. Of the several species of the genus Capillaria that infest domestic birds, at least three have been reported in turkeys Two of these, *C. annulata* and *C. contorta*, infest the upper digestive tract, while *two*, *C. caudinflata* and *C. obsignata*, are found in the intestines. Cram (1926) reported *C. annulata* in turkeys in 1926 and later (Cram, 1936) published a comprehensive review on this and other species, giving the principal morphological characteristics of each. Emmel (1939) has described symptoms and necropsy findings observed in the three outbreaks due to *C. contorta*. He calls attention to the penguinlike attitude of infested turkeys (Fig. 41.59). Figure 41.60 shows the gross lesions observed in one of Emmel's specimens. He reported that 5 per cent commercial flowers of sulfur fed in the regular mash caused marked improvement of infested birds in 4 days and prevented new cases from appearing in the flock. The injurious effect of prolonged administration of sulfur is discussed in the sections dealing with coccidiosis and nutrition. *C. obsignata*, formerly known as *P. columbae* (Craybill, 1924; Wehr, 1939b) may cause heavy losses in young turkeys. *C. caudinflata* requires one of several species of earthworms as an intermediate host (Morehouse, 1943). Its true significance as an economic factor in turkey raising is not known. Earthworms are also transmitters of *C. annulata* (Wehr, 1936).

Cecal worms. Cecal worms (*Heterakis gallinae*) are of importance because they act as carriers of *Histomonas meleagridis*, the causative organism of histomoniasis. Recommendations for their prevention will be found in the section on histomoniasis.

Gapeworms. Gapeworms (*Syngamus tra-*
FIG. 41.59—Typical penguinlike posture of a turkey in advanced stage of *C. contorta* infestation. (Emmel, Jour. A.V.M.A.)

chea) cause some mortality in young turkeys, and as shown by Wehr (1939b), survivors may carry the parasite for as long as 224 days. Such survivors are important means of transmission to susceptible chickens and poults.

Ascarids. The intestinal roundworm, *Ascaridia galli*, is not an important parasite of turkeys, and under good husbandry practices the turkey grower need not fear losses from it. Evidence that the turkey is more resistant to the *Ascaridia galli* than is the chicken has been reported by Ackert and Eisenbrandt (1933). Another species, *A. dissimilis*, according to Wehr (Chapter 34), has been reported from both domestic

and wild turkeys in the United States and Cuba. This species is similar in appearance to *A. galli* but is somewhat smaller. Remedies for control of these parasites are not recommended unless definite evidence of a severe flock infestation is found.

Tapeworms may present an economic problem to the turkey grower. Most of the cestodes that infest chickens are also parasitic for turkeys. Prevention, control, and treatment are similar to those outlined for chickens.

Combination anthelmintics designed for removal of both roundworms and tapeworms are not recommended for turkeys. Under no condition should treatment for either type be instituted unless the parasites are known to be causing losses in the flock. Emphasis should be placed on prevention, not on treatment.

Flukes. Riley and Kernkamp (1921), Riley (1931), and Marotel (1926) reported a monostome fluke, *Collyriclum faba*, which encysts in the skin of turkeys and other birds. These usually are found in the abdominal region, and especially in the perianal region, with occasional cysts on other parts of the body (Fig. 41.61) This fluke has been reported in many species of birds by other investigators. Although the complete life history has not been determined, Riley (1931) believes that snails probably act as the first intermediate host and nymphs of dragonflies as the second intermediate
FIG. 41.60 — Crop and esophagus of a turkey suffering from *C. contorta* infestation. (Emmel, Jour. A.V.M.A.)

FIG. 41.61 — A 6-week-old turkey poult showing perianal and abdominal groups of cysts of a fluke, Collyrlclum faba. (Riley and Kernkamp, Jour. A.V.M.A.)

host. English sparrows appear to be important disseminators of the parasites.

Annereaux (1940) reported the occurrence of typhlitis in poults caused by a fluke, Echinoparyphium recurvatum (von Linstow). The 10-week-old poults involved in this outbreak were being ranged along a creek where two types of snails and many tadpoles were present. The lesions found in the ceca of the affected poults were characteristic of those seen in the ceca of poults suffering from blackhead, but no liver lesions were noted. Foggie (1937) has reported an outbreak of parasitic necrosis of intestines of turkey poults in Ireland caused by a fluke, Plagiorchis laricola (Skrjabin), normally a parasite of terns and gulls

According to Macy (1939), the most important species of trematode parasite for North American poultry is Prosthogonimus macrorchis Although not found in natural outbreaks, Macy was able to infect turkeys with this parasite; typical lesions were observed in the oviducts of the parasitized birds. Few external symptoms of disease were noted, but the turkeys ceased laying 4 days after being fed the parasites. This trematode is transmitted by dragonfly nymphs (Lakela, 1932).

Other trematodes reported from turkeys, according to Wehr (Chapter 36), include the following:

Cyclocoelum mutable–Respiratory tract (Europe, Asia, and South America)

Strigea falcoins meleagris–Viscera (Texas)

Postharmostomum gallinum–Ceca (Europe, Asia, Africa, Hawaii, and Puerto Rico)

Notocotylus attenuatus–Ceca (Europe and Asia)

No satisfactory treatment has been reported for trematodes in turkeys. Prevention of infestation consists in avoiding access to marshy pastures, lake shores, or infested streams.

ECTOPARASITES

Reference is made to Chapter 33 on External Parasites for a detailed discussion, including prevention and control.

Lice. Turkeys may be infested with the common body louse of chickens, *Menacanthus stramineus* and the chicken shaft louse, *Menopon gallinae.* The large turkey louse, *Chelopistes meleagridis,* and the slender louse, *Oxylipeurus polytrapezius* are probably native to the turkey. The large turkey louse is the most common. Rearing turkeys in close confinement and unsanitary quarters favors lice more than does range rearing. It is important that breeding males and females be examined frequently for lice since parasites may be a very important cause of infertility. A common method of introducing lice to an uninfested ranch is the use of infested shipping crates that have been brought on the ranch by buyers. Growers should insist that buyers clean and disinfect all crates and equipment used to transfer stock to killing plants.

Mites. Turkeys are less affected with mites than chickens, due probably to the greater tendency to rear turkeys out of doors. Chickens reared in close proximity to turkeys, and the use of old chicken yards for turkeys constitute the chief sources of infestation.

Ticks. The only tick of economic importance is the fowl tick or "blue bug," *Argas persicus.* Spirochaetosis, a disease transmitted by this tick, has been diagnosed in the United States by Hoffman *et al.* (1946) in turkeys, and by Burroughs (1947) in chickens. For more details, see the section on spirochaetosis in turkeys, page 1308 It is important that all fowl to be purchased be inspected for the presence of these parasites. Birds (chickens and other fowl as well as turkeys) from infested ranches should never be brought onto tick-free ranches.
